Patients with diagnostic ST-segment elevation on their initial ECG do not require serum marker measurement to make treatment and disposition decisions. Conversely, serum markers are useful in patients with nondiagnostic ECGs for diagnosis of NSTEMI and risk stratification of patients with STEMI, NSTEMI, and unstable angina. Even low-level cardiac marker elevations are independent risk factors for acute (<30 days) cardiac complications and short-term (<1 year) prognosis in unstable angina.[16] A rise in serum troponin I or T, with at least one value above the 99th percentile, is diagnostic for AMI in patients with symptoms consistent with ACS.[17] Low-level elevations in either troponin correlate with risk for cardiovascular complications in unstable angina, CAD, and renal failure.[16] Troponin is sensitive and specific for cardiac myocardial necrosis, but there are many causes of myocardial necrosis unrelated to ACS (see Table 48-5). Minor elevations in cardiac troponin I and cardiac troponin T identify patients more likely to benefit from treatment with glycoprotein IIb/IIIa inhibitors, enoxaparin, and early invasive treatment strategy (catheterization within 24 to 48 hours).[18]

New high-sensitivity cardiac troponins have improved ability to detect ischemia. First-generation single assays of cardiac troponin I at the time of presentation had an AMI sensitivity of 39%. Serial sampling increased sensitivity to 90% to 100%, with specificity of 83% to 96% for cardiac troponin I and 76% to 91% for cardiac troponin T. The high-sensitivity troponins, initially used in Europe, identify 90% to 100% of patients with AMI at the time of arrival using the lowest cut point, albeit with limited specificity (between 34% and 80% depending on the cut-off used).[19-21] The concern regarding use of high-sensitivity assays focuses on the frequency of false-positive results that lead to unnecessary procedures

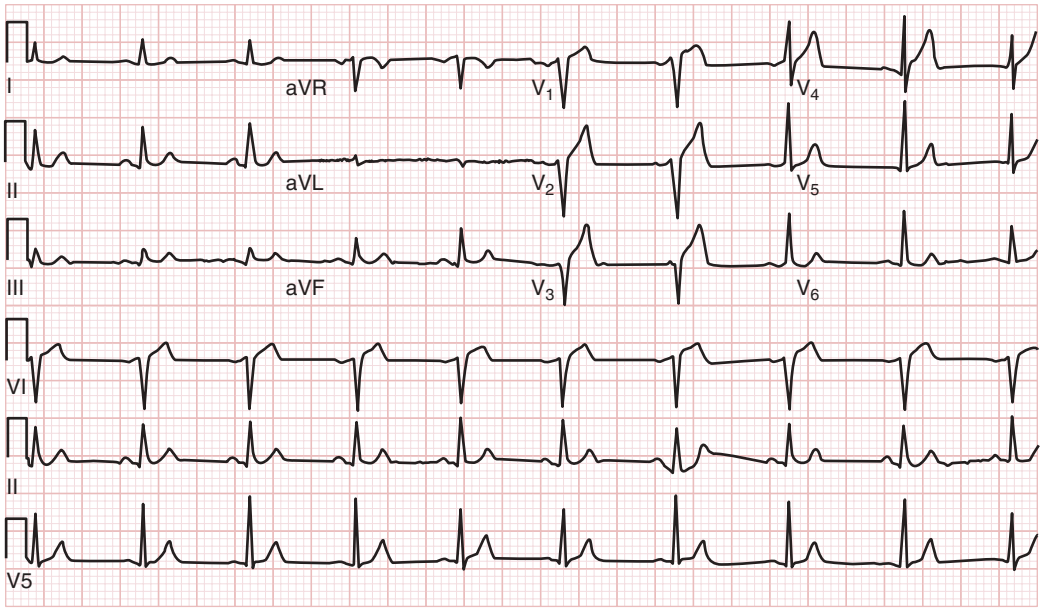

FIGURE 49-5. ECG showing anterior myocardial infarction from distal left anterior descending coronary artery occlusion. ECG from a 52-year-old man presenting with chest pain. ECG shows ST-segment elevation in V_1, V_2, and V_3, with the absence of ST-segment depression in leads II, III, and aVF. The patient was found to have 100% occlusion of the distal left anterior descending coronary artery at cardiac catheterization. [Used with permission of David M. Cline, MD, Wake Forest University.]

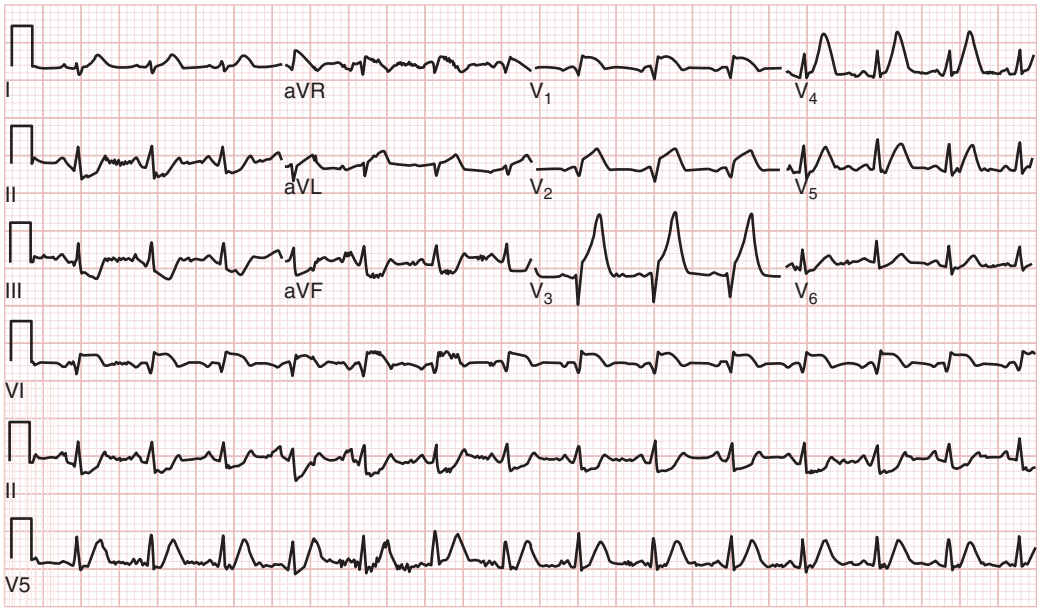

FIGURE 49-6. ECG showing anterior myocardial infarction from proximal left anterior descending coronary artery occlusion. ECG from a 65-year-old man presenting with chest pain. ECG shows ST-segment elevation in V_1, V_2, and V_3, and >1 mm of ST-segment depression in leads II, III, and aVF. The patient was found to have 100% occlusion of the proximal left anterior descending coronary artery at cardiac catheterization. [Used with permission of David M. Cline, MD, Wake Forest University.]

TABLE 49-7 Conditions in Which ECG Interpretation Can Be Difficult

May have ST-segment elevation in the absence of acute myocardial infarction
Early repolarization
Left ventricular hypertrophy
Pericarditis
Myocarditis
Left ventricular aneurysm
Hypertrophic cardiomyopathy
Hypothermia
Ventricular paced rhythms
Left bundle-branch block
May have ST-segment depressions in the absence of ischemia
Hypokalemia
Digoxin effect
Cor pulmonale and right heart strain
Early repolarization
Left ventricular hypertrophy
Ventricular-paced rhythms
Left bundle-branch block
May have T-wave inversions in the absence of ischemia
Persistent juvenile pattern
Stokes-Adams syncope or seizures
Posttachycardia T-wave inversion
Postpacemaker T-wave inversion
Intracranial pathology (CNS hemorrhage)
Mitral valve prolapse
Pericarditis
Primary or secondary myocardial diseases
Pulmonary embolism or cor pulmonale from other causes
Spontaneous pneumothorax
Myocardial contusion
Left ventricular hypertrophy
Ventricular-paced rhythms
Left bundle-branch block
Right bundle-branch block

and hospital admissions or no benefit. Authors of a large observational study advocated using a single undetectable high-sensitivity troponin plus no ECG evidence of ischemia as a decision point to discharge chest pain patients from the ED.

Despite the new sensitive assays, guidelines[1,5,6] and experts[22] recommend serial troponin testing to identify acute disease. A serial high-sensitivity troponin interval as short as 2 hours coupled with a low TIMI risk score (<2) virtually excludes AMI.[23] The European Society of Cardiology recommends a 3-hour serial interval when high-sensitivity troponins are used.[24]

Elevated levels of the cardiac troponins in patients with NSTEMI increase the short-term risk of death 3.1-fold (1.6% vs 5.2%).[19] Although patients with elevated troponins in the absence of ACS may be "false positive" for AMI, elevated troponin of any amount is associated with a high frequency of worse outcomes. Taken together, the data strongly support the claim that **any measurable elevated troponin is always worse than no elevated troponin and that more troponin elevation is always worse than less troponin elevation with respect to prognosis.**

B-type natriuretic peptide, an established marker for patients with heart failure, is also elevated in patients with ACS and can identify ACS patients who are at higher risk for adverse cardiovascular events, heart failure, or death.[5] When used in conjunction with other markers, the addition of B-type natriuretic peptide increases sensitivity at the cost of decreased specificity, with only a slightly increase in overall diagnostic accuracy.

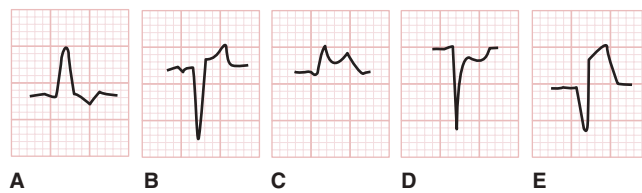

FIGURE 49-7. Discordant and concordant ST elevation and depression in the setting of left bundle-branch block. ST-segment abnormalities in left bundle-branch block. **A.** Discordant ST-segment depression ("normal"). **B.** Discordant ST-segment elevation ("normal"). **C.** Concordant ST-segment elevation (strongly suggestive of acute myocardial infarction [AMI]). **D.** Concordant ST-segment depression (suggestive of AMI). **E.** Excessive (>5 mm) discordant ST-segment elevation (weakly suggestive of AMI). [Used with permission of William Brady, MD, University of Virginia.]

For this reason, B-type natriuretic peptide is not routinely needed in those with suspected ACS.

GENERAL TREATMENT

The treatment of ACSs is based on duration and persistence of symptoms, cardiac history, and findings on physical examination and the initial ECG (see **Figure 49-8**). Establish IV access, give aspirin if not already given by EMS, and, as long as there are no contraindications, provide ECG monitoring. Many recommend supplemental O_2[6]; however, there is little evidence for benefit in patients without hypoxemia, and small studies have shown a negative effect with high-flow O_2.[25] The key treatment strategies aim to achieve immediate reperfusion and limit infarct size (**Tables 49-8** and **49-9**).

Patients with persistent symptoms and STEMI should receive reperfusion attempts. Reperfusion therapies can be mechanical or pharmacologic. **Percutaneous coronary intervention (PCI)** with or without stent placement is the dominant current approach to mechanical reperfusion.[5] Pharmacologic reperfusion is accomplished with fibrinolytic therapy, which is improved with adjuvant antiplatelet and antithrombin therapy.

American Heart Association/American College of Cardiology guidelines target a treatment goal of ≤90 minutes for a patient who arrives at a hospital with PCI capability or of ≤120 minutes for patients arriving at a hospital without PCI capability to account for transfer time.[5,6] Fibrinolysis should be given within 30 minutes of ED arrival if PCI cannot be accomplished within these time frames.[6] The concept of "first medical contact to device/balloon time" replaces the "door to needle" or "door to balloon" time.[6] Each health system and institution treating ACS patients should develop protocols to drive optimal methods of

TABLE 49-8 Drugs Used in the Emergency Treatment of STEMI

Antiplatelet Agents		
Aspirin	162–325 milligrams.	
Clopidogrel	Loading dose of 600 milligrams PO followed by 75 milligrams/d. No loading dose is administered in patients >75 y old receiving fibrinolytics.	
Prasugrel	Loading dose of 60 milligrams promptly and no more than 1 h after PCI once coronary anatomy is defined and a decision is made to proceed with PCI.	
Ticagrelor	Loading dose is 180 milligrams PO followed by 90 milligrams twice a day.	
Antithrombins		
Unfractionated heparin	Bolus of 60 units/kg (maximum, 4000 units) followed by infusion of 12 units/kg/h (maximum, 1000 units/h) titrated to a partial thromboplastin time 1.5–2.5 × control.	
Enoxaparin	30 milligrams IV bolus followed by 1 milligram/kg SC every 12 h.	
Fondaparinux	2.5 milligrams SC.*	
Fibrinolytic Agents		
Streptokinase	1.5 million units over 60 min.	
Anistreplase	30 units IV over 2–5 min.	
Alteplase	Body weight >67 kg: 15 milligrams initial IV bolus; 50 milligrams infused over next 30 min; 35 milligrams infused over next 60 min.	
	Body weight <67 kg: 15 milligrams initial IV bolus; 0.75 milligrams/kg infused over next 30 min; 0.5 milligram/kg infused over next 60 min.	
Reteplase	10 units IV over 2 min followed by 10 units IV bolus 30 min later.	
Tenecteplase	Weight	Dose (total dose not to exceed 50 milligrams)
	<60 kg	30 milligrams
	≥60 but <70 kg	35 milligrams
	≥70 but <80 kg	40 milligrams
	≥80 but <90	45 milligrams
	≥90	50 milligrams
Glycoprotein IIb/IIIa Inhibitors†		
Abciximab	0.25 milligram/kg bolus followed by infusion of 0.125 microgram/kg/min (maximum, 10 micrograms/min) for 12–24 h.	
Eptifibatide	180 micrograms/kg bolus followed by infusion of 2.0 micrograms/kg/min for 72–96 h.	
Tirofiban	0.4 micrograms/kg/min for 30 min followed by infusion of 0.1 microgram/kg/min for 48–96 h.	
Other Anti-Ischemic Therapies		
Nitroglycerin	Sublingual: 0.4 milligram every 5 min × 3 PRN pain.	
	IV: Start at 10 micrograms/min, titrate to 10% reduction in MAP if normotensive, 30% reduction in MAP if hypertensive.	
Morphine	2–5 milligrams IV every 5–15 min PRN pain.	
Metoprolol	50 milligrams PO every 12 h on first day, unless significant hypertension, may consider 5 milligrams IV over 2 min every 5 min up to 15 milligrams; withhold β-blockers initially if the patient is at risk for cardiogenic shock/adverse effects.‡	
Atenolol	25–50 milligrams PO, unless significant hypertension, may consider 5 milligrams IV over 5 min, repeat once 10 min later; withhold β-blockers initially if the patient is at risk for cardiogenic shock/adverse effects.‡	

Abbreviations: MAP = mean arterial pressure; PCI = percutaneous coronary intervention; PRN = as needed; STEMI= ST-segment elevation myocardial infarction.

*Fondaparinux should not be used as monotherapy for PCI; if used, addition of unfractionated heparin or bivalirudin is recommended before PCI.

†American College of Cardiology/American Heart Association 2009 focused update for STEMI patients recommended glycoprotein IIB/IIa inhibitors be given at the time of PCI; benefit prior to arrival in the cardiac catheterization laboratory is uncertain.

‡Risk factors for cardiogenic shock/adverse effects: 1. Signs of heart failure; 2. evidence of a low cardiac output state; 3. increased risk for cardiogenic shock (cumulatively: age >70 y old, systolic blood pressure <120 mm Hg, sinus tachycardia >110 beats/min or bradycardia <60 beats/min, and longer duration of STEMI symptoms before diagnosis and treatment); or 4. standard relative contraindications to β-blockade (PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease).

TABLE 49-9 Drugs Used in the Emergency Treatment of Unstable Angina or NSTEMI

Antiplatelet Agents	
Aspirin	162–325 milligrams
Clopidogrel	Loading dose of 300–600 milligrams PO followed by 75 milligrams/d
Prasugrel	Loading dose of 60 milligrams promptly and no more than 1 h after PCI once coronary anatomy is defined and a decision is made to proceed with PCI
Ticagrelor	Loading dose of 180 milligrams PO followed by 90 milligrams twice a day
Antithrombins	
Heparin	Bolus of 60 units/kg (maximum, 4000 units) followed by infusion of 12 units/kg/h (maximum, 1000 units/h) titrated to a partial thromboplastin time 1.5–2.5 × control
Enoxaparin	1 milligram/kg SC every 12 h
Fondaparinux	2.5 milligrams SC
Direct Thrombin Inhibitor	
Bivalirudin	0.75 milligram/kg IV bolus followed by 1.75 milligrams/kg/h infusion for duration of procedure
Glycoprotein IIb/IIIa Inhibitors	
Abciximab	0.25 milligram/kg bolus followed by infusion of 0.125 microgram/kg/min (maximum, 10 micrograms/min) for 12–24 h
Eptifibatide	180 micrograms/kg bolus followed by infusion of 2.0 micrograms/kg/min for 72–96 h
Tirofiban	0.4 microgram/kg/min for 30 min followed by infusion of 0.1 microgram/kg/min for 48–96 h
Other Anti-Ischemic Therapies	
Nitroglycerin	Sublingual: 0.4 milligram every 5 min × 3 PRN pain IV: Start at 10 micrograms/min, titrate to 10% reduction in MAP if normotensive, 30% reduction in MAP if hypertensive
Metoprolol	50 milligrams PO every 12 h first day, unless significant hypertension, may consider 5 milligrams IV over 2 min every 5 min up to 15 milligrams; withhold β-blockers initially if the patient is at risk for cardiogenic shock/adverse effects*
Atenolol	25–50 milligrams PO, unless significant hypertension, may consider 5 milligrams IV over 5 min, repeat once 10 min later; withhold β-blockers initially if the patient is at risk for cardiogenic shock/adverse effects*

Abbreviations: MAP = mean arterial pressure; NSTEMI = non-ST-segment elevation myocardial infarction; PRN = as needed.

*Risk factors for cardiogenic shock/adverse effects: 1. Signs of heart failure; 2. evidence of a low cardiac output state; 3. increased risk for cardiogenic shock (cumulatively: age >70 years old, systolic blood pressure <120 mm Hg, sinus tachycardia >110 beats/min or bradycardia <60 beats/min, and longer duration of ST-segment elevation myocardial infarction symptoms before diagnosis and treatment); or 4. standard relative contraindications to β-blockade (PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease).

reperfusion, determining which strategy it will use depending on its capabilities.

Most STEMI patients receive antiplatelet agents, antithrombins, and nitrates in the ED. Treat patients with unstable angina or NSTEMI with antiplatelet agents, antithrombins, and nitrates.[1] Those with unstable angina or NSTEMI refractory to these therapies or those scheduled to undergo PCI also may benefit from the use of glycoprotein IIb/IIIa antagonists (Tables 49-8 and 49-9).[1]

NSTEMI TREATMENT

For patients with NSTEMI (which by definition requires the time for biomarkers to become elevated and the clinical laboratory to perform the measurement), an invasive approach within 24 to 48 hours using PCI reduces the composite of death, MI, or recurrent ACS by 19% in women and 27% in men.[26] Therefore, the **very early** invasive approach deployed in STEMI is recommended in NSTEMI patients only with refractory angina or hemodynamic or electrical instability, or in patients at increased risk for clinical events.[1] Although the proportion of myocardial infarction patients with NSTEMI has increased from 52.8% in 2002 to 68.6% in 2011, utilization of the early invasive approach increased from 27.8% to 41.4% while in-hospital mortality dropped.[27]

Based on the results of these trials and a meta-analysis,[28] the American Heart Association/American College of Cardiology guidelines for the management of unstable angina/NSTEMI patients recommend early (within 48 hours) invasive therapy in patients with recurrent angina/ischemia with or without symptoms of congestive heart failure, elevated cardiac troponins, new or presumably new ST-segment depression, high-risk findings on noninvasive stress testing, depressed left ventricular function, hemodynamic instability, sustained ventricular tachycardia, PCIs within the previous 6 months, or prior coronary artery bypass grafting.[1] More aggressive and earlier PCI in these patients has not proven beneficial compared to the within 48 hours approach.[29,30]

PERCUTANEOUS CORONARY INTERVENTION

The American College of Cardiology, the American Heart Association, and the European Society of Cardiology recommend PCI as the preferred method of reperfusion therapy if the first medical contact to first balloon inflation time is less than 90 to 120 minutes.[5,6,31] In the early presenting cohort (within 3 hours of symptom onset), the decision to use primary PCI rather than fibrinolysis is based on institutional expertise, availability of the cardiac catheterization team, and the individual patient risk of complications from fibrinolysis.

Coronary angioplasty with or without stent placement is the most common PCI; alternatives include atherectomy and laser angioplasty. Balloon angioplasty increases the size of the arterial lumen through endothelial denudation; cracking, splitting, and disruption of atherosclerotic plaque; dehiscence of intima and plaque from underlying media; and stretching or tearing of underlying media and adventitia. With successful dilatation, small amounts of arterial wall dissection and aneurysmal expansion may be seen. The greater the increase in luminal size, the lower is the risk of restenosis. However, more aggressive balloon inflation can augment dissection, platelet deposition, thrombus formation, and plaque hemorrhage.

Alternative PCI procedures attempt to limit complications. Directional and rotational coronary atherectomy extract atherosclerotic tissue from the coronary artery. Excimer laser atherectomy vaporizes atheromatous tissue. It results in larger luminal diameters but has not reduced rates of restenosis or other complications associated with percutaneous angioplasty procedures.

Coronary stents are fenestrated stainless steel tubes that are expanded by a balloon to provide scaffolding within the coronary arteries.

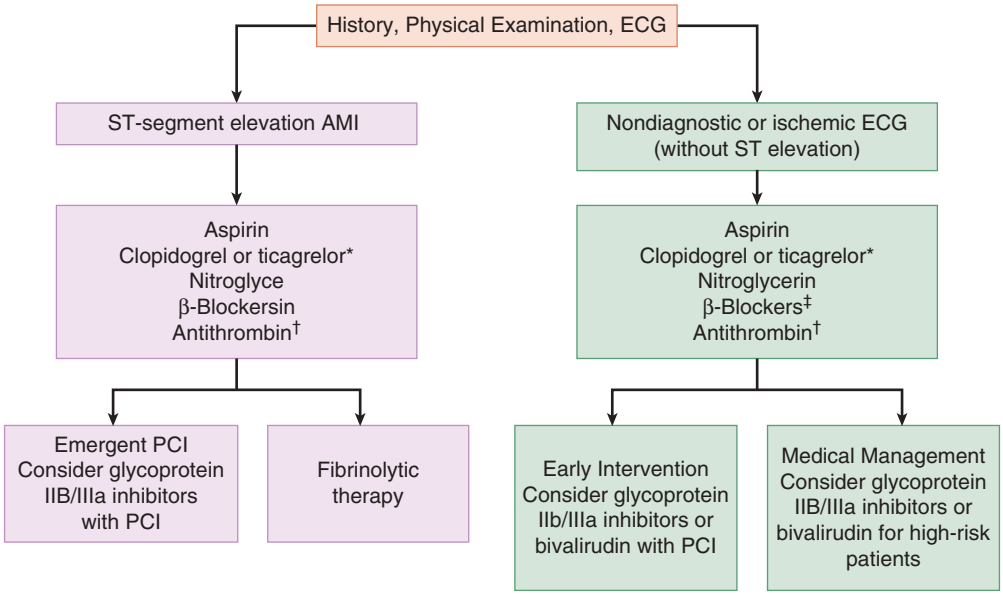

FIGURE 49-8. Treatment considerations for acute coronary syndrome patients. *Prasugrel should be considered at the time of PCI in patients who have not yet received either clopidogrel or ticagrelor. †Enoxaparin, unfractionated heparin, or fondaparinux. Note: See text for discussion of individual treatment options, indications, and contraindications. ‡Risk factors for cardiogenic shock/adverse effects: 1. Signs of heart failure; 2. evidence of a low cardiac output state; 3. increased risk for cardiogenic shock (cumulatively: age >70 y old, systolic blood pressure <120 mm Hg, sinus tachycardia >110 beats/min or bradycardia <60 beats/min, and longer duration of ST-segment elevation myocardial infarction symptoms before diagnosis and treatment); or 4. standard relative contraindications to β-blockade (PR interval >0.24 s, second- or third-degree heart block, active asthma, or reactive airway disease). AMI = acute myocardial infarction; PCI = percutaneous coronary intervention.

Adding antiplatelet therapy (in particular, thienopyridines and glycoprotein IIb/IIIa inhibitors) results in lower adverse events at 6 months. Drug-eluting stents are associated with **decreased early** (within months) vessel closure but a **higher delayed** closure, particularly once antiplatelet agents (clopidogrel) are stopped.

In centers with expertise in direct angioplasty, primary PCI reduces the cardiovascular complication rate in patients with AMI compared to fibrinolysis.[5,32,33] The longer the duration of symptoms, the greater is the benefit to primary PCI over fibrinolysis. PCI is more effective in establishing flow and reducing reocclusion in the infarct-related artery than fibrinolytic therapy and is associated with a decreased incidence of short- and long-term death, nonfatal reinfarction, and intracranial hemorrhage compared with fibrinolytic therapy.[6]

Registry data show that the targeted reperfusion time goal is met less than half the time.[31,34] Strategies[35] to optimize door to balloon time include: EMS direct or emergency physician activation of the catheterization laboratory without cardiologist consultation by a one call system (similar to trauma activations); having a trained catheterization team ready in 20 minutes; a feedback loop providing the EMS provider and emergency physician with data on the individual case; quality assurance processes in place to measure and report back times; and continually enhancing the team-based approach.

FIBRINOLYTICS

Fibrinolytic agents (tissue plasminogen activator, recombinant tissue plasminogen activator, tenecteplase, streptokinase, and anistreplase) act on the acute thrombosis directly or indirectly as plasminogen activators. Plasminogen, an inactive proteolytic enzyme, binds directly to fibrin during thrombus formation to form a plasminogen–fibrin complex. This plasminogen–fibrin complex incorporated into the clot is more susceptible than circulating plasma plasminogen to activation—thus, the concept that fibrinolytic agents are to a varying degree "clot specific," promoting fibrin proteolysis.

Fibrinolytic therapy improves left ventricular function and short-term and long-term mortality. A meta-analysis found that the net benefit of fibrinolytic treatment in the first 3 hours was >30 lives saved per 1000 patients.[36] The loss of benefit per hour delay in fibrinolytic administration was 1.6 lives per 1000 patients per hour.

Fibrinolytic therapy is indicated for patients with STEMI (as a reperfusion option) if time to treatment is <6 to 12 hours from symptom onset and the ECG has at least 1 mm of ST-segment elevation in two or more contiguous leads.[5,6] Therapy is more beneficial if given early and for larger infarctions and anterior infarctions than for smaller or inferior infarctions. In the elderly, the overall risk of mortality from AMI is high. The proportionate reduction in mortality rate appears to be less in patients >75 years old, but the absolute number of patients who may be saved is still considerable.

After failed fibrinolytic administration, rescue PCI is recommended for patients in cardiogenic shock who are <75 years old, patients with severe heart failure or pulmonary edema, patients with hemodynamically compromising ventricular arrhythmias, and patients in whom fibrinolytic therapy has failed and a moderate or large area of myocardium is at risk.[5]

Because tissue plasminogen activator, recombinant tissue plasminogen activator, and tenecteplase have similar efficacy and safety profiles, the choice of which to use is usually based on ease of administration, cost, and the local preferences.

TABLE 49-10 Contraindications to Fibrinolytic Therapy in ST-Segment Elevation Myocardial Infarction

Absolute contraindications
Any prior intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known intracranial neoplasm
Ischemic stroke within 3 mo
Active internal bleeding (excluding menses)
Suspected aortic dissection or pericarditis
Relative contraindications
Severe uncontrolled blood pressure (>180/100 mm Hg)
History of chronic, severe, poorly controlled hypertension
History of prior ischemic stroke >3 mo or known intracranial pathology not covered in contraindications
Current use of anticoagulants with known INR >2–3
Known bleeding diathesis
Recent trauma (past 2 wk)
Prolonged CPR (>10 min)
Major surgery (<3 wk)
Noncompressible vascular punctures (including subclavian and internal jugular central lines)
Recent internal bleeding (within 2–4 wk)
Patients treated previously with streptokinase should not receive streptokinase a second time
Pregnancy
Active peptic ulcer disease
Other medical conditions likely to increase risk of bleeding (e.g., diabetic retinopathy)

Contraindications to fibrinolytic therapy are those that increase the risk of hemorrhage (**Table 49-10**). The most catastrophic complication is intracranial bleeding. Clinical variables that can be assessed in the ED and predict an increased risk of intracranial hemorrhage are age (>65 years old), low body mass (<70 kg), and hypertension on presentation.[5] Intracranial hemorrhage is more common with tissue plasminogen activator than with streptokinase (odds ratio of 1.6). Patients with relative contraindications may still receive fibrinolytic therapy when the benefits of therapy outweigh the risks of the complications.

Patients treated with fibrinolytics benefit from early follow-up invasive intervention, called *pharmacoinvasive therapy*. In the TRANSFER-AMI study, high-risk patients treated with fibrinolytics for STEMI at non–PCI-capable centers were randomized to standard care or immediate transfer for PCI within 6 hours after fibrinolysis.[37] The patients who underwent the pharmacoinvasive strategy had a 6.2% absolute reduction in the composite endpoint of death, reinfarction, recurrent ischemia, new or worsening heart failure, or cardiogenic shock at 30 days.

Facilitated PCI refers to a planned initial pharmacologic treatment followed by PCI for treatment of STEMI. The ASSENT-4 PCI trial found no benefit and a higher incidence of death, congestive heart failure, or shock at 90 days in the group receiving fibrinolytics compared with the PCI-only group. Current guidelines state that a facilitated approach might be considered in high-risk patients with low bleeding risk with long duration to PCI.[5] However, no clear benefits are apparent for this method.

Fibrinolytic therapy in STEMI is limited in several ways. First, even the most potent fibrinolytic agents do not achieve early and complete restoration of coronary blood flow in 40% to 50% of patients. Fibrinolytics are plasminogen activators. When fibrin is lysed, thrombin is exposed. The exposed thrombin is a potent biologic platelet activator. As a result, the more fibrin that is lysed, the more thrombin is exposed, and the more prothrombotic substrate is engendered. This may be one reason why optimal antithrombin therapy (enoxaparin rather than unfractionated heparin) and dual antiplatelet therapy (both aspirin and clopidogrel) lead to improved outcomes. The second limitation of fibrinolytic therapy is that approximately 0.5% to 1.0% of patients have intracranial hemorrhage, which usually results in death or disabling stroke.

STEMI patients who have received fibrinolytics should receive full-dose anticoagulants for a minimum of 48 hours.[5] Recommended therapies include unfractionated heparin, enoxaparin, or fondaparinux.[5,6]

STREPTOKINASE AND ANISTREPLASE

Streptokinase is a polypeptide derived from β-hemolytic *Streptococcus* cultures. It binds 1:1 to plasminogen, causing a conformational change that activates the plasminogen–streptokinase complex. This complex cleaves peptide bonds on other plasminogen molecules to activate them. This activated complex does not have fibrin specificity with a corresponding potential for marked systemic fibrinogen depletion. Anistreplase is a modified active plasminogen–streptokinase complex. Streptokinase compared with placebo reduces mortality rate and improves left ventricular function in patients with STEMI.

Allergic reactions occur in about 5% of patients treated with streptokinase for the first time, especially those with a recent *Streptococcus* infection. Self-limited allergic reactions usually respond to antihistamines. Anaphylactic reactions are rare. During IV administration, a minority of patients will experience hypotension, which usually responds to decreasing the rate of infusion and volume expansion. Streptokinase has a serum half-life of approximately 23 minutes but produces a fibrinolytic state for up to 24 hours. Antibodies may develop after streptokinase use, so retreatment is generally avoided. Streptokinase is less costly than other fibrinolytic agents. As a result, it is the most widely used fibrinolytic in some countries.[38,39]

ALTEPLASE/TISSUE PLASMINOGEN ACTIVATOR

Alteplase (also called *tissue plasminogen activator*) is a naturally occurring enzyme produced by the vascular endothelium and other tissues. It has a binding site for fibrin that allows it to attach to a formed thrombus and trigger fibrinolysis (fibrin specificity) with only mild systemic fibrinogen depletion. Tissue plasminogen activator achieves higher infarct-related artery patency rates than streptokinase (about 75% vs 50%, respectively). However, the choice of which fibrinolytic agent to use is probably less relevant than quick door-to-needle time (which saves an additional 1.6 per 1000 lives per hour earlier when treatment is provided). The mechanism of improved benefit of tissue plasminogen activator is early patency of the infarct-related vessel, which predicts short- and long-term survival.

RETEPLASE

Reteplase (recombinant tissue plasminogen activator) is a genetically engineered modification of tissue plasminogen activator that has a longer half-life (18 minutes vs 3 minutes) but reduced fibrin binding with potential for moderate systemic fibrinogen depletion. The third Global Use of Strategies to Open Occluded Coronary Arteries III trial showed no clinical difference in outcomes (mortality and stroke) between tissue plasminogen activator and reteplase. Reteplase can be given as a double slow-IV bolus, 10 milligrams each, 30 minutes apart. The easy double-bolus administration is an advantage in the ED.

TENECTEPLASE

Tenecteplase is another tissue plasminogen activator variant with a prolonged half-life (about 20 minutes), is resistant to endogenous plasminogen activator inhibitor 1 inactivation, and has high fibrin specificity and binding with minimal systemic fibrinogen depletion. There is no difference in 30-day mortality or intracranial hemorrhage rates between tenecteplase and tissue plasminogen activator. Single-bolus administration makes this an easy fibrinolytic agent to administer, but tenecteplase requires weight-based dosing, which may not always be practical.

ANTIPLATELET AGENTS

The glycoprotein IIb/IIIa antagonists are stronger antiplatelet agents than aspirin, interrupting platelet activation regardless of the agonist. In contrast, aspirin only inhibits platelet aggregation stimulated through thromboxane A_2 and mediated through the arachidonic acid pathway.

ASPIRIN

Give aspirin, ≥162 milligrams and preferably 325 milligrams if naïve of aspirin, as soon as possible to all patients with STEMI, NSTEMI, and unstable angina. Aspirin prevents formation of thromboxane A_2, an agonist of platelet aggregation. This inhibition persists for the 8- to 12-day life of the platelet, because platelets are unable to generate new cyclooxygenase. In patients with STEMI, aspirin alone reduces relative mortality rate by 23%.[5] The estimated number needed to treat to aid is 41 patients, with the number needed to harm (nondangerous bleeding) being 167 patients.[40] Aspirin used in conjunction with fibrinolytic therapy further reduces ischemic events and coronary artery reocclusion. Aspirin doses >162 milligrams cause immediate, near-complete inhibition of thromboxane A_2. Smaller doses may not be effective for acute use. Aspirin reduces vascular events in patients with AMI and patients with unstable angina, especially in those with prior myocardial infarction or stroke (decrease by about 4%).

The side effects of aspirin are mainly GI, accumulative, and dose related. They can be reduced by using diluted or buffered aspirin solutions, lowest possible doses, or concurrent antacid or H_2 antagonist administration. Due to the substantial benefits of aspirin therapy during ACS, do not withhold this agent from patients with minor contraindications (vague allergy, history of remote peptic ulcer, or GI bleeding).[5] Other antiplatelet agents such as clopidogrel are alternatives if true aspirin allergy or active peptic ulcer disease exists.

ADENOSINE DIPHOSPHATE RECEPTOR ANTAGONISTS

Prasugrel Prasugrel is an irreversible, potent platelet receptor antagonist in this class. In the TRITON-TIMI 38 trial, prasugrel compared favorably with clopidogrel,[41] reducing the primary composite outcome by an absolute 2.2%, although with an increased frequency of bleeding. In post hoc analysis, this increased bleeding risk was greatest in patients with a history of stroke and patients age ≥75 years. The **U.S. Food and Drug Administration issued a boxed warning for prasugrel, indicating use is contraindicated in patients with a prior cerebrovascular accident or transient ischemic attack or with pathologic bleeding. Additional risk factors for bleeding are age ≥75 years, propensity for bleeding, and concomitant use of medications that increase the risk of bleeding.** Prasugrel has only been studied in patients with known coronary anatomy, so it has limited generalizability to ED patients.[42]

Ticagrelor Ticagrelor is a reversible nonthienopyridine P2Y12 receptor antagonist, with the effect gone within 3 days of stopping the agent. The PLATO study compared ticagrelor to clopidogrel[43] in patients with ACS (with or without ST elevation). The composite primary outcome in those treated with ticagrelor was 1.9% absolute frequency lower without any difference in major bleeding. In the patients with STEMI undergoing PCI, there was an increase in stroke in patients receiving ticagrelor (1.7% vs 1.0%, $P = 0.02$)

Clopidogrel The addition of clopidogrel to aspirin and antithrombin therapy improves cardiovascular outcomes in patients receiving fibrinolysis for STEMI. The CLARITY-TIMI 28 trial[44] and the COMMIT Trial[45] both demonstrated improvements in hospital and 30-day outcomes with the addition of clopidogrel to standard therapy. The American College of Cardiology/American Heart Association STEMI guidelines consider this dual therapy a Class I, level of evidence A recommendation.[5]

Clopidogrel reduces a composite outcome of death, AMI, and stroke in patients with unstable angina/NSTEMI. The CURE trial randomized patients with unstable angina/NSTEMI to clopidogrel (300-milligram loading dose and 75-milligram daily dose) or placebo,[46] with all patients receiving aspirin. The clopidogrel group had a 20% reduction in death, AMI, or stroke between 3 and 12 months. There was an excess of bleeding in the clopidogrel group compared with controls; however, this was reduced in patients who received lower doses of aspirin.

Give clopidogrel to patients with true aspirin allergy. Early administration is recommended in patients with ACS regardless of whether noninvasive management or PCI is planned.[47] For patients undergoing urgent PCI, 600 milligrams is superior to 300 milligrams in preventing postprocedure MI.[48,49] However, the results of the CURRENT-OASIS-7 trial reported that although increasing the clopidogrel dose to 600 milligrams caused a decrease in ischemic events, there was also an increased rate of bleeding.[50] Therefore, the current guidelines still provide a clopidogrel dose range of 300 to 600 milligrams in patients with unstable angina/NSTEMI.[1]

In late 2009 and early 2010, the U.S. Food and Drug Administration issued warnings on the efficacy of clopidogrel in two selected patient groups. First, patients taking omeprazole experience an approximately 50% reduction in the antiplatelet aggregation effects of clopidogrel. Second, patients with the variant *CYP2C19* gene have impaired metabolism of clopidogrel and hence a reduced ability to convert the drug to its active form, leading to an increase in stent thromboses and recurrent ischemic events. Consider alternative antiplatelet agents in this group of patients.

Because of an increased bleeding risk, withhold clopidogrel for 5 days before coronary artery bypass grafting when possible. About 5% to 20% of patients with unstable angina/NSTEMI eventually have near-term coronary artery bypass grafting; do not withhold clopidogrel unless coronary artery bypass grafting is imminent.

GLYCOPROTEIN IIB/IIIA INHIBITORS

Abciximab is a chimeric antibody that binds irreversibly to the glycoprotein IIb/IIIa antagonists. The duration of action is longer than that of the smaller peptide molecules. **Eptifibatide** is a synthetic heptapeptide that binds reversibly to the glycoprotein IIb/IIIa receptor. **Tirofiban** is a synthetic small molecule with reversible binding to the glycoprotein IIb/IIIa receptor. All require an IV infusion to demonstrate sustained benefits. Reversal of platelet inhibition after cessation of infusion is more rapid with the polypeptide or small-molecule agents eptifibatide or tirofiban, an advantage when bleeding complications occur.

Despite potential benefits, routine initiation of a glycoprotein IIb/IIIa inhibitor in the ED is not recommended due to conflicting information about the timing of PCI after administration and potential for bleeding.[51]

The glycoprotein IIb/IIIa inhibitor recommendations include patients with high-risk features, such as positive troponins, or patients who are likely to receive PCI, but initiation prior to catheterization does not have proven benefit over initiation in the catheterization laboratory. Six large trials together enrolled more than 10,000 PCI patients and found that patients treated with glycoprotein IIb/IIIa inhibitors (in addition to aspirin and an antithrombin) have an approximately 40% reduced risk of death or AMI in 30 days.[51] Some of this benefit was sustained for up to 3 years (13% reduction).

Four large trials evaluated glycoprotein IIb/IIIa antagonists for the medical stabilization of patients with unstable angina/NSTEMI. Tirofiban and eptifibatide reduced the rates of the triple composite endpoint of death, AMI, and recurrent ischemia. However, abciximab was not a benefit in patients who did not undergo coronary angiography within 48 hours. In a meta-analysis of six randomized placebo-controlled trials, a small reduction in the composite (but not individual) endpoint of death or AMI occurred in patients receiving glycoprotein IIb/IIIa inhibitors (11.8% vs 10.8%), with the most benefit and bleeding in patients undergoing PCI.[51] Thus, **the American Heart Association/American College of Cardiology guidelines for the management of unstable angina/NSTEMI patients make administration of glycoprotein IIb/IIIa inhibitors to patients in whom a PCI is planned a Class IIb recommendation.**[1] Abciximab is not recommended for patients who will be receiving medical management without PCI. A trial by Giugliano et al[52] published in 2009 found that for NSTEMI patients taken to PCI (invasive strategy), eptifibatide delayed to the time of PCI resulted in less bleeding with otherwise similar outcomes, suggesting that the preferred time for administration of glycoprotein IIb/IIa inhibitors to this group of patients is at the time of PCI.[53]

ANTITHROMBINS

UNFRACTIONATED HEPARIN

Unfractionated heparin reduces the risk of AMI and death during the acute phase of unstable angina. The combination therapy of aspirin and

heparin reduces the short-term risk of death or AMI by 56% compared with aspirin alone. When unfractionated heparin is used in combination with aspirin, recurrence of ischemia is diminished after cessation of the infusion. **Thus, combination therapy with aspirin and heparin is indicated for patients with ACS.**

Unfractionated heparin has an unpredictable anticoagulant response because the bioavailability of heparin is variable. Even in clinical trials, less than half of patients are appropriately anticoagulated within 24 hours. Unfractionated heparin requires careful laboratory monitoring and dose adjustment. The weight-adjusted regimen is recommended, with an initial bolus of 60 units/kg (maximum of 4000 units per American Heart Association/American College of Cardiology guidelines[1,5]) and an infusion of 12 units/kg/h (maximum, 1000 units/h[1,5]). Unfractionated heparin dosing according to the European Society of Cardiology is 70 to 100 units/kg IV bolus when no glycoprotein IIb/IIIa inhibitor is planned and 50 to 60 units/kg IV bolus when given with glycoprotein IIb/IIIa inhibitors.[6] Optimally, cease unfractionated heparin after 48 hours of therapy to reduce the risk of developing heparin-induced thrombocytopenia.[5] Use other agents if ongoing anticoagulation is needed.

LOW-MOLECULAR-WEIGHT HEPARINS

The low-molecular-weight heparins have greater bioavailability, lower protein binding, and a longer half-life, and achieve a more reliable anticoagulant effect. As a result, they are given in a fixed dose subcutaneously once or twice a day and achieve a stable therapeutic response without the need for monitoring anticoagulation.

Large clinical trials show that enoxaparin, rather than unfractionated heparin, improved outcome in STEMI patients treated with aspirin and fibrinolysis.[54] **Enoxaparin is not considered a first-line antithrombin for patients receiving primary PCI for treatment of STEMI**[5]; however, in the event that a patient previously started on enoxaparin goes for PCI, enoxaparin should be continued.

A meta-analysis of six trials comparing enoxaparin with unfractionated heparin demonstrates a 0.9% reduction in death or recurrent AMI in patients receiving enoxaparin rather than unfractionated heparin, in addition to other standard therapies.[55] The benefit of enoxaparin is greater in patients with higher risk, with a significant decrease in the composite endpoint of death, AMI, and recurrent ischemia requiring PCI at 14 days in patients with a TIMI risk score >3. Trials with high rates of PCI have demonstrated the safety and efficacy of low-molecular-weight heparins in patients receiving PCI. The SYNERGY trial demonstrated improved outcomes in patients with consistent therapy (use of a single antithrombin from the ED through the catheterization laboratory) and increased bleeding when the patient was changed from one antithrombin to another. **The best approach is for the emergency physician and cardiologist to work in collaboration** to choose the antithrombin agent used from ED through PCI and aftercare. If coronary artery bypass grafting is planned, hold low-molecular-weight heparin for 12 to 24 hours, bridging with unfractionated heparin.

FONDAPARINUX

Fondaparinux is a synthetic pentasaccharide that binds to antithrombin-III to form an antithrombic complex, but unlike heparin, this complex is very specific for factor Xa inhibition. Fondaparinux has been evaluated in two large clinical trials. In STEMI patients, it has similar efficacy to unfractionated heparin in patients receiving fibrinolytics or primary PCI. However, the European Society of Cardiology does not recommend fondaparinux in patients going for PCI.[6] American College of Cardiology/American Heart Association guidelines make the following caution: **fondaparinux is not a monotherapy for PCI; if used, add unfractionated heparin or bivalirudin before PCI.**[5]

In unstable angina/NSTEMI patients, bleeding was lower in fondaparinux- versus enoxaparin-treated patients. For NSTEMI patients in whom a conservative management is to be used, the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommended fondaparinux over enoxaparin,[56] as did the European Society of Cardiology,[24] but it is not yet U.S. Food and Drug Administration approved for this indication.

DIRECT THROMBIN INHIBITOR: BIVALIRUDIN

Direct thrombin inhibitors bind to the catalytic site of thrombin, bind to thrombin in clot, and are resistant to agents that degrade heparin. Bivalirudin reduces the short-term risk of postischemic complications relative to high-dose unfractionated heparin in patients undergoing PCI for unstable or postinfarction angina. The ACUITY trial demonstrated that bivalirudin is safe and effective for intermediate- to high-risk unstable angina/NSTEMI patients receiving PCI.[57] The HORIZONS-AMI trial showed that, in patients with STEMI who are undergoing PCI, anticoagulation with bivalirudin alone, as compared with unfractionated heparin plus glycoprotein IIb/IIIa inhibitors, resulted in significantly reduced 30-day rates of major bleeding.[58]

LIMITING INFARCT SIZE

NITRATES

Nitrates relax vascular smooth muscle in arteries, arterioles, and veins through the metabolic conversion of organic nitrates to nitric oxide. The pulmonary capillary wedge pressure, systemic arterial pressure, and left ventricular end-systolic and end-diastolic volumes decrease. Reduction in right and left ventricular filling pressures that result from peripheral dilatation combined with afterload reduction that results from arterial dilatation decrease cardiac work and myocardial O_2 requirements. Nitroglycerin has direct vasodilator effects on the coronary vascular bed and increases global and regional myocardial blood flows. When obstructing atherosclerotic lesions contain intact vascular smooth muscle, nitrates may dilate these vessels, thereby improving blood flow. Platelet aggregation is also inhibited by nitroglycerin.

When nitroglycerin is used in AMI patients not treated with thrombolytics, it reduces infarct size, improves regional function, and decreases the rate of cardiovascular complications. The mortality rate is lowered by 35% with the use of nitrates. It is important to note that in most studies, IV nitroglycerin titration to 10% reduction in mean arterial pressure for normotensive patients and to 30% reduction in mean arterial pressure for hypertensive patients occurred, not for symptom resolution. **In AMI, titrate IV nitroglycerin to blood pressure reduction rather than to symptom (chest pain) resolution**. Data are confounded regarding a benefit of nitroglycerin in those receiving fibrinolytic therapy.

The American College of Cardiology/American Heart Association recommends the use of IV nitroglycerin for the first 24 to 48 hours for patients with STEMI and recurrent ischemia, congestive heart failure, or hypertension.[5] Benefits are likely to be greatest in patients not receiving concurrent fibrinolytic therapy. For unstable angina/NSTEMI, IV nitroglycerin is used in patients who are not responsive to sublingual nitroglycerin tablets.[1]

The most serious side effect of nitroglycerin is hypotension, which may result in reflex tachycardia and worsening ischemia; paradoxical bradycardia can also follow nitrate use. **Use nitroglycerin cautiously for patients with inferior wall ischemia**, because one third of such patients might have right ventricular involvement and hence are volume dependent; nitrates reduce preload and commonly trigger hypotension in this setting, worsening infarct. If nitroglycerin results in hypotension, stop the drug and administer fluid for blood pressure. Avoid nitrates in patients with ACS who recently received a phosphodiesterase inhibitor for erectile dysfunction (within 24 hours of sildenafil use or within 48 hours of tadalafil use).

BLOCKERS

β-Adrenergic antagonists have antidysrhythmic, anti-ischemic, and antihypertensive properties. During AMI, they diminish myocardial O_2 demand by decreasing heart rate, systemic arterial pressure, and

myocardial contractility. Prolongation of diastole may augment perfusion to ischemic myocardium.

Contemporary trials show no benefit from early β-blocker therapy, and data from one large trial have changed the guideline recommendations for β-antagonists.[59] The COMMIT/CCS-2 trial randomized 45,852 patients within 24 hours of myocardial infarction symptom onset to receive either IV metoprolol followed by oral metoprolol or placebo. **Metoprolol reduced the absolute risks of reinfarction by 5 per 1000 and of ventricular fibrillation by 5 per 1000, but importantly, it increased the risk of cardiogenic shock by 11 per 1000.** Overall, metoprolol did not significantly reduce mortality in the hospital.[59] **American College of Cardiology/American Heart Association recommendations are to start PO (not IV) β-antagonists in patients with STEMI or NSTEMI within 24 hours provided the patient has none of the following**: (1) signs of heart failure, (2) evidence of a low cardiac output state, (3) increased risk for cardiogenic shock (cumulatively: age >70 years old, systolic blood pressure <120 mm Hg, sinus tachycardia >110 beats/min or bradycardia <60 beats/min, and longer duration of STEMI symptoms before diagnosis and treatment), or (4) standard relative contraindications to β-blockade (PR interval >0.24 seconds, second- or third-degree heart block, active asthma, or reactive airway disease).[1,5] IV therapy is reserved for patients with significant hypertension.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme inhibitors reduce left ventricular dysfunction and left ventricular dilatation and slow the development of congestive heart failure during AMI. Oral angiotensin-converting enzyme therapy lowers mortality after AMI.[60]

The American College of Cardiology/American Heart Association recommends that patients with STEMI or heart failure receive treatment with oral angiotensin-converting enzyme inhibitors within the first 24 hours (**not necessarily in the ED**).[5] For unstable angina/NSTEMI, angiotensin-converting enzyme inhibitors should be administered within the first 24 hours in patients with pulmonary congestion or a left ventricular ejection fraction <40%, in the absence of hypotension or contraindications.[1]

Contraindications to angiotensin-converting enzyme inhibitors include hypotension, bilateral renal artery stenosis, renal failure, or history of cough or angioedema due to prior angiotensin-converting enzyme inhibitor use. The efficacy of angiotensin-converting enzyme inhibitors in unstable angina has not been well evaluated.

MAGNESIUM

Magnesium produces systemic and coronary vasodilatation, possesses antiplatelet activity, suppresses automaticity, and protects myocytes from calcium influx during reperfusion. However, studies are conflicting: some have found that the mortality rate is reduced, whereas others have shown no benefit at all. In light of these conflicting data, correct documented hypomagnesemia during AMI and give magnesium for torsades-type ventricular tachycardia with a prolonged QT interval.[5] Magnesium bolus and infusion in high-risk patients, such as the elderly and those in whom reperfusion therapy is not suitable, are considered possibly beneficial.[5]

CALCIUM CHANNEL ANTAGONISTS

Calcium channel blockers have antianginal, vasodilatory, and antihypertensive properties. **Calcium antagonists do *not* reduce mortality rate after AMI, and they may be harmful to some patients with cardiovascular disease.[5]**

Verapamil and diltiazem are potentially beneficial in patients with ongoing ischemia or atrial fibrillation with rapid ventricular response who do not have congestive heart failure, left ventricular dysfunction, or atrioventricular block, and when β-adrenergic antagonists are contraindicated.

COMPLICATIONS OF ACUTE CORONARY SYNDROME

Myocardial perfusion and cardiac function affect blood flow to the entire body. As a result, any end organ can be damaged when cardiac pump function is decreased. In this section, discussion of the complications of ACS is limited to the direct effects on the heart. The systemic effects of cardiac function are discussed in organ-appropriate chapters of this book.

DYSRHYTHMIAS AND CONDUCTION DISTURBANCES

The genesis, diagnosis, and treatment of dysrhythmias are presented in chapter 18, "Cardiac Rhythm Disturbances." The effect dysrhythmias have in complicating the course of patients with ACS is the subject of this section.

Dysrhythmias occur in 72% to 100% of AMI patients treated in the coronary care unit. **Table 49-11** shows the approximate frequency of the various dysrhythmias observed in patients with AMI. Many dysrhythmias occur in the prehospital and ED settings. The main consequences of dysrhythmias are impaired hemodynamic performance, compromised myocardial viability due to increased myocardial O_2 requirements, and predisposition to even more serious rhythm disturbances due to diminished ventricular fibrillation threshold.

The hemodynamic consequences of dysrhythmias are dependent on ventricular function. Patients with left ventricular dysfunction have a relatively fixed stroke volume. They depend on changes in heart rate to alter cardiac output. The range of heart rate that is optimal becomes narrowed with increasing dysfunction. Slower or faster heart rates may further depress cardiac output.

In addition, maintenance of the atrial filling of the ventricle (or "the atrial kick") is important for patients with AMI. Patients with normal hearts have a loss of 10% to 20% of left ventricular output when the atrial kick is eliminated. Patients with reduced left ventricular compliance, common in AMI, have up to 35% reduction in stroke volume when the atrial systole is eliminated. "Pump" failure with resultant increased sympathetic stimulation can also result in sinus tachycardia, atrial fibrillation or flutter, and supraventricular tachycardias.

TABLE 49-11 Early Dysrhythmias after Acute Myocardial Infarction

Dysrhythmia	Frequency of Occurrence (%)
Bradydysrhythmias	
Sinus bradycardia	35–40
First-degree AV block	4–15
Second-degree AV block, type I	4–10
Second-degree AV block, type II	0.5–1.0
Third-degree AV block	5–8
Asystole	1–5
Tachydysrhythmias	
Sinus tachycardia	30–35
Atrial premature contractions	50
Supraventricular tachycardia	2–9
Atrial fibrillation	4–10
Atrial flutter	1–2
Ventricular premature beats	99
Accelerated idioventricular rhythm	50–70
Ventricular tachycardia, nonsustained	60–69
Ventricular tachycardia, sustained	2–6
Ventricular fibrillation	4–7

Abbreviation: AV = atrioventricular.

Sinus tachycardia is quite prominent in patients with anterior wall AMI. Because of increased myocardial O_2 use, **persistent sinus tachycardia is associated with a poor prognosis in AMI; seek the cause and resolve it**. Causes may include anxiety, pain, left ventricular failure, fever, pericarditis, hypovolemia, atrial infarction, pulmonary emboli, or use of medications that accelerate heart rate. Similarly, paroxysmal supraventricular tachycardia, atrial fibrillation, and atrial flutter are associated with an increased mortality.

Atrial fibrillation associated with AMI most typically occurs in the first 24 hours and is usually transient. It more often occurs in patients with excess catecholamine release, hypokalemia, hypomagnesemia, hypoxia, chronic lung disease, and sinus node or left circumflex ischemia. Patients with supraventricular tachycardia, atrial fibrillation, or atrial flutter who have hemodynamic compromise are best treated with direct current cardioversion (see chapter 18). Patients who are partially/fully compensated or who do not respond to cardioversion can receive amiodarone or-β-adrenergic antagonists to slow the ventricular rate[61] absent any contraindications. Patients with ongoing ischemia but without hemodynamic compromise, clinical left ventricular dysfunction, reactive airway disease, or heart block should have rate control with β-adrenergic antagonists, such as atenolol (2.5 to 5.0 milligrams over 2 minutes to a total of 10 milligrams) or metoprolol (2.5 to 5.0 milligrams every 2 to 5 minutes to a total of 15 milligrams). Patients with contraindications to β-adrenergic antagonists can be treated with digoxin (0.3- to 0.5-milligram initial bolus with a repeat dose in 4 hours) or a calcium channel antagonist.[5] Anticoagulate patients with atrial fibrillation and AMI to limit systemic embolization.

Sinus bradycardia without hypotension does not appear to increase mortality during AMI. Prognosis is related to the site of infarction, the site of the block (intranodal vs infranodal), the type of escape rhythm, and the hemodynamic response to the rhythm. Atropine is used for sinus bradycardia when it results in hypotension, ischemia, or ventricular escape rhythms and for treatment of symptomatic atrioventricular block occurring at the atrioventricular nodal level (such as second-degree type I). Atropine can improve heart rate, systemic vascular resistance, and blood pressure; use it with caution in the setting of AMI since the parasympathetic tone is protective against infarct extension, ventricular fibrillation, and excessive myocardial O_2 demand.

Complete heart block can occur in patients with anterior and inferior AMI, because the AV conduction system receives blood supply from the atrioventricular branch of the right coronary artery and the septal perforating branch of the left anterior descending coronary artery. In the absence of right ventricular involvement, the mortality is approximately 15%. It rises to >30% when right ventricular involvement is present. Complete heart block in the setting of an anterior myocardial infarction portends a grave prognosis. Junctional rhythms are usually transient and occur within 48 hours of infarction.

The increased mortality in patients with heart block during AMI is related to more extensive myocardial damage and not to the heart block itself. As a result, pacing does not reduce mortality in patients with atrioventricular block or intraventricular conduction delay. Nonetheless, pacing is recommended to protect against sudden hypotension, acute ischemia, and precipitation of ventricular dysrhythmias in certain patients.

Use temporary **transcutaneous** pacers in patients at moderate to high risk of progression to atrioventricular block (see Table 49-12). **Transvenous** pacing follows for patients with a high likelihood (>30%) of requiring permanent pacing (**Table 49-12**). Patients with right ventricular infarction who are very dependent on atrial systole may require atrioventricular sequential pacing to maintain cardiac output.

Ventricular premature contractions are common in patients with AMI and are benign. **Accelerated idioventricular rhythms** in patients with AMI do not affect prognosis or require treatment. **Ventricular tachycardia** shortly after AMI is often transient and does not confer a poor prognosis. When ventricular tachycardia occurs late in the course of AMI, it is usually associated with transmural infarction and left ventricular dysfunction, induces hemodynamic deterioration, and is associated with a mortality rate approaching 50%. Primary **ventricular fibrillation** occurring shortly after symptom onset does not appear to have a large effect on mortality and prognosis, as long as it is quickly and effectively treated. Delayed or secondary ventricular fibrillation during hospitalization is associated with severe ventricular dysfunction and 75% in-hospital mortality.

TABLE 49-12 Indications for Temporary Pacemaker Placement

Temporary transcutaneous pacemaker indications
Unresponsive symptomatic bradycardia
Mobitz II or higher AV blocks
New LBBB and bifascicular blocks
RBBB or LBBB with first-degree block
Some cases with stable bradycardia and new or indeterminate-age RBBB
Temporary transvenous pacemaker indications
Asystole
Unresponsive symptomatic bradycardia
Mobitz II or higher AV blocks
New or indeterminate-age LBBB
Alternating bundle-branch block
RBBB or LBBB with first-degree block
Consider in RBBB with left anterior or posterior hemiblocks
Overdrive pacing in unresponsive ventricular tachycardia
Unresponsive recurrent sinus pauses (>3 s)

Abbreviations: AV = atrioventricular; LBBB = left bundle-branch block; RBBB = right bundle-branch block.

New right bundle-branch block occurs in approximately 2% of AMI patients, most commonly with anteroseptal AMI; it is associated with an increased mortality and complete atrioventricular block. **New left bundle-branch block** occurs in <10% of patients with AMI and is also associated with a higher mortality than in patients without left bundle-branch block. Recognizing STEMI in the presence of left bundle-branch block is difficult,[8] and due to this uncertainty and false catheterization lab activation, new or suspected new left bundle-branch block alone has been removed from the most recent recommendations for emergency perfusion.[5] The left posterior fascicle is larger than the left anterior fascicle. Thus, left posterior hemiblock is associated with a higher mortality than is isolated left anterior hemiblock, because it represents a larger area of infarction. Bifascicular block (right bundle-branch block and a left hemiblock) has an increased likelihood of progression to complete heart block; it represents a large infarction and has more frequent pump failure and greater mortality.[20] See chapter 18, "Cardiac Rhythm Disturbances" for more detail.

HEART FAILURE

Some 15% to 20% of patients with AMI present with some degree of heart failure. One third of these patients have circulatory shock. In AMI, heart failure occurs from diastolic dysfunction alone or a combination of systolic and diastolic dysfunction. Left ventricular diastolic dysfunction leads to pulmonary congestion. Systolic dysfunction is responsible for decreased forward flow, reduced cardiac output, and reduced ejection fraction. In general, the more severe the degree of left ventricular dysfunction, the higher is the mortality. The degree of left ventricular dysfunction in any single patient depends on the net effect of prior myocardial dysfunction (prior myocardial infarction or cardiomyopathy), baseline myocardial hypertrophy, acute myocardial necrosis, and acute reversible myocardial dysfunction ("stunned myocardium"). For further discussion, see chapters 53, "Acute Heart Failure" and 50, "Cardiogenic Shock."

Mortality for patients with AMI increases as cardiac output decreases or pulmonary congestion increases, with mortality rates as follows: no heart failure, 10%; mild heart failure, 15% to 20%; frank pulmonary edema, 40%; and cardiogenic shock, 50% to 80%. Elevated levels of B-type natriuretic peptide or pro-B-type natriuretic peptide early in the hospital course portend a worse 30-day outcome.

The presence of shock in AMI results in a complex spiral relationship. Coronary obstruction leads to myocardial ischemia, which impairs

myocardial contractility and ventricular outflow. The resulting reduction in arterial blood pressure leads to further decreases in coronary arterial perfusion, resulting in worsening myocardial ischemia and more severe myocardial necrosis. Interruption of this downward spiral requires careful attention to fluid management and the use of inotropic agents. Resolution of ischemia and preventing or minimizing the area of stunned myocardium that progresses to infarction are imperative; guidelines recommend that patients with STEMI and cardiogenic shock who are <75 years of age should be considered for PCI.[5] For further discussion, see chapters 50 and 53.

MECHANICAL COMPLICATIONS

Sudden decompensation of previously stable patients should raise concern for the mechanical complications of AMI. These complications usually involve the tearing or rupture of **infarcted** tissue, not seen in unstable angina. The clinical presentation of these entities depends on the site of rupture (papillary muscles, interventricular septum, or ventricular free wall).

Ventricular free wall rupture occurs in 10% of AMI fatalities, usually 1 to 5 days after infarction. Rupture of the left ventricular free wall usually leads to pericardial tamponade and death (in >90% of cases). Patients may complain of tearing pain or sudden onset of severe pain. They will be hypotensive and tachycardic and may have onset of confusion and agitation. Increased neck veins, decreased heart sounds, and pulsus paradoxus may be present. In the ED, echocardiography is the diagnostic test of choice. Near equalization of right atrial, right ventricular mid-diastolic, and right ventricular systolic pressures on pulmonary artery catheterization is also useful but seldom available in the ED. Treatment is surgical.

Rupture of the interventricular septum is more often detected clinically than rupture of the ventricular free wall. The size of the defect determines the degree of left-to-right shunt and the ultimate prognosis. Clinically, interventricular septal rupture presents with chest pain, dyspnea, and sudden appearance of a new holosystolic murmur. The murmur is usually accompanied by a palpable thrill and is heard best at the lower left sternal border. Doppler echocardiography is the diagnostic procedure of choice. Demonstration of left-to-right shunt by pulmonary catheter blood sampling may be useful. An O_2 step-up of >10% from right atrial to right ventricular samples is diagnostic. Rupture of the interventricular septum is more common in patients with anterior wall myocardial infarction and patients with extensive (three-vessel) coronary artery disease. Treatment is surgical.

Papillary muscle rupture occurs in approximately 1% of patients with AMI, is more common with inferior myocardial infarction, and usually occurs 3 to 5 days after AMI. In contrast to rupture of the interventricular septum, papillary muscle rupture often occurs with a small- to modest-sized AMI. Patients present with acute onset of dyspnea, increasing heart failure and pulmonary edema, and a new holosystolic murmur consistent with mitral regurgitation. The posteromedial papillary muscle is most commonly ruptured, because it receives blood supply from one coronary artery, usually the right coronary artery. Echocardiography often can distinguish rupture of a portion of the papillary muscle from other etiologies of mitral regurgitation. Treatment is surgical.[5,6]

PERICARDITIS

In the era of PCI intervention, early post-AMI pericarditis occurs in less than 5% of patients,[62] a drop from 20% since the 1980s. It is more common in patients with transmural AMI and delayed initial presentations. Pericarditis results from inflammation adjacent on the epicardial surface of a transmural infarction, often 2 to 4 days after AMI. Pericardial friction rubs are detected more often with inferior wall and right ventricular infarction, because the right ventricle lies immediately beneath the chest wall. The pain of pericarditis can be confused with that of infarct extension or post-AMI angina. Classically, the discomfort of pericarditis becomes worse with a deep inspiration and may be relieved by sitting forward.

Echocardiography may demonstrate a pericardial effusion, but pericardial effusions are much more common than pericarditis and often are present in the absence of pericarditis. Similarly, pericarditis can be present in the absence of a pericardial effusion. The resorption rate of post-AMI pericardial effusions is slow, often taking several months. Treatment is symptomatic with aspirin, 650 milligrams PO every 4 to 6 hours, or colchicine, 0.6 mg twice daily. Ibuprofen is not recommended because it interferes with the antiplatelet effect of aspirin and can cause myocardial scar thinning and infarct expansion. **Dressler's syndrome** (late post-AMI syndrome) occurs 2 to 10 weeks after AMI and presents with chest pain, fever, and pleuropericarditis. Dressler's syndrome is treated with aspirin and colchicine.[63]

RIGHT VENTRICULAR INFARCTION

Isolated right ventricular infarction is extremely rare and is usually seen as a complication of an inferior infarction. The right ventricle most commonly receives its blood supply from the right coronary artery. In patients with left dominant systems, the blood supply may come from the left circumflex. The anterior portion of the right ventricle is supplied by branches of the left anterior diagonal artery. Approximately 30% of inferior wall myocardial infarction involves the right ventricle. The presence of right ventricular infarction is associated with a significant increase in mortality and cardiovascular complications. Right ventricular infarction can be diagnosed by the presence of ST-segment elevation in the precordial V_4R lead in the setting of an inferior wall myocardial infarction (Figure 49-4). The presence of elevated neck veins or hypotension in response to nitroglycerin is also suggestive. Echocardiography or nuclear imaging can be diagnostic, but they are less readily available in the ED.

The most serious complication of right ventricular infarction is shock. The severity of the hemodynamic derangement in the setting of right ventricular infarction is related to the extent of right ventricular dysfunction, the interaction between the ventricles (the right and left ventricles share the interventricular septum), and the interaction between the pericardium and the right ventricle. Right ventricular infarction results in a reduction in right ventricular end-systolic pressure, left ventricular end-diastolic size, cardiac output, and aortic pressure as the right ventricle becomes more of a passive conduit to blood flow. Left ventricular contraction causes bulging of the interventricular septum into the right ventricle, with resultant ejection of blood into the pulmonary circulation. As a result, right ventricular infarction with concurrent left ventricular infarction has a particularly devastating effect on hemodynamic function. Fluid balance and maintenance of adequate preload are critical in the treatment of right ventricular infarction. Factors that reduce preload (volume depletion, diuretics, and nitrates) or decrease right atrial contraction (atrial infarction and loss of atrioventricular synchrony) and factors that increase right ventricular afterload (left ventricular failure) can lead to significant hemodynamic derangements.

Treatment of right ventricular infarction includes maintenance of preload, reduction of right ventricular afterload, and inotropic support of the ischemic right ventricle, in addition to early reperfusion. Patients with right ventricular infarction should not be treated with drugs, such as nitrates, that reduce preload. **In the setting of right ventricular infarction, nitrates often will reduce cardiac output and produce hypotension.** Instead, patients with marginal preload or hypotension should be treated with volume loading (normal saline). The increased preload will improve right ventricular cardiac output. **If cardiac output is not improved after 1 to 2 L of normal saline, begin inotropic support with dobutamine.**

High-degree heart block is very common in patients with right ventricular infarction. The loss of right atrial contraction can greatly compromise right ventricular cardiac output. Restitution of atrioventricular synchrony is important. Patients who do not attain hemodynamic improvement after placement of a ventricular pacer may still improve with atrioventricular sequential pacing.

When right ventricular infarction is accompanied by left ventricular dysfunction, the use of nitroprusside to reduce afterload or intra-aortic balloon counterpulsation may be of benefit. Reduction in left

ventricular afterload may help passive movement of blood through the right ventricle.

OTHER COMPLICATIONS

Other complications of AMI that occur but are not usually seen in the ED include left ventricular thrombus formation, arterial embolization, venous thrombosis, pulmonary embolism, postinfarction angina, and infarct extension. With the more rapid discharge of uncomplicated AMI patients, keep these possibilities in mind for patients who return to the ED shortly after hospital discharge.

RECURRENT OR REFRACTORY ISCHEMIA

Patients unresponsive to medical management with continued ischemia require an individualized approach to treatment. Depending on the infarct distribution and coronary anatomy, decisions could be made regarding continued medical management, rescue angioplasty, or coronary artery bypass grafting. Refractory ischemia is investigated with coronary catheterization. Treat patients with ACS after stent placement with antithrombin and antiplatelet therapy, and these patients may require urgent coronary catheterization.

In situations where emergent catheterization is not available or the patient is hemodynamically unstable, an **intra-aortic balloon pump** may be used. Intra-aortic balloon counterpulsation delivers phased pulsations synchronized to the electrocardiograph, so that balloon inflation will occur at the time of aortic valve closure and deflation occurs just before onset of systole. The augmented coronary perfusion pressure during diastole enhances coronary blood flow. Balloon deflation during systole allows the left ventricle to eject blood against a lower resistance. The net effect of intra-aortic balloon counterpulsation is an increase in cardiac output, reduction in systolic arterial pressure, increase in diastolic arterial pressure, little change in mean arterial pressure, and reduction in heart rate. The reduction in left ventricular afterload leads to reduced myocardial O_2 consumption, thereby decreasing the amount of myocardial ischemia. Intra-aortic balloon counterpulsation is recommended for patients with ACS who are refractory to aggressive medical management or are hemodynamically unstable as a means to bridge a patient's stability en route to definitive treatment.

SPECIAL POPULATIONS

POSTPROCEDURE CHEST PAIN

Patients who present with symptoms of an ACS shortly after PCIs, such as angioplasty or stent placement, should be assumed to have had abrupt vessel closure, until proven otherwise. Subacute thrombotic occlusion after stent placement occurs in approximately 4% of patients 2 to 14 days postprocedure. **Bare metal stents are more likely to restenose in the short term. Drug-eluting stents are more likely to present with late stent thrombosis after cessation of daily clopidogrel, 9 to 12 months later.** Treat patients aggressively for an ACS, and obtain emergent cardiology consultation. Patients with chest pain syndromes after coronary artery bypass grafting also may have abrupt vessel closure. However, symptoms of recurrent ischemia can be confused with post-AMI pericarditis, as discussed above.

COCAINE- AND AMPHETAMINE-INDUCED ACUTE CORONARY SYNDROME

AMI occurs in approximately 6% of patients who present to the ED with chest pain after cocaine use. Cocaine-associated myocardial infarction occurs in younger patients, but over the past two decades, the average age has increased from 38 years[64] to 50 years,[65] highlighting the increased use of cocaine in middle-age patients. The initial evaluation of the patient with suspected cocaine-associated myocardial infarction should begin as recommended in the "History and Associated Symptoms" and "Physical Examination" sections of this chapter. The sensitivity, specificity, positive predictive value, and negative predictive value of the ECG to identify cocaine-associated MI are 36%, 89.9%, 17.9%, and 95.8%, respectively.[66] Cardiac troponin is the most sensitive biomarker for cocaine-associated myocardial infarction. Aspirin, nitrates, and benzodiazepines are the mainstays of therapy for initial stabilization; β-blockers are contraindicated in the first 24 hours.[66] Patients with cocaine-associated STEMI are best managed with PCI.[66] Antithrombotic and antiplatelet therapy may be given according to current guidelines for non–cocaine-related ACS.

There are fewer cases of amphetamine-induced MI to guide therapy and no care guidelines. The initial ECG may be unreliable in the setting of methamphetamine-related ACS, with false-positive ST-segment elevation prompting unneeded thrombolytic therapy. In one case series of 33 patients admitted for chest pain who were methamphetamine positive, nine (25%) were diagnosed with ACS (positive markers or required revascularization). Three patients (8%) (two ACS and one non-ACS) suffered cardiac complications (ventricular fibrillation, ventricular tachycardia, and supraventricular tachycardia, respectively). Only one patient had Q-wave myocardial infarction treated with PCI. Medical management was the mainstay of therapy.

ACUTE MEDICAL DISORDERS ASSOCIATED WITH ACUTE CORONARY SYNDROME

Those with GI bleeding,[67] stroke,[68,69] and severe infection have a higher frequency of ACS[70]; even those with disorders considered otherwise benign, such as acute anxiety or emotional upset, have a higher frequency of MI.[71] In the case of stroke and GI bleeding, the primary disease process (which came first) is sometimes unclear or underdiagnosed until late in the patient's course. In a group of patients admitted to the intensive care unit for GI bleeding, approximately 13% sustained MI; however, this did not affect mortality in this intensive care unit population. A case-control study found increased risk of death in patients with GI bleeding meeting criteria for myocardial infarction when compared with those with negative markers (33% vs 8%).[67] In general, treatment of the GI bleed takes priority, which precludes the major treatments for AMI. **For patients with acute ischemic stroke, 17% have positive troponin assessment, which is associated with 3.2 relative risk of death compared with patients with normal troponin.** The risk of stroke complicating the course of AMI has been formerly reported as 2.4% to 3.5%,[72] but with improved treatments for AMI, the risk has dropped to 0.6% to 1.8%. Hospital mortality in patients with stroke after AMI is high (17% to 27%). ECG abnormalities are common in patients with subarachnoid hemorrhage, and elevated troponin levels occur in 28%, with over half of these demonstrating transient left ventricular dysfunction. However, simultaneous STEMI is not common with a subarachnoid hemorrhage. Approximately 50% of patients with severe sepsis and septic shock have impairment of left ventricular systolic function, frequently with an elevated troponin level.[71] AMI occurs in 5.3% of patients hospitalized with community-acquired pneumonia, with the risk increasing to 15% in those with severe pneumonia.[73]

For all patients with dual or multiple acute medical issues, individualize management and weigh the risks of AMI guideline therapies. When indicated, use PCI over thrombolysis to identify the lesion and need for additional therapy.

AFTER HOURS AND WEEKEND PRESENTATIONS

The management of patients with ACS is time sensitive and intensive. Patients who present "after hours" and on weekends wait longer for interventions, and this has an adverse impact on outcome. Patients who present when the ED is busy with other ill patients (e.g., trauma patients) or in settings with increased health system dysfunction and high levels of ED boarding, as well as patients who are not expeditiously transferred to an inpatient bed, have worse outcomes.[74-76] Systems solutions to improve hospital flow for patients with ACS will help optimize the care of patients with ACSs.

CHAPTER 50

Cardiogenic Shock

Casey Glass
David Manthey

INTRODUCTION AND EPIDEMIOLOGY

Cardiogenic shock is an acute state of decreased cardiac output resulting in inadequate tissue perfusion despite adequate circulating volume. Cardiogenic shock is the leading cause of in-hospital death in patients with acute myocardial infarction (AMI).[1] The true incidence of cardiogenic shock is unknown because many patients die before arrival and escape estimates. Cardiogenic shock is seen in 4% to 8% of patients with ST-segment elevation myocardial infarction (STEMI).[2,3] The incidence is declining in part as a result of the increased use of percutaneous intervention for AMI.[3-6] Cardiogenic shock occurs less frequently (2.5%) in those with non–ST-segment elevation myocardial infarction (NSTEMI) compared with those with STEMI.[7,8] Only ~10% of AMI patients who will develop cardiogenic shock have it at ED presentation, with the median time of onset after arrival being approximately 6 hours.[2,9] This underscores the therapeutic opportunity that exists by thwarting ongoing myocardial ischemia.

During the past decade, a strategy of early revascularization by percutaneous coronary intervention or coronary artery bypass surgery improved survival of cardiogenic shock patients with acute ischemia compared to medical therapy alone.[3,10-12] Despite these advances, the mortality remains high (~50%), with half of the deaths occurring within the first 48 hours after presentation.[3,13-15] **Early recognition of cardiogenic shock or ongoing myocardial ischemia is the key for emergency physicians. Prompt and successful efforts to restore perfusion optimize patient outcomes.**

The more risk factors that are present (**Table 50-1**), the greater is the amount of vulnerable myocardium and the greater is the likelihood of cardiogenic shock.

PATHOPHYSIOLOGY

The most common cause of cardiogenic shock is extensive myocardial infarction that depresses myocardial contractility. Additional causes are listed in **Table 50-2**. Regardless of the precipitating cause, cardiogenic shock is primarily "pump failure," which results in reduced cardiac output. The systolic blood pressure drops due to poor cardiac output, and vital organ perfusion is limited. Absent a rise in systemic vascular resistance, the diastolic blood pressure also drops, resulting in coronary artery hypoperfusion. This creates a cycle of worsening myocardial ischemia and pump dysfunction, and eventual decompensation.

Historically, many believed cardiogenic shock was associated with a reflex compensatory vasoconstriction that would increase systemic vascular resistance. Contemporary data refute this belief, showing the average systemic vascular resistance was not elevated in cardiogenic shock patients, even with vasopressor use.[16] Furthermore, the average left ventricular ejection fraction (EF) was only moderately depressed (~30%),[17] and diastolic dysfunction was seen early and frequently, and was associated with greater depression of EF and an increased need for mechanical support.[18,19]

A systemic inflammatory response syndrome occurs after AMI and in cardiogenic shock, due to complement system activation and release of systemic inflammatory mediators, including cytokines and inducible nitric oxide synthase.[20,21] The inflammatory response also depresses pump function, dilates the peripheral vasculature, and increases the risk of death.[22] However, targeting nitric oxide with tilarginine does not alter mortality, although it improves blood pressure.[23] The monoclonal c5 antibody pexelizumab has been studied as an adjunct to percutaneous intervention in an effort to blunt the activation of the complement cascade associated with infarction. The largest trial of pexelizumab failed to show a mortality benefit compared to placebo.[24]

Resolution of severe ischemia, neurohormonal, and inflammatory abnormalities may explain the reversible nature of cardiogenic shock in some patients. The wide variations in EF, ventricular size, and vascular resistance suggest that the pathophysiology of cardiogenic shock is diverse and poorly understood.

TABLE 50-1 Risk Factors for Cardiogenic Shock

Elderly
Female
Acute or prior ischemic event associated with the following:
Impaired ejection fraction
Extensive infarct (evidence of large myocellular leak)
Proximal left anterior descending coronary artery occlusion
Anterior myocardial infarction
Multivessel coronary artery disease
Prior medical history:
Previous myocardial infarction
Congestive heart failure
Diabetes

TABLE 50-2 Causes of Cardiogenic Shock

Mechanical complications:
Acute mitral regurgitation secondary to papillary muscle dysfunction or chordal rupture
Ventricular septal defect
Free wall rupture
Right ventricular infarction
Acute aortic insufficiency (aortic dissection)
Severe depression of cardiac contractility:
Acute myocardial infarction
Sepsis
Myocarditis
Myocardial contusion
Cardiomyopathy
Medication toxicity (e.g., β-blocker overdose, calcium channel blocker overdose)
Unstable dysrhythmia
Mechanical obstruction to forward blood flow:
Aortic stenosis
Hypertrophic cardiomyopathy
Mitral stenosis
Left atrial myxoma
Pericardial tamponade

CLINICAL FEATURES

HISTORY

History can be difficult to obtain if the patient is severely ill. EMS personnel, family, or the medical record may offer additional historical information, notably of existing ischemic heart disease. Patients commonly complain of shortness of breath, chest pain, or weakness. Through history, try to exclude other causes of shock, such as sepsis, massive pulmonary embolism, hemorrhage, or a viral prodrome suggesting myocarditis. Ask about a history of preexisting valvular disease, recent illnesses, hypercoagulable states, substance abuse, or other risk factors for cardiogenic shock as outlined in Table 50-1. Assess for other causes of shock because treatment differs depending on the cause of cardiovascular system failure (**Table 50-3**).

TABLE 50-3 Cardiogenic Shock: A Limited Differential Diagnosis

Acute pulmonary decompensation:
Chronic obstructive pulmonary disease exacerbation
Cor pulmonale
Massive pulmonary embolism
Distributive shock:
Sepsis
Anaphylaxis
Neurogenic shock (spinal cord injury)
Hypovolemic shock:
Hemorrhage
Severe dehydration
Dissociative shock:
Toxins/drugs of abuse (cyanide)

PHYSICAL EXAMINATION

Cardiogenic shock is characterized by hypoperfusion; this is not always accompanied by hypotension.[9] Systolic blood pressure is usually <90 mm Hg, although it can be higher with preexisting hypertension. A pulse pressure <20 mm Hg is another finding if systemic resistance has not plummeted, and sinus tachycardia is common unless the patient is on medications that block a tachycardic response. Unless the patient has advanced to the stage of respiratory fatigue or agonal respirations, tachypnea is common. The lung examination demonstrates rales due to the presence of pulmonary edema, except in cases of isolated right-sided failure. Jugular venous distention and a positive hepatojugular reflex are usually present. Patients are usually pale or cyanotic and may have cool skin and mottled extremities or other signs of hypoperfusion. Peripheral edema suggests preexisting heart failure. Diaphoresis indicates activation of the sympathetic nervous system. Cerebral hypoperfusion may result in altered mental status, and renal hypoperfusion may decrease urine output.

If the cardiac point of maximal impulse is normally located, shock is likely due to an acute event. If the point of maximal impulse is laterally shifted and diffuse from cardiac remodeling and enlargement, long-standing cardiac disease with acute decompensation can be presumed. **About 10% of cardiogenic shock after AMI is caused by mechanical complications.**[14] A new murmur may be the only physical exam finding of mechanical catastrophe; carefully seek any loud or new systolic murmurs. **Acute mitral regurgitation** can occur from chordae tendineae rupture or papillary muscle dysfunction, accompanied by a soft holosystolic murmur at the apex radiating to the axilla with rales. With papillary muscle dysfunction, the murmur starts with the first heart sound but terminates before the second. An **acute ventral septal defect** is associated with a new loud holosystolic left parasternal murmur, often with a palpable thrill, that decreases in intensity as the intraventricular pressures equalize. **Acute aortic insufficiency** is characterized by a soft diastolic murmur and a softer S_1 sound.

DIAGNOSIS

Clinical signs of cardiogenic shock include evidence of poor cardiac output with tissue hypoperfusion (hypotension, mental status changes, cool mottled skin) and evidence of volume overload (dyspnea, rales, jugular venous distention). Hemodynamic criteria for cardiogenic shock include (1) sustained hypotension (systolic blood pressure <90 mm Hg), (2) reduced cardiac index (<2.2 L/min/m^2), and (3) an elevated (>18 mm Hg) pulmonary artery occlusion pressure. The causes and differential diagnosis of cardiogenic shock are listed in Tables 50-2 and 50-3.

LABORATORY TESTING

There are no laboratory markers specific for the diagnosis of cardiogenic shock. Cardiac biomarkers (primarily troponin) may not be elevated upon initial presentation from an acute myocardial ischemic triggering event, but will eventually elevate. A CBC excludes anemia, which can contribute to cardiac ischemia. The clinical presentation guides the need for specific drug levels (e.g., digoxin, ethanol, or illicit drugs). Hypoperfusion commonly results in an elevated serum lactate, so checking serum lactate may aid diagnosis when overt hypotension is absent. Serum electrolytes and renal and hepatic studies can identify end-organ dysfunction.

The level of **serum B-type natriuretic peptide (BNP)** is an indicator of left ventricular dysfunction. Because of its high negative predictive value, a normal BNP level (<100 picograms/mL) eliminates cardiogenic shock as the cause of hypoperfusion unless very early after onset or with isolated right heart failure. Conversely, an elevated BNP does not diagnose cardiogenic shock.[25,26]

Although elevated inflammatory markers such as C-reactive protein have some prognostic value, these are rarely needed in the acute phase of care.[27] Arterial blood gas measurements help identify those at risk of carbon dioxide retention, quantify the presence and severity of acidosis, and determine the contribution of metabolic or respiratory components to acidosis.

IMAGING AND ANCILLARY STUDIES

Electrocardiogram The ECG helps detect ischemia or STEMI, evaluates for rhythm abnormalities, and provides evidence of electrolytic abnormalities (e.g., hypokalemia) or drug toxicity (e.g., digoxin).

It is important to assess for right ventricle (RV) involvement whenever ischemia is considered because RV infarction is associated with an increased risk for cardiogenic shock and death.[28] **RV infarction is best evaluated by obtaining right-sided ECG leads (usually V_4R and V_5R) (Figure 50-1)**. RV infarction complicating inferior myocardial infarction is detected by ST elevation in lead V_1 with depression in V_2.

Chest Radiography Obtain a portable chest radiograph in all patients. Chest x-ray typically shows pulmonary congestion or edema, alveolar infiltrates, and pleural effusion. These findings may lag by hours, so their absence does not exclude cardiogenic shock. Another confounder to interpreting the chest radiograph is underlying preexisting cardiopulmonary disease; pulmonary edema is difficult to detect on chest radiography in patients with severe chronic obstructive lung disease or interstitial lung disease. Cardiomegaly is the end result of long-standing myocardial remodeling, and its presence may not explain the acute symptoms. The chest radiograph can suggest alternative or confounding diagnoses, such as pneumonia, pneumothorax, aortic dissection, or progressive pericardial effusion (globular cardiac shape).

Bedside Echocardiography In the setting of cardiogenic shock, emergency bedside echocardiography can help exclude alternative etiologies of shock, identify some mechanical complications, and guide therapy. Assessment should include evaluation of the inferior vena cava (IVC) to determine volume status and estimate right atrial pressure. A subcostal four-chamber view is helpful to visualize pericardial effusion and identify cardiac tamponade. When tamponade is present, there is a pericardial effusion with associated dilation of the IVC and diastolic collapse of the RV with systolic collapse of the right atrium. When cardiac rupture has occurred, there may be a visible clot in the pericardial space. Subcostal, parasternal, and apical views together can help estimate EF and cardiac contractility. An aortic root measurement greater than 3 cm is concerning for ascending aortic dissection, especially when associated with a pericardial effusion. Also assess mitral valve morphology and motion. Apical four-chamber views are helpful for evaluating chamber size. In cases of acute right heart failure due to ischemia, the RV will be dilated and the left ventricle (LV) will appear to be smaller than expected due to low filling pressures. In left heart failure there will be dilation of the LV secondary to decreased cardiac output and increased filling pressure.

Bedside echocardiography is not a substitute for emergent formal transthoracic echocardiography. Formal echocardiography is better able to use color and spectral Doppler to identify mechanical complications and to characterize the nature of cardiac impairment. Echocardiography can detect regional wall motion abnormalities and identify a lack of compensatory hyperkinesis in uninvolved cardiac segments. Loss of RV contractility, RV dilatation, and normal estimated pulmonary pressures occur more commonly with RV infarction.

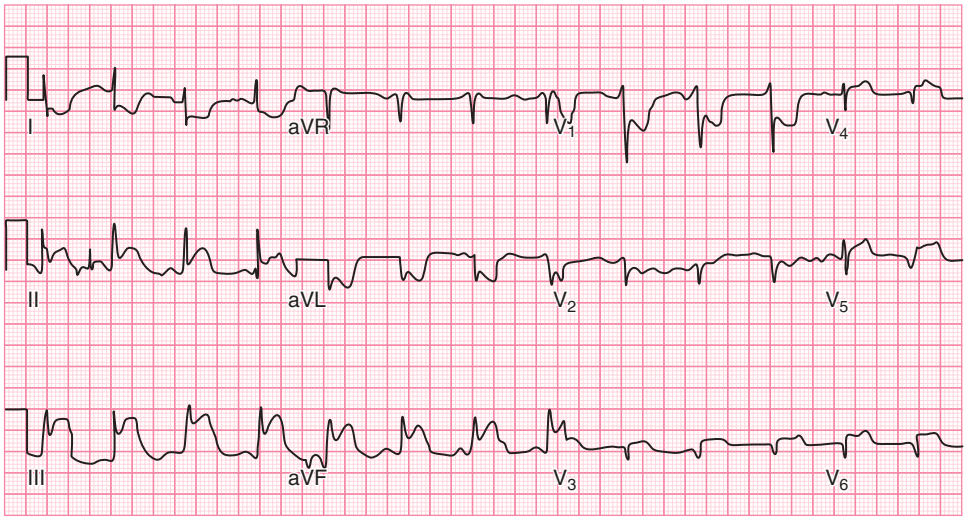

FIGURE 50-1. Right-sided leads demonstrating right ventricular infarction associated with inferior wall myocardial infarction. Right sided leads have replaced the normal left-sided V leads. In this example, the ST-segment elevation is prominent in leads VR_{3-6}.

Color flow Doppler transthoracic echocardiography can identify mechanical causes of cardiogenic shock, such as acute mitral regurgitation or ventricular septal defect. Echocardiography can detect other causes of decreased cardiac output, notably pulmonary embolism. Acute RV dilatation, tricuspid insufficiency, paradoxical systolic septal motion, and high estimated pulmonary artery and RV pressures suggest pulmonary hypertension from an acute pulmonary embolus.

Mechanical Catastrophe Diagnosis If mechanical catastrophe is suspected, consult cardiothoracic surgery immediately while obtaining a bedside echocardiogram. In the case of **myocardial free wall rupture**, death is probable unless a pseudoaneurysm forms. Pseudoaneurysm is detected as an acute pericardial effusion on echocardiography. An acute **ventricular septal defect** is confirmed by color Doppler echocardiography or right heart catheterization demonstrating oxygen saturation step-up from the right atrium to the RV. **Acute mitral regurgitation**, from papillary muscle rupture or dysfunction, can complicate AMI.

Hemodynamic Monitoring Patients in cardiogenic shock typically have low cardiac index (<2.2 L/min/m^2) and elevated LV end-diastolic pressure (pulmonary artery occlusion pressure >18 mm Hg).[29] Invasive hemodynamic monitoring with a pulmonary artery catheter can provide data and guide treatment but is unavailable in most EDs.[29] Central venous pressure measurements can help guide fluid resuscitation, with the trend in venous pressures being more important than absolute values. Most patients will require continuous blood pressure monitoring, often with an indwelling catheter.

TREATMENT

The most important intervention for ischemic-related cardiogenic shock is emergent revascularization.[10,11,14,30] ED stabilization is a temporizing measure while arranging for definitive therapy such as revascularization in the cardiac catheterization laboratory or surgical intervention for mechanical catastrophe. In the prehospital setting, EMS should direct any suspected cardiogenic shock patient to a facility that has 24-hour emergency cardiac revascularization capability (i.e., cardiac bypass team).[31]

Initial management focuses on airway stability and improving myocardial pump function to maintain end-organ perfusion. Diagnosis, therapy, and arrangements for definitive cardiac care must proceed simultaneously.

AIRWAY

Give supplemental oxygen, and monitor closely for impending or acute respiratory failure that will require immediate mechanical ventilation. Continuous positive airway pressure or bilevel positive airway pressure can provide temporary airway support, but these methods require a hemodynamically stable, cooperative patient—a set of conditions rare in those with cardiogenic shock.

Endotracheal intubation is often necessary to maintain oxygenation and ventilation. However, **the change to positive pressure ventilation may further decrease preload and cardiac output and worsen hypotension.** Be prepared to administer a fluid bolus in the absence of pulmonary congestion, initiate an appropriate inotrope if congested with a compensated blood pressure, or start a vasopressor if hypotension exists.

STABILIZATION

Cardiac monitoring and IV access are necessary. Correct any hypoxemia, hypovolemia, rhythm disturbances, electrolyte abnormalities, and acid-base alterations rapidly. Place a urinary drainage catheter to monitor urine output in response to therapy.

In AMI, give aspirin early (if not already taking long term) unless there is an absolute contraindication.[32] If blood pressure is >90 mm Hg systolic, chest pain may be relieved by careful use of IV nitroglycerin or morphine. **Do not use β-blockers in patients with myocardial infarction in cardiogenic shock or who are at risk for cardiogenic shock** (Table 50-1).[32] Withhold angiotensin-converting enzyme inhibitors or other vasodilators.

HYPOTENSION

Initial therapy is guided by clinical findings. Give crystalloid fluid boluses (250 to 500 cc) for an RV infarct with hypotension, if pulmonary congestion is absent. If there is no improvement with the fluid bolus or if pulmonary congestion develops, vasopressors or inotropes are indicated (**Table 50-4**).

TABLE 50-4 Inotropic Medications Used in Cardiogenic Shock

Drug	Dose	Comments
Dobutamine	2–5 micrograms/kg/min, titrated up to 20 micrograms/kg/min	Inotrope and potential vasodilator; lowers blood pressure; give as individual agent as long as systolic blood pressure (SBP) ≥90. Can use with dopamine.
Dopamine	3–5 micrograms/kg/min, titrated up to 20–50 micrograms/kg/min as needed	Inotrope and vasoconstrictor; increases left ventricular end-diastolic pressure and causes tachycardia. Can use with dobutamine.
Norepinephrine	2 micrograms/min, titrate to response	Vasoconstrictor and inotrope; preferred as a single agent over dobutamine if SBP <70. Can use combined with dobutamine.
Epinephrine	0.1–0.5 micrograms/kg/min	Inotrope and vasoconstrictor; second-tier choice because it causes acidosis and dysrhythmias.
Milrinone	0.5 micrograms/kg/min	Inotrope and vasodilator; lowers blood pressure. Second tier to dobutamine.

Inotropes do not change outcome alone but can temporize while ED personnel arrange interventions to restore coronary artery perfusion and LV function.[33] In the absence of profound hypotension, **dobutamine** is a mainstay of initial pharmacologic treatment. Dobutamine may increase cardiac contractility and should be considered as an individual agent if systolic blood pressure is ≥90 mm Hg without signs of overt shock or organ dysfunction. Avoid the use of dobutamine alone when the systolic blood pressure is <90 mm Hg because of its vasodilatory potential. Often, a vasoconstrictor is needed in addition to dobutamine. **Dopamine** may increase cardiac work by increasing heart rate and may also increase LV end-diastolic pressure by its β-agonist effect. Combination therapy with a vasopressor (dopamine) and an inotrope (dobutamine) may be more effective than either agent alone. **Norepinephrine** when combined with dobutamine may have more of an effect on peripheral vasoconstriction than dopamine when combined with dobutamine. If the systolic blood pressure is <70 mm Hg, norepinephrine is preferred over dobutamine due to its antithrombotic effect.[34] If shock persists despite use of these agents, an intra-aortic balloon pump is typically placed, although long-term evidence of benefit is lacking.[25,35-39]

Epinephrine is an alternative to norepinephrine/dobutamine when dobutamine is not available; however, it is associated with increased systemic acidosis, tachycardia, and dysrhythmias compared to the combination of norepinephrine and dobutamine.[40]

Patients on β-blocker therapy may have an attenuated response to dobutamine, making norepinephrine a better choice. **Milrinone** (a selective phosphodiesterase inhibitor) **can be substituted for the catecholamine if dobutamine is ineffective.**

Pure vasoconstrictors and α_1-adrenergic receptor agonists, such as phenylephrine, are contraindicated because they increase cardiac afterload without augmenting cardiac contractility.

EARLY REVASCULARIZATION

In ischemic cardiogenic shock, early revascularization by percutaneous coronary intervention or coronary artery bypass grafting is the treatment of choice. The greatest short-term benefit is reported in patients <75 years old, those without previous myocardial infarction, and those treated within 6 hours of symptom onset. However, patients >75 years old who receive revascularization have improved survival over those >75 years old who have delayed or no revascularization, even though those >75 years old are less likely to receive revascularization.[41] Coronary artery bypass grafting requires extensive surgical and medical resources and poses operative risk for seriously ill patients. The cardiac surgeon will make an overall judgment, with operative intervention chosen often for those with good prior functional status and less severe, early presentation of shock. Survival is higher in those receiving early revascularization compared with medical stabilization, even when elderly.[41] Current guidelines do not have an age cutoff for percutaneous coronary intervention.[27,38,39,42]

THROMBOLYTIC THERAPY

Emergency coronary intervention in the catheterization laboratory or operating suite is the preferred definitive treatment for cardiogenic shock.[43,44] Thrombolytic therapy is not as effective in establishing reperfusion in AMI with cardiogenic shock as it is in uncomplicated AMI. Survival from cardiogenic shock is highest with emergency coronary intervention, followed by intra-aortic balloon pump combined with thrombolytic therapy; thrombolytic therapy alone is least effective in reducing mortality. Rescue percutaneous coronary intervention does not convey the same mortality benefit as primary percutaneous coronary intervention for these patients.[45] If no other definitive treatment modalities for cardiogenic shock are available, if the hospital does not have a catheterization laboratory, or if there is prolonged transport time for coronary intervention, thrombolytic therapy should be given to reduce mortality compared to supportive treatment alone.

INTRA-AORTIC BALLOON PUMP COUNTERPULSATION

Intra-aortic balloon pump counterpulsation provides hemodynamic support by decreasing afterload (which lowers myocardial oxygen consumption) and increasing diastolic blood pressure (which augments coronary perfusion).[38,42] Intra-aortic balloon pump improves survival after thrombolytic therapy by augmenting diastolic perfusion pressure and unloading the LV.[11,46,47] Outside of those receiving reperfusion, the long-term benefits of intra-aortic balloon pump use are not clear.[36,37]

Resolution of hemodynamic instability with intra-aortic balloon pump support has positive prognostic value.[48] In hospitals without direct angioplasty capability, stabilization with intra-aortic balloon pump and thrombolysis followed by transfer to a tertiary care facility may be the best management option.[38,42]

PERCUTANEOUS LEFT VENTRICULAR ASSIST DEVICES

If cardiogenic shock persists despite revascularization and maximal medical therapy, a left ventricular assist device may augment cardiac output. This device is currently approved by the U.S. Food and Drug Administration only as a bridge to transplantation, and most cardiogenic shock patients are not such candidates. Case studies have described successful support and weaning of patients suffering from cardiogenic shock in the setting of acute infarction.[49-53] A recent meta-analysis failed to demonstrate a mortality benefit for left ventricular assist devices compared with intra-aortic balloon pumps in patients with cardiogenic shock refractory to inotropic and vasopressor support.[54]

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation can provide almost total circulatory support for a failing heart. Extracorporeal membrane oxygenation is typically instituted in emergency situations when maximum medical therapy has failed. The treating physician must consider the likelihood of recovery before instituting extracorporeal membrane oxygenation; patients with a very poor prognosis are not appropriate for extracorporeal membrane oxygenation. In the best cases, extracorporeal membrane oxygenation can provide support until percutaneous coronary intervention can be performed or until the heart begins to recover after intervention. In other cases, it can provide a "bridge to decision" for transplant or permanent left ventricular assist device placement.

DISPOSITION AND FOLLOW-UP

All patients with cardiogenic shock require admission to the intensive care unit at an institution with invasive revascularization capability.[10,30] In noncapable institutions, transfer should be accomplished as quickly as possible.[55,56] If no other definitive treatment modalities for cardiogenic shock are available, if the hospital does not have a catheterization laboratory, or if there is prolonged transport time for coronary intervention, thrombolytic therapy should be given.

SPECIAL CONSIDERATIONS

Compliance with guidelines for AMI has improved over the last two decades, although compliance in patients with cardiogenic shock may be less.[3,57,58] Some populations continue to face barriers to effective care, especially the elderly and minorities.[58,59] Compliance with recommended guidelines is needed in order to improve outcomes. The most recent American College of Cardiology/American Heart Association guidelines from 2011 recommend aggressive management of patients in cardiogenic shock. Class 1 recommendations include percutaneous coronary intervention or coronary artery bypass graft for STEMI patients in shock (level of evidence B), percutaneous coronary intervention or coronary artery bypass graft for NSTEMI patients in shock (level of evidence B), and transfer for rescue or facilitated percutaneous coronary intervention in patients with persistent ischemia or shock despite lytic therapy (level of evidence B). European guidelines reflect the same treatment priorities.[60]

CHAPTER 51

Low-Probability Acute Coronary Syndrome

Kathleen A. Hosmer
Chadwick D. Miller

INTRODUCTION AND EPIDEMIOLOGY

This chapter discusses the features of *low-probability or possible acute coronary syndrome (ACS)*, which includes patients who have chest pain or another equivalent ischemic symptom but no objective evidence of acute coronary ischemia or infarction—that is, no characteristic ECG ST-segment elevation or depression and normal levels of cardiac markers. Patients with diagnostic ECG or cardiac marker levels or with other high-risk features are discussed in chapter 49, "Acute Coronary Syndromes."

Of ED patients with undifferentiated chest pain, 7% will have ECG findings consistent with acute ischemia or infarction, and 6% to 10% of those in whom cardiac markers are ordered will have initially positive results.[1] The remaining patients who do not have diagnostic ECG changes or initially positive cardiac marker results have *low-probability* or *possible ACS*. The evaluation of those with possible or actual ACS costs approximately $10 billion to $12 billion each year in the United States.[2]

Of all patients with *possible ACS*, 5% to 15% ultimately prove to have ACS.[3] The rate of discharge from the ED for patients with ACS remains approximately 4%. Patients with ACS who are discharged home from the ED have worse clinical outcomes and higher mortality compared with patients who are initially hospitalized. The clinical data readily available to the emergency physician, such as historical features, examination findings, and ECG results, cannot exclude ACS among most patients, because 3% to 6% of patients thought to have noncardiac chest pain or a clear-cut alternative diagnosis will have a short-term adverse cardiac event.[4,5] Therefore, most patients with *possible ACS* undergo further observation and testing.

PATHOPHYSIOLOGY

ACS is a constellation of signs and symptoms resulting from an imbalance of myocardial oxygen supply and demand. There are three general ACS classifications: unstable angina, non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). Unstable angina is a type of ACS with no elevation of biomarkers and no pathologic ST-segment elevation, resulting in ischemia but not infarction. Acute myocardial infarction (AMI) occurs when myocardial tissue is devoid of oxygen and substrate for a sufficient period of time to cause myocyte death. NSTEMI is characterized by biomarker elevation and no pathologic ST-segment elevation. STEMI is characterized by ST-segment elevation and biomarker elevation (STEMI), although biomarker elevation is not required at onset to make this diagnosis. Detailed discussion is in chapter 49.

The distinction between NSTEMI and unstable angina is based on elevated cardiac markers of necrosis in the case of NSTEMI. Troponin I and troponin T are the most specific cardiac markers of cell injury or death available. These biomarkers may not reach detectable thresholds for up to 6 hours after infarction. Patients presenting soon after infarction may have normal biomarker results and initially be categorized as having *possible ACS*. Patients with evolving myocardial infarctions represent approximately 4% of patients undergoing serial cardiac markers and generally have other high-risk features of ACS such as ST-segment depression.[6,7]

CLINICAL FEATURES

HISTORY AND COMORBIDITIES

The history is one tool to help assess patients with suspected or possible ACS but cannot be used to exclude ACS. Obtain detailed information, including symptom quality, location, duration, severity, associated symptoms, precipitating and relieving factors, and similarity to prior episodes. Consider other noncardiac but life-threatening causes of chest pain (see Tables 48-3 and 48-4 in chapter "Chest Pain").

Among patients with possible ACS, historical features can be categorized as low risk, probable low risk, probable high risk, and high risk. **However, even patients with low-risk features or in a low-risk category have a residual risk of ACS.**[8] Lowest risk features include pleuritic, positional, reproducible, or sharp/stabbing pain. Another low-risk feature is pain that is not exertional or located in a small inframammary area. Higher risk features include chest pressure (positive likelihood ratio [LR+] 1.3), pain similar to or worse than prior cardiac pain (LR+ 1.8), and associated nausea/vomiting or diaphoresis (LR+ 1.9 and 2.0, respectively). The highest risk features include radiation to the right arm or shoulder (LR+ 4.7), left arm (LR+ 2.3), or both arms or shoulders (LR+ 4.1), and exertional chest pain (LR+ 2.4).

Traditional cardiac risk factors, such as hypertension, diabetes mellitus, tobacco use, family history of coronary artery disease (CAD) at an early age, and hypercholesterolemia, are modestly predictive of the presence of CAD in asymptomatic patients. In acute decision making**, cardiac risk factors are poor predictors of cardiac risk for myocardial infarction or other ACS**.[9] CAD is rare in patients <30 years old, but possible and usually accompanied by other risk(s).

Although a true alternative diagnosis decreases the likelihood of ACS, many patients with ACS are mistakenly diagnosed with gastric reflux or musculoskeletal pain.[5] Clinical response to treatment with antacids (18% to 45% of ACS patients have relief of pain with antacids), viscous lidocaine, or nonsteroidal anti-inflammatory medications cannot exclude ACS. Lack of pain relief with nitroglycerin is similarly unreliable, because 65% of patients with an ACS in one study failed to have relief of pain.

Prior cardiac testing (previous ECG tracings, echocardiograms, cardiac catheterization reports, and stress testing reports) aids the ED evaluation. ECG changes offer strong bedside evidence of new disease. Recent cardiac catheterization reports are especially useful, because a truly negative (defined as no luminal irregularities) result is associated with a very low incidence of subsequent infarction or ACS in the next 2 years. Although a prior positive stress test increases the likelihood of a subsequent acute cardiac event,[10] a prior negative stress test provides little reassurance that a current chest pain event is benign. Patients with a recent negative evaluation for ACS that included objective cardiac testing (mostly stress testing) have a 6-month incidence of ACS as high as 14%. Furthermore, patients with a prior negative stress test have a similar incidence of ACS compared with those with no prior stress testing when presenting with chest pain to the ED.[11] Overall, previous stress test results add evidence but cannot confirm disease presence or absence.

PHYSICAL EXAMINATION

Usually, the exam in the low-risk or possible ACS patient seeks complications or alternative causes of the symptoms. When an alternate diagnosis is not clear, the physical examination alone cannot distinguish between those with and without ACS. However, pay special attention to examination findings that make ACS more or less likely. High-risk features on physical examination are uncommon and include signs of cardiac failure such as hypotension, diaphoresis, pulmonary rales, jugular venous distention, new mitral regurgitation, bradycardia, tachycardia, and an S_3 cardiac gallop.[12] Cardiac rate abnormalities are also a high-risk feature, including either bradycardia (seen with ischemia, especially in the inferior myocardium, or infarction that has led to disturbance of the conduction system) or tachycardia (may signify pump failure, pain, or stress, or could be a clue to an alternative diagnosis such as pulmonary embolism). Positional changes in the pain severity can be easily assessed at the bedside and may suggest pericarditis or another pleural-based syndrome as a cause of pain.

CARDINAL FEATURES

The classic patient with possible ACS has chest pain or another symptom (weakness, dyspnea, other upper body pain), no clear alternative

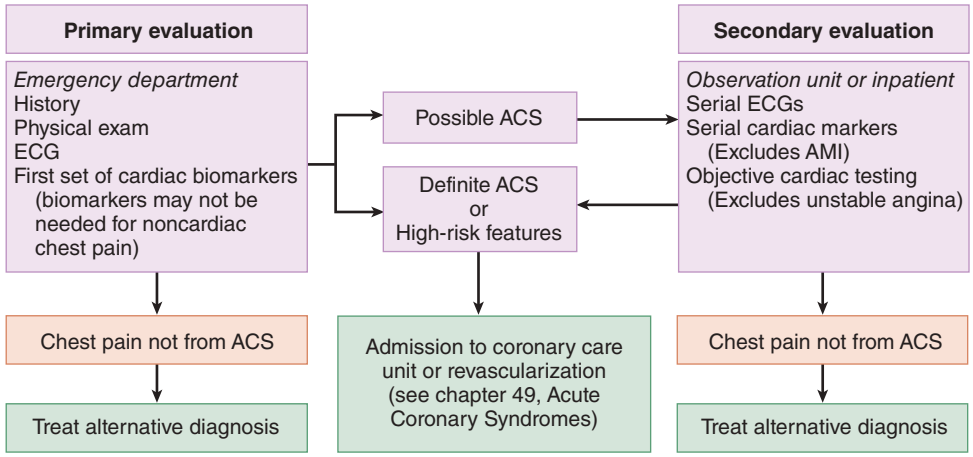

FIGURE 51-1. Evaluation process for patients with possible acute coronary syndrome (ACS). AMI = acute myocardial infarction

cause, and no clear evidence of cardiac injury or stress on ECG and biomarker tests. **In this group, the likelihood of ACS is >2% but still low, making the diagnosis of *possible ACS*.**

DIAGNOSIS

The diagnostic process is conceptually split into a primary and secondary evaluation (**Figure 51-1**).

PRIMARY EVALUATION

The goal during the primary evaluation is to distinguish patients with definite ACS from those with possible ACS and those with symptoms that are definitely not from ACS. This process involves gathering information from the history, physical examination, ECG, chest radiography, and medical record. This information is used to produce an initial risk assessment that guides the subsequent laboratory testing and initial treatment.

ECG

For adult patients with chest pain in whom cardiac causes are possible, obtain a 12-lead ECG rapidly[12,13] and compare to any previous tracings. Patients with ST-segment elevation, a new left bundle-branch block, or ST-segment depression have an ACS and are treated as outlined in chapter 49. Between 1% and 6% of patients with a normal ECG will ultimately prove to have NSTEMI, and at least another 4% will prove to have unstable angina.[12] Obtaining follow-up ECG(s) in patients with ongoing or worsening symptoms helps detect changes diagnostic of ACS, or it can show reversal of previous ST-segment or T-wave changes thought to be old—both define *dynamic changes* and the high likelihood of ACS. In the setting of dynamic ECG changes, incidence of CAD is 84% with classic anginal symptoms and 8% with nonclassic anginal symptoms as assessed by coronary angiography.[14]

CHEST RADIOGRAPH

Chest radiography provides additional cardiovascular information, including cardiac silhouette size, pulmonary edema, and aortic contour. Additional causes of chest pain, such as pneumothorax, bony metastasis, rib fracture, and pneumonia, may also be detected on chest radiography. Patients presenting with anterior chest pain have findings on chest radiography that influence management 14% of the time.

RISK ASSESSMENT

The goal of early decision making is to determine if the patient actually belongs in the *possible ACS* cohort and is at high enough risk to warrant cardiac testing. All available data are used to create a composite picture for decision making. **Some posit that when the pretest probability of ACS is ≤2%, further testing is not indicated[15]; others have suggested a threshold of <1% to stop testing.[16] Detecting patients with a zero chance of any ACS in the presence of ACS-like symptoms is virtually impossible.**

Most computer algorithms, risk scores, and clinical decision rules have been unsuccessful at identifying a very-low-risk (<2%) cohort that does not require further testing. The HEART score is one tool that identifies low-risk patients who are eligible for evaluation and possible early discharge home from the ED (**Table 51-1**). Large-scale validation data are lacking, although current evidence suggests that patients with a

Calculate total score giving 1 point for each positive answer.

*Risk factors for CAD include diabetes, cigarette smoking, hypertension (≥140/90 mm Hg or on antihypertensive medication), low high-density lipoprotein cholesterol (<40 mg/dL), family history of premature CAD (CAD in male first-degree relative age <55, or female first-degree relative <65).

TABLE 51-3 Prognosis-Based Classification System for ED Chest Pain Patients*

I.	**Acute myocardial infarction: immediate revascularization candidate**
II.	**Probable acute ischemia: high risk for adverse events (any of the following):**
	Evidence of clinical instability (i.e., pulmonary edema, hypotension, arrhythmia, transient mitral regurgitation murmur, diaphoresis)
	Ongoing pain thought to be ischemic (consider chest pain or discomfort as chief symptom, reproducing documented angina, or pain in setting of known coronary artery disease, including myocardial infarction)
	Pain at rest associated with ischemic ECG changes (consider new, or presumably new, transient, ST-segment deviation, 1 mm or greater, or T-wave inversion in multiple precordial leads)
	One or more positive myocardial marker measurements
	Positive perfusion imaging study
III.	**Possible acute ischemia: intermediate risk for adverse events. History suggestive of ischemia with absence of high-risk features, and any of the following:**
	Rest pain, now resolved
	New onset of pain
	Crescendo pattern of pain
	Ischemic pattern on ECG not associated with pain (may include ST-segment depression <1 mm or T-wave inversion >1 mm)
IV.	**Possible acute ischemia: low risk for adverse events. Requires all of the following:**
	History not strongly suggestive of ischemia
	ECG normal, unchanged from previous, or nonspecific changes
	Negative myocardial marker measurement
	or (requires all of the following)
	>2 wk of unchanged symptom pattern or long-standing symptoms with only mild change in exertional pain threshold
	ECG normal, unchanged from previous, or nonspecific changes
	Negative initial myocardial marker measurement
V.	**Definitely not ischemia: very low risk for adverse events. Requires all of the following:**
	Clear objective evidence of nonischemic symptom etiology
	ECG normal, unchanged from previous, or nonspecific changes
	Negative initial myocardial marker measurement†
	or
	Unstructured clinician estimate of acute coronary syndrome ≤2%

†Literature not conclusive.

HEART score of 0 to 3 have a 1% to 2% risk for major adverse cardiac events within 6 weeks of presentation.[17,18]

The Heart Pathway involves using the HEART score with the addition of a 4- to 6-hour repeat troponin to increase the sensitivity for major adverse cardiac events.[19] Preliminary data note 100% sensitivity for major adverse cardiac events while decreasing the amount of index visit cardiac testing (CT or stress imaging).

The Accelerated Diagnostic Protocol uses Thrombolysis in Acute Myocardial Infarction (TIMI) study[20] risk scores and ED testing to stratify risk (**Table 51-2**). Patients with ACS-consistent pain, a Thrombolysis in Acute Myocardial Infarction score of 0, no new ischemic changes on ECG, and negative troponins at 0 and 2 hours have a very low risk of subsequent cardiac events and may be discharged. In a prospective observational study, the Accelerated Diagnostic Protocol was 99.7% sensitive (95% confidence interval [CI] 98.1% to 99.9%) for major adverse cardiac events at 30 days.[21] A subsequent randomized trial demonstrated that 19.3% of patients were discharged within 6 hours using the Accelerated Diagnostic Protocol compared to 11.0% of control group patients (P = 0.008), and 1.9% (95% CI 0% to 10%) of patients had a major adverse cardiac event in 30 days.[22] This method also needs wider impact testing to determine safety and utility before mainstream implementation.

When risk-stratifying patients with possible ACS, be wary of overconfidence in an alternative diagnosis, because the rate of ACS is as high as 4% among patients with chest pain and a "clear-cut" noncardiac alternative diagnosis.[5] Reserve determinations of noncardiac chest pain to patients with a very low likelihood of coronary disease (<1%) and clear evidence of an alternative diagnosis or with atypical historical features. The rest of patients with ACS-consistent symptoms should have further testing.

After determination that the patient is appropriately categorized as possible ACS, further stratification occurs (**Table 51-3**).[12,13,23] Patients in category I (AMI) and category II (probable acute ischemia) are discussed in chapter 49. Patients in category III (possible ischemia) and IV (probably not ischemia or stable angina pectoris) undergo primary and secondary assessments as detailed below.

CARDIAC MARKERS

Laboratory testing during the primary evaluation focuses on two goals: detecting myocardial cellular necrosis and excluding alternative causes of chest pain. Usual testing includes a CBC, serum electrolytes with renal function, and serum cardiac markers. Other testing is guided by the history and physical examination.

Serum markers of necrosis are used to diagnose AMI. AMI is one component of ACS, which also includes unstable angina. The difference between these two clinical syndromes is the presence of myocardial necrosis. **Thus, although serum markers performed over a period of time can exclude AMI, they cannot exclude unstable angina.**

See chapter 48, "Chest Pain" for an introduction to the use of cardiac markers for the diagnosis of myocardial infarction. In that chapter, Figure 48-1 shows the typical pattern of serum marker elevation after AMI; Table 51-5 lists conditions associated with elevation of troponin; and Table 51-6 lists conditions that elevate CK-MB, the isoform of the MB fraction of creatine kinase. The unique release kinetics of each marker should be evaluated in the context of the patient's time of symptom onset, compared with the time of presentation. **Patients with positive troponin results *have* ACS.**

Other markers such as C-reactive protein, ischemia-modified albumin, myeloperoxidase, and B-type natriuretic peptide are not robust enough for incorporation into standard ED decision making.

Single-Marker Measurement Although single-sample normal myocardial marker measurements cannot exclude the diagnosis of AMI in the ED, very-low-risk (Table 51-3) patients may benefit from at least one myocardial marker measurement before discharge, especially if pain is present and unremitting for >6 hours. This area is evolving with the introduction of higher sensitivity troponin assays.

Change in Marker Measurements In AMI, the initial CK-MB measurement obtained is elevated in about 30% to 50% of patients. Seeking a change in values, referred to as the *delta CK-MB* (ΔCK-MB), helps detect ACS even if threshold positive values are not reached.[24] ΔCK-MB

also outperforms Δ myoglobin for early AMI diagnosis. The same principle can be applied with serial measurements of troponin.

SECONDARY EVALUATION

RISK REASSESSMENT

Patient risk is reevaluated as results from diagnostic tests become available. At the beginning of the secondary evaluation, review the results of the initial and any subsequent ECGs and cardiac markers, chest radiography, and previous cardiac evaluations. After data collection, stratify patients into one of five classifications (Table 51-3).

THE DIAGNOSTIC PLAN

Base the diagnostic plan for patients with possible ACS after the primary evaluation on the clinical data and the available resources at each facility. This may include inpatient secondary testing, hospital-based observation testing, or ED-based observation testing. Once ACS is determined to be present or likely, admission and care by an internist or cardiologist are started.

Serial Marker Approach Patients with possible ACS require serial serum markers to detect necrosis. The purpose of serial markers is twofold. First, evidence of myocardial necrosis confirms the diagnosis of ACS and should change treatment. Second, the presence of necrosis places the patient at higher risk for an adverse event during provocative cardiac testing. Most facilities use a traditional protocol for serial marker timing, whereas some use an accelerated testing protocol in concert with early myocardial imaging. Traditional testing protocols for patients with possible ACS involve obtaining serial troponin and/or serial creatine kinase and CK-MB at presentation and after 6 hours of observation. Accelerated protocols may have similar efficacy. ΔCK-MB measurements over a 2-hour period have 93% sensitivity for AMI.[24] Similarly, changes in myoglobin over 90 minutes when used with troponin results may also have high sensitivity.[25] However, given the imperfect sensitivity and inability to exclude unstable angina, accelerated cardiac marker protocols are not the sole determination to exclude ACS but are used in combination with cardiac imaging.

INDICATIONS FOR ADVANCED CARDIAC TESTING

Normal serial ECGs and myocardial marker measurements reduce the likelihood of AMI but do not exclude unstable angina, which still puts the patient at high risk for a subsequent adverse cardiac event. Therefore, patients with possible ACS should undergo some form of direct cardiac testing to evaluate coronary anatomy, cardiac function, or both. Common modalities used include stress electrocardiography, stress echocardiography, resting and/or stress nuclear medicine testing, stress cardiac MRI, and CT coronary angiography (CTCA).

Advanced cardiac testing is performed after normal biomarkers are present and no clear ischemic ECG changes exist; this happens either as an inpatient or during an observation unit stay, with the latter being less expensive. Another option proffered by the American College of Cardiology/American Heart Association guidelines is to do the advanced testing as an outpatient and within 72 hours of ED discharge if patients are at low risk for ACS, are pain free without recurrent symptoms, have no evidence of ischemia on their ECG, and have normal serial cardiac markers over 6 to 8 hours.[12] This latter approach simply uses the ED stay as the observational interval.

Available data suggest that low-risk patients may safely undergo immediate stress testing. One center performed over 3000 immediate exercise stress tests in low-risk patients who had at least one negative serum cardiac marker, noting no adverse events.[26]

CARDIAC TESTING MODALITIES

ECG-Based Exercise Treadmill Testing The accuracy of ED stress testing is particularly difficult to quantify, because test sensitivity and specificity are greatly influenced by characteristics of the population being tested. As the pretest probability of CAD increases, the likelihood of a false-negative test also increases. Conversely, when a population with a very low pretest probability of disease is tested, the likelihood of a false-positive result increases. **Based on current data, diagnostic stress testing is recommended for patients with a low to moderate pretest probability of CAD but is unlikely to be helpful in those at very low risk or at high risk.** Guidelines to assist with stress test selection are summarized in **Figure 51-2**.[27]

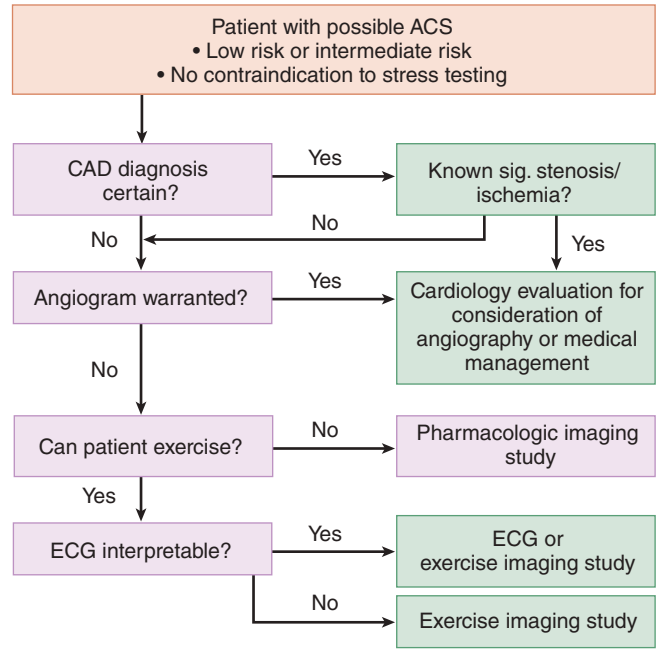

FIGURE 51-2. Stress testing decision making for patients with possible acute coronary syndrome (ACS). CAD = coronary artery disease; sig = significant.

ECG-based exercise treadmill testing is commonly used for patients without known coronary disease who are placed in an observation unit. Subjects exercise, most commonly on a treadmill, until a predetermined percentage of predicted maximum heart rate or other end points are reached. The most commonly used definition of a positive exercise test result from an ECG standpoint is ≥1 mm of horizontal or downsloping ST-segment depression or elevation for at least 60 to 80 milliseconds after the end of the QRS complex; ST-segment elevation is not sought because it defines acute ischemia.

Sensitivity of exercise treadmill testing depends on the risk and severity of disease of the patient population to which it is applied. Meta-analysis of 24,000 patient encounters notes that the sensitivity and specificity for significant coronary disease are 68% and 77%, respectively.[27] Advantages of exercise treadmill testing are low cost, wide availability, and short test performance time. Exercise stress testing is contraindicated for various reasons (**Table 51-4**).[27] Exercise testing may not be safe for patients at high risk for acute ischemia or those with other uncontrolled cardiovascular or pulmonary pathologies. Furthermore, patients with an abnormal baseline ECG, such as those with left ventricular hypertrophy, bundle-branch block, or digoxin effect, are less likely to benefit from standard exercise testing due to difficulties in interpretation of exercise-induced ECG changes.

Echocardiography Echocardiography to evaluate wall motion at rest and while under stress (either exercise or pharmacologically induced) is widely used in patients with possible ACS. Advantages of stress echocardiography over exercise treadmill testing are improved accuracy for coronary disease and nondependence on the ECG. Compared with other cardiac imaging techniques, echocardiography is noninvasive, delivers no ionizing radiation, and provides information on myocardial function.

Detection of wall-thickening abnormalities defines acute ischemia; this is dependent on imaging technique and interpretative skills, with

TABLE 51-4 Contraindications to Exercise Testing

Absolute
Acute myocardial infarction (within 2 d)
High-risk unstable angina
Uncontrolled cardiac dysrhythmias causing symptoms or hemodynamic compromise
Symptomatic severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Acute myocarditis or pericarditis
Acute aortic dissection
Relative*
Left main coronary stenosis
Moderate stenotic valvular heart disease
Electrolyte abnormalities
Severe arterial hypertension (>200 mm Hg systolic, >110 mm Hg diastolic)
Tachydysrhythmias or bradydysrhythmias
Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Mental or physical impairment leading to inability to exercise adequately
High-degree atrioventricular block

*Relative contraindications can be superseded if the benefits of exercise outweigh the risks.

up to 10% of tests being technically inadequate. The echocardiogram cannot distinguish between myocardial ischemia and acute infarction, cannot reliably detect subendocardial ischemia, and may be falsely interpreted as positive in the presence of several conditions (notably conduction disturbances, volume overload, heart surgery, or trauma). Timing of the test relative to the onset of symptoms is critical, because transient wall motion abnormalities may resolve within minutes of an ischemic episode. Resting echocardiography within 12 hours of ED arrival does not provide additional predictive value for myocardial infarction over myocardial markers alone. **Thus, a normal resting echocardiogram in the ED cannot exclude ACS, although it lowers the likelihood.**

Stress echocardiography combines a standard ECG stress test with cardiac imaging at rest and after exercise or pharmacologically induced tachycardia. Overall, stress echocardiography is 80% sensitive and 84% specific for significant coronary disease, superior to ECG-based stress testing. In low-risk ED patients, three studies have reported negative predictive values for subsequent cardiac events to be 97% to 100%, comparable to that of stress testing using nuclear imaging techniques.

Nuclear Medicine Nuclear medicine techniques use an IV-injected radioactive tracer. Local myocardial uptake and images depend on regional coronary flow and myocardial cell integrity. Tracer uptake occurs in direct proportion to regional myocardial blood flow.

Thallium-201 has been in use longest and is rapidly redistributed after initial uptake. The image generated after thallium injection represents blood flow at the moment of imaging. Areas of positive uptake reflect adequate coronary flow and viable myocardium, whereas areas without uptake represent infarcted or ischemic myocardium. On repeat imaging several hours later, continued lack of perfusion ("irreversible defect") indicates an area of infarction, and tracer uptake only on delayed images ("reversible defect") represents ischemic but not infarcted myocardium. Combined with conventional ECG-based stress testing, thallium imaging offers improved sensitivity and specificity for detection of significant CAD over ECG-based testing alone, and it is not hampered by baseline ECG abnormalities. Thallium-based imaging must be performed soon after injection, making it impractical for use in patients with ongoing chest pain. Also, the long half-life requires a lower injected dose to avoid excessive radiation exposure. This may impair imaging and create false-negative and false-positive results, especially in women and obese patients. Due to these limitations and the lack of ED-based outcome studies, thallium-201 imaging alone is not an ideal agent for use in the ED.

Myocardial perfusion imaging using technetium-99m (^{99m}Tc)-labeled agents such as **sestamibi** offers advantages over thallium for ED use. Because the half-life of ^{99m}Tc is much shorter than that of thallium (6 vs 73 hours), a larger dose is possible without harm to the patient. This produces superior image quality, decreased tissue attenuation–related artifacts, and higher ACS detection specificity for sestamibi imaging. In contrast to thallium, ^{99m}Tc is stable for several hours, allowing accurate imaging up to 3 hours after injection; the image represents the blood flow at the moment of injection. By using "gated" image acquisition technology, sestamibi scanning also estimates ejection fraction. As with thallium, resting and stress (exercise or pharmacologic) images can be compared to yield additional data.

Perfusion sestamibi imaging of patients *with current or recent* (within 30 minutes of injection) *pain* and no cardiac ischemia on ECG and biomarker analysis is very sensitive in detecting physiologic ischemia; a negative test would allow discharge to home. This latter approach requires broader study but is promising in select patients.

Dual-isotope stress testing using thallium and sestamibi is an increasingly common component of ED ACS evaluation protocols. In this technique, a resting thallium scan is first performed. Patients without resting defects can then immediately undergo stress testing with sestamibi imaging, thereby avoiding the delay usually required for isotope "washout" in single-isotope techniques. Dual-isotope stress testing in one trial reliably identified or excluded ACS.

Cardiac MRI Cardiac MRI assesses wall motion, perfusion, and coronary anatomy, either at rest or after pharmacologic stress. It is noninvasive and does not expose the patients to radiation. However, cardiac MRI cannot be performed on approximately 11% of ED patients with chest pain due to contraindications such as claustrophobia and implanted metallic objects. Another limit is the longer test performance time, although this is improving with newer scanners and software. Cardiac magnetic resonance stress imaging has excellent test performance but currently is not a common tool for early ACS evaluation.

CT Coronary Angiography CTCA allows gated images of the coronary arteries after rapid, peripheral (not central) IV contrast. Images are improved when the heart rate is <65 beats/min in 16-slice CT scanners, sometimes necessitating β-blocking medications; dual-source scanners (128-slice) can image adequately at higher heart rates but are less available. The advantages of CTCA are ready access to necessary equipment, rapid image acquisition, and the ability to image coronary structure. Notable disadvantages include ionizing radiation exposure, IV contrast exposure (and risk of allergy or kidney injury), need for specially trained technicians, and nondiagnostic scans due to nonvisualization of coronary segments. Additionally, CTCA provides a limited assessment of cardiac function. CTCA-detected lesions of >50% stenosis correlate with lesions on standard left-heart angiography; this means the test offers limited information in those with known coronary disease. Patients with positive scans require confirmation either with a cardiac catheterization or a functional advanced cardiac test.

Two recent clinical trials evaluated the usefulness of CTCA in decreasing ED length of stay and assessing for serious cardiac events within 30 days of discharge.[28,29] Both studies included patients with low to intermediate risk for ACS and considered CTCA results of <50% stenosis as negative. These trials found that patients randomized to CTCA versus traditional care had a higher rate of discharge from the ED and a decreased overall length of stay. No significant coronary disease was missed on CTCA evaluation versus traditional stress testing, although one study found that patients with positive CTCA findings had more overall testing and increased radiation exposure. The cost of care was similar for both groups of patients. Overall, these studies provide evidence that CTCA allows for faster and safe discharge of patients from the ED.[28,29]

CTCA findings also have a strong correlation with 1-year prognosis as demonstrated in a meta-analysis that included 18 studies with 9592 patients. Researchers evaluated for major adverse cardiac events, including death, myocardial infarction, and need for revascularization. The overall event rate for patients with positive CTCA (>50% stenosis

of any vessel) versus normal CTCA was 8.8% versus 0.17% per year, thus demonstrating that major adverse events in patients with negative CTCA imaging are rare.[30]

While ED CTCA helps deliver a prompt, safe disposition of patients in the ED, up to 24% of patients will have nondiagnostic CTCA imaging.[2] The ideal approach to these patients is undefined and usually reverts to the previous strategies for evaluating low-risk ACS patients.

DIAGNOSTIC PATHWAYS FOR PATIENTS WITH POSSIBLE ACUTE CORONARY SYNDROME

INPATIENT ADMISSION

In settings without an observation unit, all patients with low or higher risk of ACS are admitted to an inpatient bed. Specific destinations and care level are driven by stratification; those with a prior history of CAD, evidence of congestive heart failure on physical examination, recurrent chest pain, or new or presumed new ischemic ECG changes are at higher short-term risk and may be more appropriately managed in an intermediate-care (step-down) unit.

ED OBSERVATION AND TESTING

ED observation unit management decreases hospital admissions, length of stay, and hospital cost while providing a high level of care. The traditional observation unit chest pain protocol was refined by Lateef and colleagues,[32] with patients observed for 9 hours with continuous 12-lead ST-segment ECG monitoring and serial CK-MB testing at 0, 3, 6, and 9 hours after presentation. Those who completed a negative 9-hour evaluation subsequently underwent echocardiography followed by graded exercise stress testing in the ED before discharge. With this approach, 82.1% of patients were released home from the cardiac evaluation unit. The approach of **serial cardiac markers followed by objective cardiac testing remains the foundation of ED and other observation unit protocols**. Although early observation unit protocols focused on low-risk patients, more recent investigations successfully studied patients with intermediate-risk chest pain.

Figure 51-3 describes alternative approaches to the observation unit management of patients with possible ACS. For approach 3,[33] patients with intermediate- and low-risk chest pain underwent immediate resting myocardial perfusion imaging and serial cardiac markers. Patients with negative results were discharged for outpatient evaluation and stress testing. At 30 days, no patients with normal perfusion imaging experienced AMI, and 2% required revascularization. Based on this work, immediate perfusion imaging, serial cardiac markers, and outpatient stress testing are diagnostic options for patients with possible ACS.

After identification of patients as having possible ACS, immediate exercise stress testing is a safe option (Approach 4, Figure 51-3).[26] This approach had no stress testing–related adverse outcomes and allowed discharge of approximately two thirds of evaluated patients.[26] Immediate exercise stress testing has also been successfully extended to patients with known coronary disease.

The Erlanger chest pain evaluation protocol[34] (Approach 5, Figure 51-3) incorporates baseline and 2-hour marker determinations along with continuous ST-segment monitoring and serial ECGs. Those with positive results or any increase in markers are admitted for further evaluation.

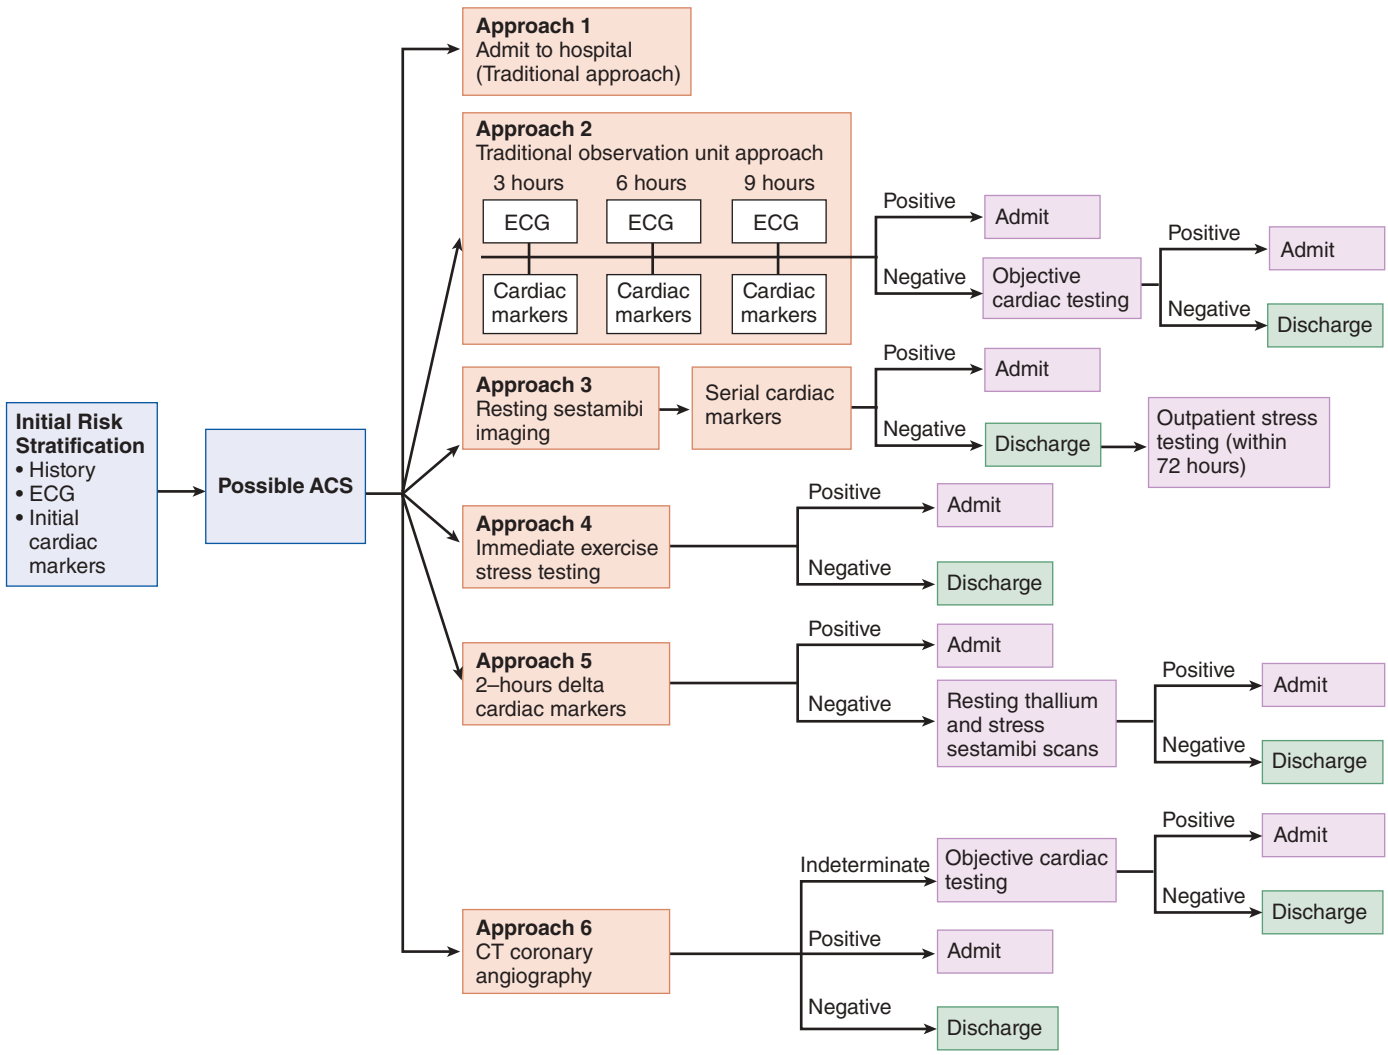

FIGURE 51-3. Pathways for secondary assessment of patients with possible acute coronary syndrome (ACS).

Patients thought to be at very low risk for ACS do not undergo stress testing and are discharged home, whereas those with low-risk chest pain undergo cardiac imaging with resting thallium and stress sestamibi scans. This protocol demonstrated a sensitivity of 99% and specificity of 87% for ACS at 30 days.

Some observation units adequately manage patients at intermediate risk for ACS, whereas some facilities manage these patients in the hospital. Any protocol that treats all patients with possible ACS equally should incorporate serial cardiac markers and stress testing. Second, no data exist to support exclusion of ACS based on cardiac markers without cardiac imaging except possibly in very-low-risk patients. Third, early stress testing after a negative ultra-short cardiac marker testing strategy, or exercise stress testing after one negative cardiac marker in patients with possible ACS, appears safe in low- and intermediate-risk patients. Fourth, outpatient stress testing is an option for low-risk patients in whom AMI has been excluded in reliable patients presenting to a facility where a mechanism exists to arrange this testing. Compliance with follow-up testing is better when scheduled before discharge.[35]

TREATMENT

STANDARD TREATMENT

Clinical trials often do not include patients with possible ACS and instead focus on the higher risk patients with positive cardiac markers or ST-segment changes on their ECG. Therefore, treatment recommendations for patients with possible ACS are derived from reviewing the risk-to-benefit profile suggested from clinical trial results in the higher risk patient populations. Additional information on the mechanisms of action and data from clinical trials are discussed in chapter 49.

Therapy for patients with possible ACS is linked to the patient's stratification level (Table 51-3). In general, patients at low risk of adverse events (Level IV) receive aspirin, anti-ischemic therapy with nitroglycerin, and β-blockers. Patients at intermediate risk (Level III) additionally receive antithrombin therapy and dual antiplatelet therapy (**Table 51-5**).[12]

Contraindications to aspirin include allergy, active bleeding, hemophilia, active retinal bleeding, severe untreated hypertension, an active peptic ulcer, or other serious causes of GI or GU bleeding.[12] Use clopidogrel in patients who are unable to tolerate aspirin due to allergy or GI intolerance.[12]

Very little data are available to support or refute β-blocker use in patients with possible ACS. No evidence suggests superiority of one β-blocker medication over another; however, cardioselective β_1 antagonism is often preferred over the nonselective effects of other agents, making metoprolol, esmolol, and atenolol common choices. β-Blocker medications also offset reflex tachycardia that can be seen with nitrates, and thus, these medications should be administered simultaneously.[12] The first dose of β-blockers can be administered PO or IV, with oral administration preferred and IV administration reserved for patients with hypertension at the time of treatment.[12] Do not use β-blockers with in those with signs of acute heart failure, low cardiac output, heart blocks, active asthma, or reactive airway disease, or in those at risk for cardiogenic shock (age >70 years old, systolic blood pressure <120 mm Hg systolic, sinus tachycardia >110 beats/min).[12]

DISPOSITION AND FOLLOW-UP

ADMISSION AND DISCHARGE CRITERIA

Disposition after the Primary Evaluation After the primary evaluation, if the treating physician estimates that the probability of ACS is <2%, further testing for ACS is not warranted. After exclusion of other life-threatening causes of chest pain, these patients may be discharged home. These patients may benefit from primary care follow-up or care from

TABLE 51-5 Recommended Treatment for Patients with Possible Acute Coronary Syndrome (ACS)

Class	Common Dosing	Common Contraindications (all include known hypersensitivity)
Core Therapy for Patients with Possible ACS		
Oxygen	As needed to keep O_2 saturation >95%	Not applicable
Aspirin	160–325 milligrams PO	Active bleeding; see text for further details
Nitroglycerin	0.4 milligram sublingual or spray	Right ventricular infarction, phosphodiesterase use, hypotension
Morphine sulfate	1–5 milligrams IV	—
β-Blockers (metoprolol, esmolol)	Metoprolol: 25–50 milligrams PO in the first 24 h	Bradycardia, heart block, hypotension, chronic obstructive pulmonary disease, severe left ventricular dysfunction, active reactive airway disease, PR interval >0.24 s, at risk for cardiogenic shock (age >70 y old, systolic blood pressure <120 mm Hg systolic, sinus tachycardia >110 beats/min)
Adjunctive Therapy for Patients at Intermediate Risk for Adverse Events*		
Dual antiplatelet therapy		
Clopidogrel (in addition to aspirin)	300–600 milligrams PO (loading dose)	Active bleeding
Antithrombin therapy		
Unfractionated heparin	60 units/kg IV bolus (maximum bolus 4000 units) 12 units/kg/h IV infusion (maximum infusion 1000 units/h)	Active bleeding, history of heparin-induced thrombocytopenia
Low-molecular-weight heparin	Enoxaparin, 1 milligram/kg SC every 12 h	
Direct thrombin inhibitors	Bivalirudin (only for patients undergoing an initial invasive approach), 0.1 milligram/kg IV bolus, 0.25 milligram/kg/h IV infusion	Active bleeding
Factor Xa inhibitor	Fondaparinux, 2.5 milligrams SC once daily	Active bleeding, creatine clearance <30 mL/min, body weight <50 kg

A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients with Unstable Angina/Non ST-Elevation Myocardial Infarction). *J Am Coll Cardiol* 50: e1, 2007.

another specialty physician depending on the suspected cause (e.g., GI, pulmonary).

Disposition after the Secondary Evaluation Most patients with possible ACS undergo further evaluation to diagnose or exclude ACS. Upon completion of these protocols, those with negative cardiac markers, no dynamic ECG changes, and negative objective cardiac testing can be safely discharged home. Patients with positive cardiac markers, diagnostic ECG changes, or diagnostic testing supporting ACS are admitted to the hospital for cardiac care. Those with nondiagnostic cardiac testing are handled on a case-by-case basis after discussion with a cardiologist.

SUGGESTED FOLLOW-UP INTERVAL

Despite advanced testing, a negative evaluation does not entirely exclude ACS. Patients discharged after exclusion of ACS should be given detailed precautions describing reasons to return to the ED. Ideally, patients should follow up with their primary care physician within the next 2 to 3 days.

SPECIAL POPULATIONS

Age, ethnic, racial, and gender differences are well described in patients presenting with ACSs. Most current knowledge of ACS-related symptoms and risk factors comes from population-based studies. Studies have suggested that women are more likely to present without chest pain and often have a prodrome of fatigue. Similarly, the elderly less often present with a chief complaint of chest pain and, less frequently, have typical chest pain. Other studies have noted delayed presentation for ACS in black women[36] and less frequent chest pain with ACS in those of Asian descent.[37] The Framingham criteria overestimate the risk of coronary disease when applied to Chinese patients,[38] and these patients are less likely to experience classic symptoms of ACS. Be aware of all these confounders as you assess the clinical likelihood of ACS.

COCAINE-ASSOCIATED CHEST PAIN

In a study of 130 patients with cocaine-associated myocardial infarction, the mean age was 38 years. AMI occurs in approximately 6% of patients who present to the ED with chest pain after cocaine use. The initial evaluation of the patient with cocaine-associated chest pain is the same as outlined earlier, using the history, exam, ECG, and cardiac biomarkers as the foundation. The sensitivity, specificity, positive predictive value, and negative predictive value of the ECG to identify cocaine-associated myocardial infarction are 36%, 89.9%, 17.9%, and 95.8%, respectively. Cardiac troponin is the most sensitive biomarker for cocaine-associated myocardial infarction. Aspirin, nitrates, and benzodiazepines are the mainstays of therapy for chest pain; β-blockers are contraindicated. Thrombolysis in Acute Myocardial Infarction scoring has little predictive value in patients with cocaine-associated chest pain,[39] but patients with nondiagnostic initial ECGs can be managed in an observation unit using serial ECGs and biomarkers over 6 to 12 hours. There is no difference in the outcomes of patients managed with or without stress testing. The American Heart Association guideline recommends stress testing as an option for patients with cocaine-associated chest pain absent other higher risk factors or features.[40] In one study, the 1-year rate of myocardial infarction after a negative chest pain observation evaluation for patients with cocaine-associated chest pain was <1%, despite a 66% rate of ongoing cocaine use.[41]

PRACTICE GUIDELINES

The American College of Cardiology and American Heart Association offer guidance for the management of patients with unstable angina and NSTEMI.[12]

CHAPTER 52

Syncope

James Quinn

INTRODUCTION AND EPIDEMIOLOGY

Syncope or fainting is a symptom complex consisting of a brief loss of consciousness associated with an inability to maintain postural tone that spontaneously resolves without medical intervention. Syncope accounts for approximately 1% to 2% of ED visits each year and up to 6% of hospital admissions.[1-3] In the **Framingham Heart Study**, 7814 patients were followed for 17 years, and 10.5% reported syncope.[4] Syncope in the preceding year is the best predictor of recurrence.[5] It can affect the young and the old, with the elderly having the greatest morbidity.[6] **Near-syncope**, a premonition of fainting without loss of consciousness, shares the same basic pathophysiologic process as syncope and may carry the same risks.[7,8]

PATHOPHYSIOLOGY

The final common pathway of syncope is the same regardless of the underlying cause: about 10 seconds of complete disruption of blood flow or nutrient delivery to both cerebral cortices or to the brainstem reticular activating system, or reduction of cerebral perfusion by 35% to 50%. Most commonly, an inciting event causes a drop in cardiac output, which decreases oxygen and substrate delivery to the brain. Less commonly, vasospasm reduces CNS blood flow. Cerebral perfusion and consciousness are restored by the supine position, the response of autonomic autoregulatory centers, or restoration of a perfusing cardiac rhythm.

The causes of syncope are numerous (**Table 52-1**). The major causes of syncope identified in the Framingham Heart Study were vasovagal (reflex mediated, 21%), cardiac (10%), orthostatic (9%), medication related (7%), neurologic (4%), and unknown (37%).[4] In most studies, even with exhaustive patient evaluation, the cause remains unknown in about 40% of individuals.[9,10] After ED investigation, the unknown proportion may be 50% to 60%. Diagnosis is important, because each diagnostic classification carries with it prognostic risk. In the Framingham study, cardiac syncope doubled the risk of death, neurologic syncope increased the risk of death by 50%, and syncope of unknown cause increased the risk of death by 30%, compared to the general population cohort of the study. Individuals with neurally/reflex-mediated or vasovagal syncope had no increased risk of death compared with the general population cohort.[4]

CLINICAL FEATURES

CARDIAC-RELATED SYNCOPE

Cardiac-related syncope is the most dangerous type and is a risk for sudden death. Because patients with documented cardiac syncope have a 6-month mortality rate that exceeds 10%, timely and thorough evaluation is warranted.[4,10] Well-appearing patients with undiagnosed cardiac disease are the most challenging group. The causes of cardiac syncope are divided into two categories: structural disease and dysrhythmias (**Table 52-1**). In both settings, the heart is unable to provide adequate cardiac output to maintain cerebral perfusion.

Syncope can occur if **structural disease** limits the heart's ability to increase cardiac output to meet demand. Examples of structural cardiac disease associated with syncope include aortic stenosis, hypertrophic cardiomyopathy, pulmonary embolism, and myocardial infarction. **Consider aortic stenosis as a structural cardiac cause of syncope in the elderly.** The classic symptom constellation of aortic stenosis is chest pain, dyspnea on exertion, and syncope. **Hypertrophic cardiomyopathy** is characterized by a stiff noncompliant left ventricle, diastolic dysfunction, and outflow tract obstruction. It is the most common cause

TABLE 52-1 Causes of Syncope

Cardiac*	Neural/Reflex Mediated
Structural cardiopulmonary disease	*Vasovagal*
Valvular heart disease	*Situational*
Aortic stenosis	Cough
Tricuspid stenosis	Micturition
Mitral stenosis	Defecation
Cardiomyopathy	Swallow
Pulmonary hypertension	Neuralgia
Congenital heart disease	*Carotid sinus syndrome*
Myxoma	Other
Pericardial disease	**Orthostatic hypotension** (see text)
Aortic dissection	**Psychiatric**
Pulmonary embolism	**Neurologic**
Myocardial ischemia	Transient ischemic attacks
Myocardial infarction	Subclavian steal
Dysrhythmias	Migraine
Bradydysrhythmias	**Medications (Table 52-2)**
Short or long QT syndromes	**Breath holding** (pediatric)*
Stokes-Adams attack	
Sinus node disease	
Second- or third-degree heart block	
Pacemaker malfunction	
Tachydysrhythmias	
Ventricular tachycardia	
Torsade de pointes	
Supraventricular tachycardia	
Atrial fibrillation or flutter

of sudden cardiac death in young adults, but the disorder may be first recognized in those >60 years old.[11] Massive acute **pulmonary embolism** may cause syncope due to obstruction of the pulmonary vascular bed and reduction in cardiac output.[12] **Acute myocardial infarction** may cause syncope if myocardial dyskinesia reduces cardiac output. Individual chapters in the Cardiovascular Disease section of this text provide more discussion on structural cardiopulmonary disorders that may cause syncope.

Although both **brady- and tachydysrhythmias** may lead to transient cerebral hypoperfusion (**Table 52-1**), there is no absolute high or low heart rate that will predictably produce syncope. Symptoms depend on both the autonomic nervous system's ability to compensate for a decrease in cardiac output and the degree of underlying cerebrovascular disease. Dysrhythmias may also result from of a primary electrolyte imbalance, as in hypomagnesemia (e.g., torsade de pointes). Dysrhythmias can occasionally occur in structurally normal hearts, such as in the familial disorders of **Brugada syndrome**, long or short **QT syndromes**, and catecholamine-associated polymorphic ventricular tachycardia. **Syncope from dysrhythmias is typically sudden and usually without prodromal symptoms.**

Antidepressants
Phenothiazines
Nitrates
Alcohol
Cocaine

VASOVAGAL AND NEURALLY/REFLEX-MEDIATED SYNCOPE

Vasovagal syncope, a form of reflex-mediated or neurally mediated syncope, is associated with inappropriate vasodilatation, bradycardia, or both, as a result of inappropriate vagal or sympathetic tone.[13,14] A prodrome of lightheadedness, with or without nausea, pallor, and/or sweating, and an associated feeling of warmth may accompany vasovagal syncope. **A slow, progressive onset with associated prodrome suggests vasovagal syncope**. Vasovagal syncope may occur after exposure to an unexpected or unpleasant sight, sound, or smell; fear; severe pain; emotional distress; or instrumentation. It may also occur in association with prolonged standing or kneeling in a crowded or warm place. **Situational syncope** occurs during or immediately after coughing, micturition, defecation, or swallowing.

Carotid sinus hypersensitivity, characterized by bradycardia or hypotension, is another type of reflex-mediated syncope. The carotid body, located at the carotid bifurcation, contains pressure-sensitive receptors. The stimulation of an abnormally sensitive carotid body by external pressure may lead to two autonomic responses. Most commonly, there is an abnormal vagal response, leading to bradycardia and asystole of >3 seconds. Less commonly, there is a vasodepressor response, leading to a decrease in blood pressure of >50 mm Hg without a significant change in heart rate. Both responses may occur simultaneously. Carotid sinus hypersensitivity is more common in men, the elderly, and among those with ischemic heart disease, hypertension, and certain head and neck malignancies. Although some patients may demonstrate a hypersensitive carotid sinus response on provocative testing, unless this response culminates in syncope or recurrence of prodromal symptoms, and unless it is associated with an inciting event, such as shaving or turning of the head, it cannot be definitely diagnosed as the cause of syncope. About 25% of patients with carotid sinus hypersensitivity have true carotid sinus syndrome with spontaneous symptoms.[5] **Consider carotid sinus hypersensitivity in older patients with recurrent syncope and negative cardiac evaluations.**

ORTHOSTATIC SYNCOPE

Orthostatic syncope is suggested when postural hypotension is associated with syncope or presyncope.[15] When a person assumes an upright posture, gravity shifts blood to the lower part of the body, and cardiac output drops. This change triggers the healthy autonomic nervous system to increase sympathetic output and decrease parasympathetic output, increasing heart rate and peripheral vascular resistance, and thus increasing cardiac output and blood pressure.[16,17] If the autonomic response is insufficient to counter the drop in cardiac output upon standing, decreased cerebral perfusion and syncope may follow. Symptom onset is usually within the first 3 minutes after assuming the upright posture, but may be more delayed in some patients. However, positive orthostatic changes have been documented in up to 40% of asymptomatic patients >70 years old and in about a quarter of those <60 years old, so orthostasis does not always result in syncope.[14,18] Causes of orthostatic syncope include intravascular volume loss and poor vascular tone caused by α-receptor disorders or medications. **Many serious causes of syncope may be associated with orthostatic changes, so consider other life-threatening causes before attributing syncope to orthostasis, especially in the elderly.**

PSYCHIATRIC DISORDERS

Psychiatric disorders are found in a modest percentage of patients with syncope[19]—up to 40% of those with vasovagal syncope and up to 62% of those with unexplained syncope.[20] In one study, the most frequent psychiatric diagnoses associated with syncope were generalized anxiety disorder and major depressive disorder.[21] Hyperventilation has been used as a provocative maneuver in diagnosing panic disorder and

generalized anxiety disorders and can lead to hypocarbia, cerebral vasoconstriction, and syncope.[22] Hyperventilation may not be obvious to the observer but can be documented by end-tidal carbon dioxide monitoring. In general, a patient with syncope and a psychiatric disorder is likely to be young, with repeated episodes of syncope and multiple prodromal symptoms.[21] A psychiatric cause for syncope should be one of exclusion, assigned only after organic causes have been excluded.

NEUROLOGIC SYNCOPE

Neurologic causes of syncope are rare. To meet the definition of syncope, symptoms must be transient and with no persistent neurologic deficits. **Thus, patients with loss of consciousness with persistent neurologic deficits or altered mental status do not have true syncope.** Brainstem ischemia, vertebrobasilar atherosclerotic disease, or basilar artery migraine may result in a decrease in blood flow to the reticular activating system, leading to sudden, brief episodes of loss of consciousness. Loss of consciousness is typically preceded by other signs or symptoms, such as diplopia, vertigo, focal neurologic deficits, or nausea. **Subclavian steal syndrome** is a rare cause of brainstem ischemia. It is characterized by an abnormal narrowing of the subclavian artery proximal to the origin of the vertebral artery, so that with exercise of the ipsilateral arm, blood is shunted, or "stolen," from the vertebrobasilar system to the subclavian artery supplying the arm muscles. Anatomically, narrowing is more common on the left. Physical examination may identify decreased pulse volume and diminished blood pressure in the affected arm.

Subarachnoid hemorrhage may present with syncope but is usually accompanied by other symptoms such as focal neurologic deficits, headache, or persistent altered mental status. The mechanism for syncope is thought to be an increase in intracranial pressure with a decrease in cerebral perfusion pressure. **Subarachnoid hemorrhage can also follow a fall and head injury from syncope secondary to another cause.** See chapter 166, Spontaneous Subarachnoid and Intracerebral Hemorrhage, for further discussion.

Seizure may be confused with syncope, because brief tonic-clonic movements are often associated with syncope. However, confusion (postictal state) lasting several minutes, tongue biting, incontinence, or an epileptic aura suggests a seizure.

MEDICATION-INDUCED SYNCOPE

Medications may contribute to syncope by a variety of means (**Table 52-2**), but the most common is orthostasis.[23] β-Blockers or calcium channel blockers may lead to a blunted heart rate response after orthostatic stress. Diuretics may produce volume depletion, and some medications have proarrhythmic properties, increasing the concern for dysrhythmia as the cause of syncope.

PRINCIPLES OF EVALUATION

The goal of ED evaluation is to identify those at risk for immediate and future morbidity or sudden death. For patients with a specific diagnosis, the diagnosis directs the disposition plan. For patients without a specific diagnosis, risk stratification is based on a careful history, thorough physical examination, and electrocardiogram interpretation, with additional testing as needed.

HISTORY

Obtain clinical history from the patient and any witnesses of the event. Begin with a detailed description of the events preceding the loss of consciousness, including patient position, environmental stimuli, strenuous activity, or arm exercise. Record premonitory symptoms such as headache, diplopia, vertigo, or focal weakness. Ask about chest pain and palpitations. Clarify the duration of loss of consciousness and symptoms occurring after regaining consciousness. Symptoms associated with syncope that should raise concern of an immediately life-threatening diagnosis include **chest pain** (acute myocardial infarction, aortic dissection, pulmonary embolism, aortic stenosis), **palpitations** (dysrhythmia), shortness of breath (pulmonary embolism, congestive heart failure), **headache** (subarachnoid hemorrhage), and **abdominal or back pain** (leaking abdominal aortic aneurysm, ruptured ectopic pregnancy). A sudden event without warning and events associated with exertion raise suspicion for a cardiac dysrhythmia or structural cardiopulmonary lesion.[24] Ask about antecedent illness and alcohol ingestion or substance abuse. The past medical history should include questions regarding underlying structural heart disease, including congenital heart disease, valvular heart disease, coronary artery disease, congestive heart failure, pulmonary embolism, and ventricular dysrhythmias. Document any prior history of syncope, as patients with more than five syncopal episodes in 1 year are more likely to have vasovagal syncope or a psychiatric diagnosis than dysrhythmia as the cause.[5] All medications should be recorded, including over-the-counter medications such as laxatives. Patients aggressively dieting to lose weight may have electrolyte disturbances or may be taking amphetamine-like medications. The family history is important in regard to history of prolonged QT syndrome, dysrhythmias, sudden cardiac death, or other cardiac risks.

Special attention should be paid to patients presenting after single-car motor vehicle crashes (frequently with a history of driving off the road), particularly if the patients are elderly. Clinicians may become preoccupied by the trauma evaluation and miss the possibility of a syncopal event.

Seizure is the most common event mistaken as syncope. Mild, brief, tonic-clonic activity ("convulsive syncope") may accompany syncope of any etiology. The two conditions do not share the same pathophysiologic mechanisms. History is very important in differentiating syncope from seizure.[25] Premonitory and postevent symptoms may assist in differentiation. A classic aura or postictal confusion and muscle pain indicate seizure, whereas characteristic prodromal symptoms of nausea and diaphoresis suggest reflex-mediated (vasovagal) syncope. Witness information of the event may also be useful. Witnessed head turning or unusual posture during the event is consistent with seizure. A prolonged postictal phase is more common with seizure. Urinary incontinence is not useful in the distinction.

PHYSICAL EXAMINATION

Evidence of trauma without defensive injuries to the hands or knees should raise suspicion of a sudden event without warning, such as a dysrhythmia, but patients with noncardiac syncope are also just as likely to suffer significant facial and head trauma. The physical examination should focus on both the cardiovascular and neurologic systems. Obtain blood pressure measurements in both arms. Unequal blood pressures should increase suspicion of aortic dissection or subclavian steal. Take orthostatic blood pressures after 5 minutes in the supine position. Repeat measurements after 1 and 3 minutes of standing. A symptomatic decrease of >20 mm Hg in the systolic pressure is considered abnormal, as is a drop in pressure below 90 mm Hg independent of the development of symptoms. Cardiac examination may reveal the murmur of hypertrophic cardiomyopathy or aortic stenosis. The neurologic examination may uncover findings of focal neurologic disease or evidence of autonomic instability such as peripheral neuropathy. Perform rectal examination to check stool guaiac to evaluate for GI bleeding.

DIAGNOSIS

The diagnosis of syncope is clinical, with careful evaluation of the presentation and selected use of diagnostic tests. History is most important, and most diagnostic tests have low diagnostic yield.[26] The differential diagnosis is presented in **Tables 52-1** and **52-2**.

ELECTROCARDIOGRAM

Obtain a 12-lead electrocardiogram. Even though the electrocardiogram leads to a diagnosis in only a few patients, it is a simple, noninvasive test and is important for risk stratification.[27] Assess the electrocardiogram for evidence of prior cardiopulmonary disease, acute ischemia or new electrocardiogram changes, dysrhythmia, heart block, and prolonged or short QTc interval. A prolonged QTc interval has a variable definition, but the literature suggests it is defined as >470 milliseconds, with >500 milliseconds associated with significant outcomes,[28-30] whereas a short QTc interval <350 milliseconds is concerning as well.[31] New or old left

bundle conduction abnormalities (left bundle-branch block, posterior or anterior fascicular block, QRS widening) are 3.5 times more likely to be associated with morbidity than electrocardiograms lacking these findings. Non-sinus rhythms are 2.5 times more likely to be associated with morbidity than sinus rhythms.[32] For further discussion, see chapter 18, Cardiac Rhythm Disturbances.

LABORATORY TESTING

Laboratory testing is directed by results of the history and physical examination. For example, a patient with orthostatic symptoms and a heme-positive stool test warrants at least a CBC. A reproductive-age female should have a urine pregnancy test. A transitory, wide anion gap acidosis follows a generalized seizure but is not present in simple syncope. Serum electrolytes rarely determine the cause of syncope. B-type natriuretic peptide or pro–B-type natriuretic peptide levels appear to be predictive of those at risk for morbidity. One study suggests that a level >300 pg/mL in the setting of syncope indicates risk,[33] but whether this adds any value over a history of congestive heart failure or structural disease is unclear.[34,35] See chapter 53, Acute Heart Failure, for a discussion of the diagnostic use of B-type natriuretic peptide.

ANCILLARY TESTING

Carotid Massage Carotid massage is used to diagnose carotid sinus hypersensitivity in the patient with a history suggestive of carotid sinus syndrome. Although not generally used in emergency medicine at this time, carotid massage can be done at the bedside in the ED with continuous electrocardiographic and blood pressure monitoring, after obtaining informed consent. Each carotid body is separately massaged for 5 to 10 seconds. The test is considered positive if symptoms are reproduced in the presence of asystole >3 seconds or a decrease in systolic blood pressure of >50 mm Hg. **Do not perform carotid massage if the patient has known carotid stenosis, if bruits are present, if there is history of recent (<3 months) stroke or myocardial infarction, or if there is a history of ventricular tachycardia or fibrillation.** Neurologic deficits resulting from cardiac massage are rare, with deficits lasting more than 24 hours in approximately 0.1% of patients.[36] Only a small number of patients with carotid hypersensitivity will have the true carotid sinus syndrome. Given the small benefit of the maneuver and that the rare potential adverse events are catastrophic, most physicians do not routinely perform carotid massage.

Hyperventilation Maneuver A hyperventilation maneuver (open-mouthed, slow, deep breaths at a rate of 20 to 30 breaths per minute for 2 to 3 minutes) can be very useful in the young patient with undiagnosed syncope and suspected psychiatric illness. This test can easily be performed in the ED. A recurrence of prodromal symptoms or syncope significantly correlates with psychiatric (anxiety-provoking) causes of syncope.[21]

Neurologic Testing When the history or physical examination does not suggest trauma or a neurologic cause for syncope, the clinical yield of routine CT scanning, electroencephalogram, or lumbar puncture is very low. Consequently, in asymptomatic patients who have experienced an isolated syncopal event, and in those without head trauma from the event, a head CT scan or MRI scan is not warranted.

DECISION MAKING AND RISK ASSESSMENT

DIAGNOSIS ESTABLISHED

If a cause of syncope can be determined by the initial history, physical examination, and ECG, the disposition is simple. Patients with cardiac or neurologic syncope should be admitted. Patients with vasovagal, orthostatic, and medication-related syncope have no increased risk of cardiovascular morbidity or mortality[6] and do not need admission as long as deficits are corrected.

UNEXPLAINED SYNCOPE

Despite best efforts, a diagnosis will not be established in about 40% of the patients with syncope. Several studies have assessed risk stratification variables to identify patients at risk of both short-term and 1-year morbidity and mortality. Martin et al[37] performed derivation and validation studies on cohorts of consecutive ED patients with syncope to identify predictors of arrhythmia and death at 1 year. Important risk factors were a history of arrhythmia, an abnormal electrocardiogram, a history of congestive heart failure, and age >45 years. Quinn et al[2,38] assessed adverse outcomes at 7 and 30 days in their derivation and validation of the **San Francisco Syncope Rule**. Significant predictors of adverse events (primarily arrhythmia) included (1) a history of congestive heart failure, (2) an abnormal electrocardiogram (a rhythm other than sinus, including those on rhythm strips or monitoring, conduction delays or new changes as minimal as first-degree atrioventricular block, or any morphologic changes to the QRS complex or ST segment that could not be proven to be old by prior tracings), (3) a hematocrit of <30, (4) a complaint of shortness of breath, and (5) a systolic blood pressure of <90 mm Hg in the ED. There have been inconsistent findings when validating the San Francisco Syncope Rule, which have been primarily related to definitions of syncope and when applying variables.[39] The Osservatorio Epidemiologico sulla Sincope nel Lazio study group developed a risk score based on predictors of death at 1 year, which they found to be an abnormal electrocardiogram, a history of cardiovascular disease (including congestive heart failure), age >65 years, and syncope without prodrome.[40] Sarasin et al[41] developed a prediction score for subsequent arrhythmia in patients with unexplained syncope after a standard ED evaluation; they found the significant variables to be an abnormal electrocardiogram, a history of congestive heart failure, and age >65 years. Continued analysis of the San Francisco syncope cohort, assessing 1418 consecutive patients with syncope, found the death rate to be 1.4% at 30 days, 4.3% at 6 months, and 7.6% at 1 year. The five high-risk criteria listed earlier had an 89% sensitivity and 52% specificity for death at 1 year.[42]

Using the risk factors identified in these studies can help clinicians determine patient risk and appropriate disposition. Although each study may be limited by the size of the cohort, the number of adverse events, and the definition of these events, there is a consistent theme that patients with an abnormal electrocardiogram on presentation and/or a history of heart disease, particularly structural heart disease especially characterized by a history of congestive heart failure, are clearly at increased risk.

GENERAL MANAGEMENT ALGORITHM

A general management algorithm is shown in **Figure 52-1**, which follows the recommendations of the American College of Emergency Medicine guidelines for the disposition of patients with syncope presenting to the ED and lists essential risk factors.[43]

Risk factors not included in Figure 52-1, but suggested by guidelines[44,45] as factors that could be used for admission or expedited follow-up decision making, include **syncope while supine, syncope during exercise, syncope without prodromal symptoms, palpations preceding syncope, and the specific age cut points of >60 or >65 years**.

TREATMENT

Treatment should be guided by the diagnosis. Patients with or at risk for life-threatening dysrhythmias can be treated with pacemakers or automatic implantable defibrillators as indicated. For patients with suspected medication causes, remove the offending agent. Rehydrate those with orthostasis and dehydration. Educate patients with vasovagal syncope; episodes are likely to recur, and patients should lie or sit down when they sense a prodrome. β-Blockers do not decrease episodes of vasovagal syncope.[46]

DISPOSITION AND FOLLOW-UP

INPATIENT EVALUATION

With the exception of patients with acute life-threatening diagnoses (e.g., stroke, aortic dissection), the core of the inpatient evaluation is focused on identification of underlying heart disease and detection of

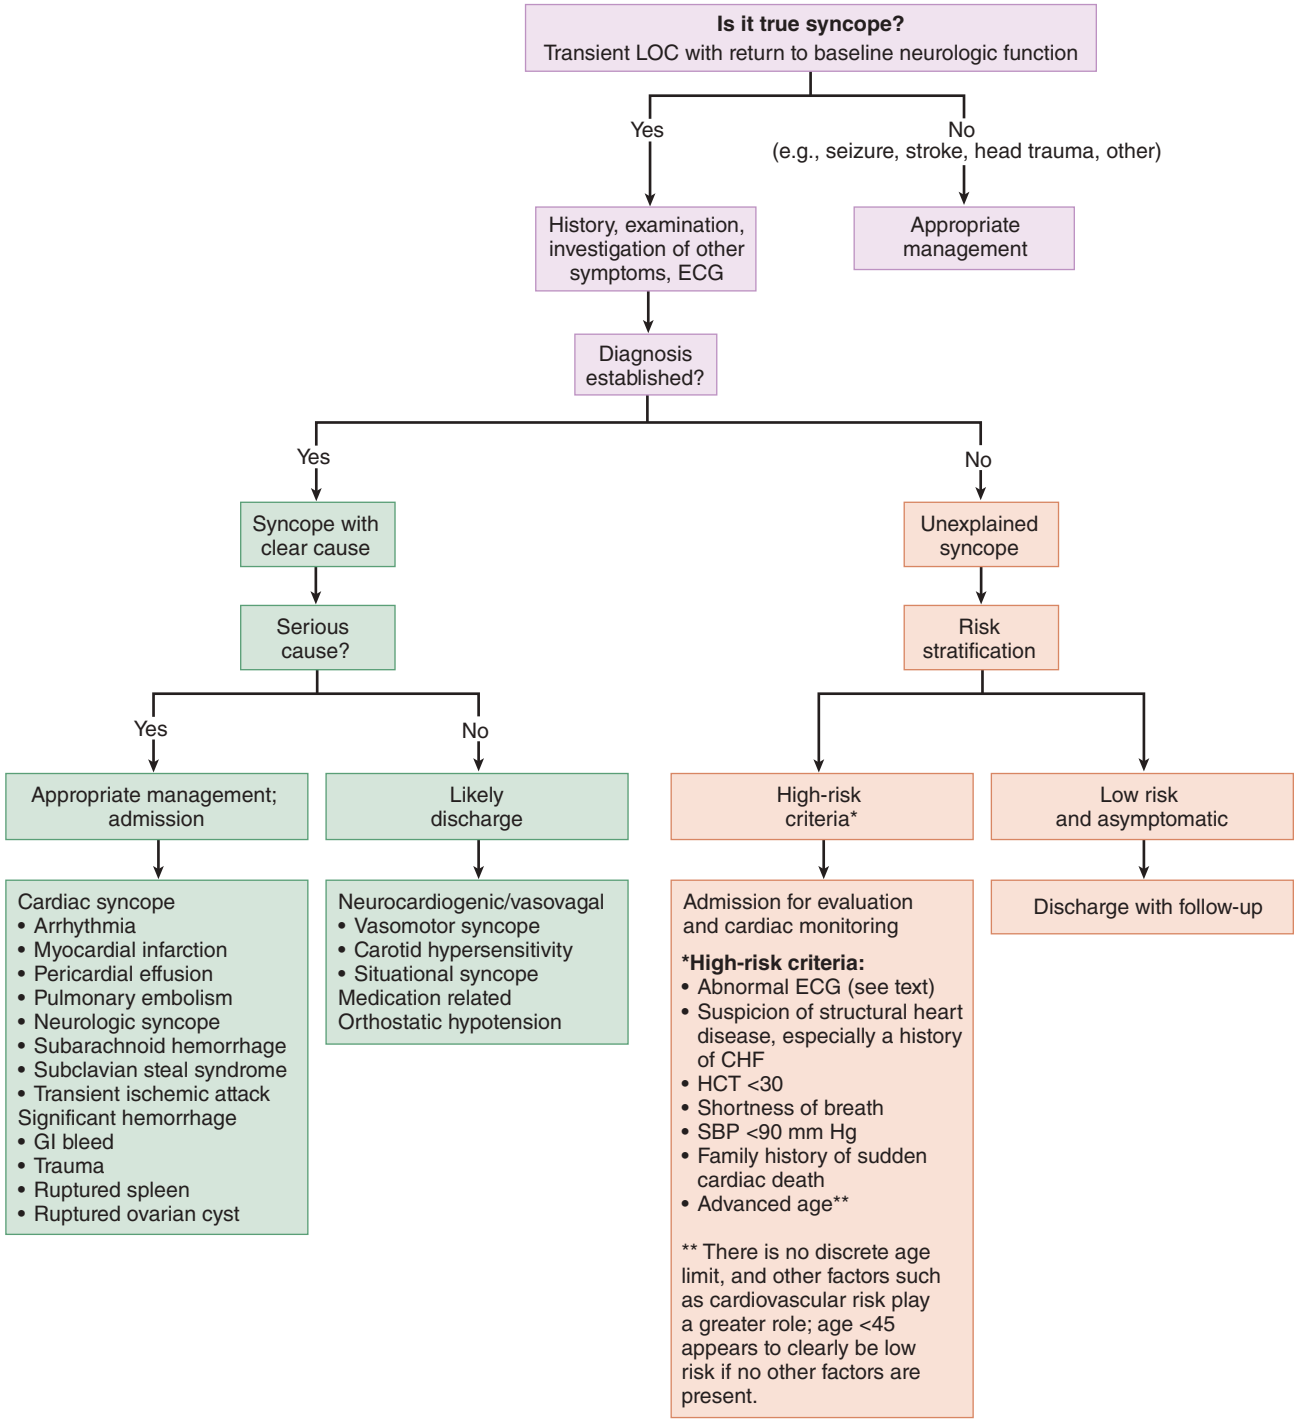

FIGURE 52-1. ED evaluation of syncope provides a general management strategy. CHF = congestive heart failure; ECG = electrocardiogram; HCT = hematocrit; LOC = loss of consciousness; SBP = systolic blood pressure.

dysrhythmias (**Table 52-3**). Although admitted patients undergo continuous electrocardiographic monitoring, the utility of admission and monitoring is questioned.[26,47] Dysrhythmia as the cause of syncope is confirmed in the patient with recurrent symptoms during a monitored dysrhythmia and excluded in the patient with recurrent symptoms and sinus rhythm. An echocardiogram should be performed on patients with known or suspected heart disease to evaluate for valvular disorders, congenital anomalies, and cardiomyopathies and to determine overall cardiac function. Echocardiogram abnormalities are usually clinically apparent and will seldom be found in patients with a normal cardiac examination and electrocardiogram. Stress testing is used to identify exercise-induced dysrhythmias or ischemia or to reproduce exertional syncope once hypertrophic cardiomyopathy has been excluded by echocardiography. Electrophysiology testing is typically reserved for patients with documented dysrhythmia, preexcitation, or underlying heart disease. Electrophysiology testing involves invasive electrical stimulation and cardiac monitoring to uncover possible conduction abnormalities that predispose to tachydysrhythmias (both ventricular and supraventricular) or bradydysrhythmias.

OUTPATIENT EVALUATION

Patients directed to outpatient syncope evaluation should be at low risk for serious cardiac dysrhythmias. Long-term cardiac monitoring, which

TABLE 52-3 Post-ED Testing for Syncope/Syncope Mimics

Test	Indication	Utility
Cardiac syncope		
Electrocardiographic monitoring	Admission Outpatient ambulatory monitoring if no significant cardiac disease suspected	Cardiac syncope confirmed if recurrent symptoms occur during monitored dysrhythmia; excluded if recurrent symptoms reported during sinus rhythm
Implantable loop recorder	Recurrent syncope after admission evaluation	Long-term use with diagnostic yield of >50% in patients with recurrent syncope
Echocardiography	History, examination, or electrocardiogram suggestive of structural heart disease	Confirms and quantifies suspected structural heart disease
Electrophysiology testing	Documented dysrhythmia or serious underlying heart disease	Identifies inducible tachydysrhythmias and some bradydysrhythmias
Stress testing	Exercise-related syncope	Identifies exercise-induced dysrhythmias and postexercise syncope
Neurologic syncope		
CT/magnetic resonance angiography/ carotid Doppler	Neurologic signs or symptoms	Identifies cerebrovascular abnormality or subclavian stenosis
Electroencephalography	Suspected seizure	Documents underlying seizure disorder
Reflex-mediated syncope		
Tilt-table testing	Recurrent syncope, cardiac etiology excluded	Positive test establishes diagnosis of neurocardiogenic syncope
Psychogenic		
Psychiatric testing	Young patient, no underlying heart disease	Identifies underlying psychiatric disorder predisposing to syncope

includes ambulatory or event monitors, is useful to identify dysrhythmias (**Table 52-3**). The duration one should wear an ambulatory monitor is debatable, but monitors are now more portable and can be worn for long periods.[48] Long-term use of implantable loop recorders have a diagnostic yield of >50% in patients with recurrent syncope.[49-51] Tilt-table testing is also suggested for patients with recurrent, unexplained syncope. This test is designed to identify reflex-mediated syncope by rapidly moving the patient from a supine position on the tilt table to an upright position of 60 degrees for 45 minutes. A positive end-point is reached if syncope, hypotension, or the patient's typical symptoms are reproduced. Repeat testing with isoproterenol or sublingual nitroglycerin is performed if the initial evaluation is negative. Recurrent reflex-mediated syncope resistant to conservative therapies can be treated with a cardiac pacemaker. Psychiatric referral is recommended for young patients without underlying heart disease who have frequent syncopal events. Generalized anxiety and depressive disorders are the most commonly assigned diagnoses. Patients with a prolonged QT segment should be referred for genetic testing for the *LQTS* gene. Those who are gene negative have very little risk for fatal syncope.[52]

SPECIAL POPULATIONS

THE ELDERLY

Because of both normal physiologic changes with aging and age-related disease processes, the elderly are at increased risk for syncope and adverse outcomes.[8] Syncope in the elderly is often multifactorial, and the cause is often difficult to establish, particularly in the ED.

Various specified ages have been studied as risk factors for fatal or serious outcomes after syncope; however, there is a gradual continuum of increasing risk with increasing age. Cardiovascular risk factors appear to be better predictors than age itself. As a person ages, the blood vessels become calcified and less compliant, leading to diminished flow rates. The left ventricle also becomes less compliant, resulting in increased diastolic filling pressures and an increased dependence on the "atrial kick." There is a general decrease in adrenergic receptor responsiveness of both the heart and the peripheral blood vessels. Decreased adrenergic responsiveness contributes to the diminished chronotropic response seen after orthostatic stresses in the elderly. The incidence of vasovagal syncope actually decreases with age, in part as a consequence of the decreased responsiveness of the autonomic nervous systems. The elderly also have a less sensitive thirst mechanism and a decreased endocrine response to volume depletion, exacerbating orthostatic hypotension. Postprandial hypotension is more common in the elderly, especially in nursing home patients, and is thought to be due to a rapid rate of nutrient delivery from the stomach into the small intestine. Pathophysiologic processes that may contribute to diminished cerebral perfusion include disorders such as hypertension, atherosclerosis, and valvular disease. Atherosclerotic disease leads to ischemia, myocardial infarction, congestive heart failure, and dysrhythmias. Aortic stenosis is the most common obstructive cardiac lesion in the elderly, producing a fixed cardiac output. Diabetes may lead to autonomic dysfunction and peripheral neuropathy. Finally, medication usage is much more common in the elderly population, increasing the risk of orthostasis and decreasing autonomic responsiveness to orthostatic stress.[18]

PREGNANT WOMEN

Pregnancy is associated with numerous physiologic changes, including increased heart rate, decreased peripheral resistance, and increased stroke volume. In late pregnancy, the enlarged uterus may compress the inferior vena cava, decreasing venous return. The incidence of cardiac dysrhythmias, especially premature ventricular contractions, increases during normal pregnancy in young healthy women. However, there is no positive correlation between symptoms of presyncope or syncope and cardiac dysrhythmia in pregnant women. Important considerations for syncope in pregnancy include ruptured ectopic pregnancy and pulmonary embolism, although these disorders typically have other associated symptoms such as abdominal or dyspnea.

CHILDREN

Syncope in children is discussed in chapter 127, "Syncope, Dysrhythmias, and ECG Interpretation in Children."

PRACTICE GUIDELINES

Guidelines for the management of patients sustaining syncope have been published by the American College of Emergency Physicians,[43] the European Society of Cardiology,[44] the Canadian Cardiovascular Society,[45] and the American Heart Association/American College of Cardiology Foundation.[53]

CHAPTER 53

Acute Heart Failure

Sean P. Collins
Alan B. Storrow

INTRODUCTION AND EPIDEMIOLOGY

Acute heart failure covers a wide spectrum of illness, ranging from a gradual increase in leg swelling, shortness of breath, or decreased exercise tolerance to the abrupt onset of pulmonary edema. While alternative terms such as *decompensated heart failure*, *acute heart failure syndrome*, or *hospitalized with heart failure* have been used nearly interchangeably over the last decade, we refer to patients with either an acute exacerbation of chronic heart failure or a new-onset heart failure as having *acute heart failure*. The term *congestive heart failure* is outdated and describes patients with signs and symptoms of fluid accumulation.

Most ED visits for acute heart failure result in hospital admission.[1] With the aging population, increased survival from acute myocardial infarction, and evidence-based outpatient treatment options, the prevalence of heart failure is expected to increase over the next decade.[2-4] ED physicians drive most disposition decisions.[5,6] There have been tremendous advances in outpatient management of heart failure patients. While long-term heart failure management has improved through the use of β-blockers, angiotensin-converting enzyme inhibitors, spironolactone, and cardiac resynchronization therapy,[2,3] acute therapy is largely unchanged. Acute therapies include nitrates, diuretics, and positive-pressure ventilation, the same as in 1974.[7] Only one therapy, nesiritide, has been approved for heart failure treatment in the last three decades, but it is not significantly better than standard treatment.[8]

Heart failure has a poor prognosis, with approximately 50% of patients diagnosed dying within 5 years.[9] Hospitalization also marks an inflection point in a patient's HF trajectory, with those hospitalized having higher mortality than a matched nonhospitalized cohort.[10]

PATHOPHYSIOLOGY

Heart failure is a complicated syndrome manifested by cardinal symptoms (shortness of breath, edema, and fatigue) occurring from functional or structural cardiac damage, impairing the ability of the heart to act as an efficient pump. A clinically useful definition of heart failure is as follows: a complex clinical syndrome that results from any structural or functional impairment of ventricular filling or ejection of blood. The cardinal manifestations of heart failure are dyspnea and fatigue, which may limit exercise tolerance, and fluid retention, which may lead to pulmonary and/or splanchnic congestion and/or peripheral edema.[2] There are numerous responsive adaptations in the kidney, peripheral circulation, skeletal muscle, and other organs to maintain short-term circulatory function. Eventually, these responses may become maladaptive, contribute to long-term disease progression, and contribute to acute exacerbations.

Threats to cardiac output from myocardial injury or stress trigger a neurohormonally mediated cascade that includes activation of the renin-angiotensin-aldosterone system and the sympathetic nervous systems. Levels of norepinephrine, vasopressin, endothelin (a potent vasoconstrictor), and tumor necrosis factor-α are increased. Although not measured in routine care, elevated levels of these hormones correlate with higher mortality.

The combined clinical effects of neurohormonal activation are sodium and water retention coupled with increased systemic vascular resistance. These maintain blood pressure and perfusion, but at the cost of increasing myocardial workload, wall tension, and myocardial oxygen demand. Although some patients are initially asymptomatic, a secondary pathologic process called cardiac remodeling begins to occur, eventually triggering more dysfunction.

Natriuretic peptides are the endogenous counterregulatory response to neurohormonal activation in heart failure. Three types are recognized: atrial natriuretic peptide, primarily secreted from the atria; B-type natriuretic peptide, secreted mainly from the cardiac ventricle; and C-type natriuretic peptide, localized in the endothelium. Natriuretic peptides produce vasodilation, natriuresis, decreased levels of endothelin, and inhibition of the renin-angiotensin-aldosterone system and the sympathetic nervous systems. B-type natriuretic peptide is synthesized as N-terminal pre–pro-B-type natriuretic peptide, which is cleaved into two substances, inactive N-terminal pro-B-type natriuretic peptide, with a half-life of approximately 2 hours, and physiologically active B-type natriuretic peptide, with a half-life of about 20 minutes. Assays for both B-type natriuretic peptide and N-terminal pro-B-type natriuretic peptide are available for ED use. Because elevated levels of neurohormones portend a worse prognosis in heart failure, their attenuation provides the basis for most chronic therapies proven to delay heart failure morbidity and mortality. These include treatment with angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, aldosterone antagonists, and β-blockers.

Heart failure may also result from pump dysfunction from acute myocardial infarction. Mechanistically, loss of a critical mass of myocardium results in immediate symptoms. If there is symptomatic hypotension with inadequate perfusion, cardiogenic shock is present (see chapter 50 "Cardiogenic Shock"). Acute pulmonary edema may be precipitous and is the clinical manifestation of a downward spiral of rapidly decreasing cardiac output and rising systemic vascular resistance on top of underlying cardiac dysfunction. Even relatively small elevations of blood pressure can result in decreased cardiac output. Decreasing cardiac output triggers increasing systemic vascular resistance, which further decreases cardiac output. Acute pulmonary edema can present acutely with severe symptoms, and if not promptly reversed, it may be a terminal event.

ACUTE HEART FAILURE CLASSIFICATION

There are many causes for heart failure (**Table 53-1**).

Patients can be categorized into six phenotypes to assist with investigating the causes and precipitants for the acute presentation, as well as directing initial therapy (**Table 53-2**).[11] Those with acute heart failure and hypertension often have a precipitous presentation and may have significant pulmonary edema and hypoxia. Symptoms may be due to fluid redistribution more than fluid overload, and treatment initially focuses on antihypertensive therapy.[12,13] Pulmonary edema may benefit from noninvasive ventilation to decrease the work of breathing and avoid intubation.[14,15] For heart failure accompanied by hypotension or poor perfusion without another cause, think of an ischemic or structural heart trigger creating cardiogenic shock; patients often benefit from inotropic agents and invasive hemodynamic monitoring to guide other therapies.

Patients with acute-on-chronic heart failure tend to present with gradual symptoms and weight gain over days to weeks. High-output heart failure is distinguished by a relatively normal ejection fraction and is often caused by anemia or thyrotoxicosis. Isolated right heart failure is characterized by lower extremity edema and jugular venous distension but little or no pulmonary congestion, and the cause is usually from pulmonary disease, valvular disease such as tricuspid regurgitation, or obstructive sleep apnea. Treatment approaches center on identifying and treating the underlying cause, often without volume removal because low-output states may coexist.

SYSTOLIC AND DIASTOLIC HEART FAILURE

Heart failure is classified as systolic or diastolic by ejection fraction, which is normally 60%. **Systolic dysfunction**, or heart failure with reduced ejection fraction, is defined as an ejection fraction <50%. Mechanistically, the ventricle has difficulty ejecting blood, leading to increased intracardiac volume and *afterload sensitivity*. With circulatory stress (e.g., walking), failure to improve contractility despite increasing venous return results in increased cardiac pressures, pulmonary congestion, and edema.

Diastolic dysfunction, or heart failure with is preserved ejection fraction, is characterized by impaired ventricular relaxation, causing an abnormal relation between diastolic pressure and volume. This results in a

TABLE 53-1 Common Causes of Heart Failure and Pulmonary Edema

†Includes idiopathic (see chapter 55, "Cardiomyopathies and Pericardial Disease").

TABLE 53-2 Classification of Acute Heart Failure

Classification	Characteristics
Hypertensive AHF	Signs and symptoms of AHF with relatively preserved left ventricular function, systolic blood pressure >140 mm Hg, typically with a chest radiograph compatible with pulmonary edema and symptom onset less than 48 h
Pulmonary edema	Respiratory distress, rales on chest auscultation, reduced oxygen saturation from baseline, verified by chest radiograph findings
Cardiogenic shock (see chapter 50)	Evidence of tissue hypoperfusion (systolic blood pressure typically <90 mm Hg)
Acute-on-chronic HF	Signs and symptoms of AHF that are mild to moderate and do not meet criteria for hypertensive HF, pulmonary edema, or cardiogenic shock, systolic blood pressure <140 mm Hg and >90 mm Hg, typically associated with increased peripheral edema and symptom onset over several days
High-output failure	High cardiac output, typically with tachycardia, warm extremities, and pulmonary congestion
Right heart failure	Low-output syndrome with jugular venous distention, hepatomegaly, and may have hypotension

Abbrevitions: AHF = acute heart failure; HF = heart failure.

left ventricle that has difficulty receiving blood. Decreased left ventricular compliance necessitates higher atrial pressures to ensure adequate left ventricular diastolic filling, creating a *preload sensitivity*. The frequency of diastolic dysfunction increases with age and is more common in chronic hypertension, which leads to left ventricular hypertrophy. Coronary artery disease also contributes, as diastolic dysfunction is an early event in the ischemic cascade.

DIAGNOSIS

Most hospitalized patients with heart failure are admitted through the ED. Commonly, patients will present with dyspnea, which has a large differential diagnosis including heart failure, chronic obstructive pulmonary disease, asthma, pneumonia, and acute coronary syndrome. Misdiagnosis increases mortality, prolongs hospital stay, and increases treatment costs.[16-20] **Table 53-3** lists common causes of dyspnea in ED patients. ***There is no single diagnostic test*** for heart failure; it is a clinical diagnosis based on the history and physical examination. Having an understanding of the diagnostic certainty regarding the history, physical examination, and laboratory and radiographic testing is extremely important when caring for ED patients with undifferentiated dyspnea.

HISTORY AND PHYSICAL EXAMINATION

There is ***no singular historical or physical*** **examination finding** that achieves both 70% sensitivity and 70% specificity for the diagnosis of acute heart failure.[19] The initial global clinical judgment has a sensitivity of 61% and specificity of 86%. A history of heart failure is the most useful historical parameter, but only has a sensitivity of 60% and specificity of 90% (positive likelihood ratio [LR+] = 5.8; negative likelihood ratio [LR–] = 0.45). Risk factors for acute heart failure sometimes may be helpful, including hypertension, diabetes, valvular heart disease, old age, male sex, and obesity. The symptom with the highest sensitivity for diag-

TABLE 53-5 Natriuretic Peptide Cut Points for Clinical Decision Making

	Low Cut Point (rule out HF)	High Cut Point (HF likely)		
BNP	100 pg/mL	500 pg/mL		
	Sensitivity 90%	Sensitivity 75%		
	Specificity 73%	Specificity 90%		
N-terminal pro-BNP[29]	300 pg/mL	450 pg/mL if <50 years old	900 pg/mL if 50–75 years old	1800 pg/mL
	Sensitivity 99%	Sensitivity 97%	Sensitivity 90%	Sensitivity 85%
	Specificity 60%	Specificity 93%	Specificity 82%	Specificity 73%

Abbreviations: BNP = B-type natriuretic peptide; HF = heart failure.

nosis is dyspnea on exertion (84%).[19,20] The most specific symptoms are paroxysmal nocturnal dyspnea, orthopnea, and edema (76% to 84%).[19,20] Evaluation for historical precipitating factors (**Table 53-4**) is also useful.

On exam, an S_3 has the highest LR+ for acute heart failure (11), but its absence is not useful as a negative predictor (0.88).[19] However, the inter-rater reliability of an S_3 is not good,[21-23] and the ambient noise in a busy ED may interfere with S_3 detection. Abdominojugular reflux (LR+ = 6.4) and jugular venous distension (LR+ = 5.1) are the only other two physical examination findings that have an LR+ greater than 5. Increased neck size, obesity, and rapid breathing may diminish the ability to accurately measure jugular venous distension at the bedside in the ED.

When clinicians are 80% confident of the diagnosis of acute heart failure, the "clinical gestalt" outperforms diagnostic tests available in the ED for the diagnosis[19]; however, clinical gestalt may be about 50% accurate in an outpatient setting.[24] Data from the Breathing Not Proper Trial found that clinical judgment and a single B-type natriuretic peptide value had a similar accuracy performance.[25]

CHEST RADIOGRAPHY

Chest radiographs showing pulmonary venous congestion, cardiomegaly, and interstitial edema are most specific for a final diagnosis of acute heart failure,[18,19] but the absence of these does not rule it out, because up to 20% of patients subsequently diagnosed with heart failure have chest radiographs without signs of congestion at the time of prior ED evaluation.[26] Particularly in late-stage heart failure, patients may have few radiographic signs, despite symptoms and elevated pulmonary capillary wedge pressure.[18]

ECG

The ECG is not useful for diagnosis, but it may reveal an underlying cause or precipitant. ECG signs of ischemia, acute myocardial infarction, or dysrhythmias may point to the precipitating cause. The presence of atrial fibrillation has the highest LR+ for a diagnosis of heart failure; however, new T-wave changes were also associated with the diagnosis.[19]

BIOMARKERS

The most widely investigated markers have been the natriuretic peptides, B-type natriuretic peptide, and N-terminal pro-B-type natriuretic peptide. Other novel biomarkers have been explored for both diagnosis and prognosis, such as ST2, galectin 3, and neutrophil gelatinase-associated lipocalin. Their role in the ED is not established; B-type natriuretic peptide and N-terminal pro-B-type natriuretic peptide remain the most important biomarkers in clinical use. Natriuretic peptide tests may add value in the setting of undifferentiated dyspnea in the ED, improving diagnostic discrimination in a variety of settings[25,27] and correlating with cardiac filling pressures and ventricular stretch.[28] As a result, B-type natriuretic peptide or N-terminal pro-B-type natriuretic peptide testing is recommended and helpful when the cause of dyspnea is unclear after standard evaluation (**Table 53-5**).

Despite the established value of natriuretic peptide testing, there are many situations where interpretation of results is unclear. Levels can be affected by age, gender, and body mass, and may elevate later in patients who present with flash pulmonary edema.[30] Dyspnea and modest B-type natriuretic peptide elevation are evident in conditions such as pulmonary hypertension, pulmonary embolism, pneumonia, sepsis, and renal failure. As many as 25% of patients will fall into the diagnostic "grey zone" (100 to 500 pg/mL for B-type natriuretic peptide), complicating test interpretation. **B-type natriuretic peptide/N-terminal B-type natriuretic peptide testing is best used when diagnostic uncertainty exists and as an addition to the physician assessment, rather than as a routine measurement.**[27] Similarly, while marked natriuretic peptide elevations are associated with worse short-term outcomes, even low elevations have increased mortality risk, limiting usefulness in bedside prognostication in the ED.[31,32]

POINT-OF-CARE ULTRASOUND (US)

Point-of-care cardiopulmonary US can help to determine the cause of dyspnea, including cardiac tamponade, and can determine left ventricular function and volume status, but is not a substitute for comprehensive echocardiography.[31,32] Bedside cardiopulmonary US can also address three questions (**Figure 53-1**): (1) Are there signs of pulmonary congestion? (2) Are there signs of volume overload by measuring the size of the inferior vena cava and its collapsibility? (3) Is the left ventricular ejection fraction low or normal?

Pulmonary US is used first to determine if pulmonary congestion is present by looking for B lines. **Sonographic B lines** (**Figure 53-2**) are ring-down artifacts that arise from the interface of the visceral and parietal pleura when there is swelling of the lung's interlobular septa due to lymphatic congestion as is seen in pulmonary edema.[33] They are the sonographic equivalent of Kerley B lines seen on chest radiography.[34] More than two B lines in any one sonographic window along the anterior and anterolateral chest are pathologic and highly specific for alveolar and interstitial edema.[35]

Because bilateral B lines can be present in other conditions not caused by pulmonary edema (e.g., pulmonary fibrosis, pulmonary contusion, bilateral pneumonia), rapid assessment for elevated central venous pressure as a marker of right heart congestion is needed.[36] An inferior vena cava size greater than 2 cm or collapsibility index of <50% is indicative of elevated central venous pressure. In the absence of significant pulmonary disease, these measures are highly correlated with pulmonary capillary wedge pressure and are specific for acute heart failure. One should also use US to look for other clinical conditions that cause an elevation in right heart pressure, including pulmonary embolism or clinically significant tricuspid regurgitation, because both conditions could cause inferior vena cava changes consistent with heart failure.

Determination of left ventricular ejection fraction is the final piece of ED-based bedside ultrasonography. Many of the methods for measuring left ventricular ejection fraction are highly technical and are not

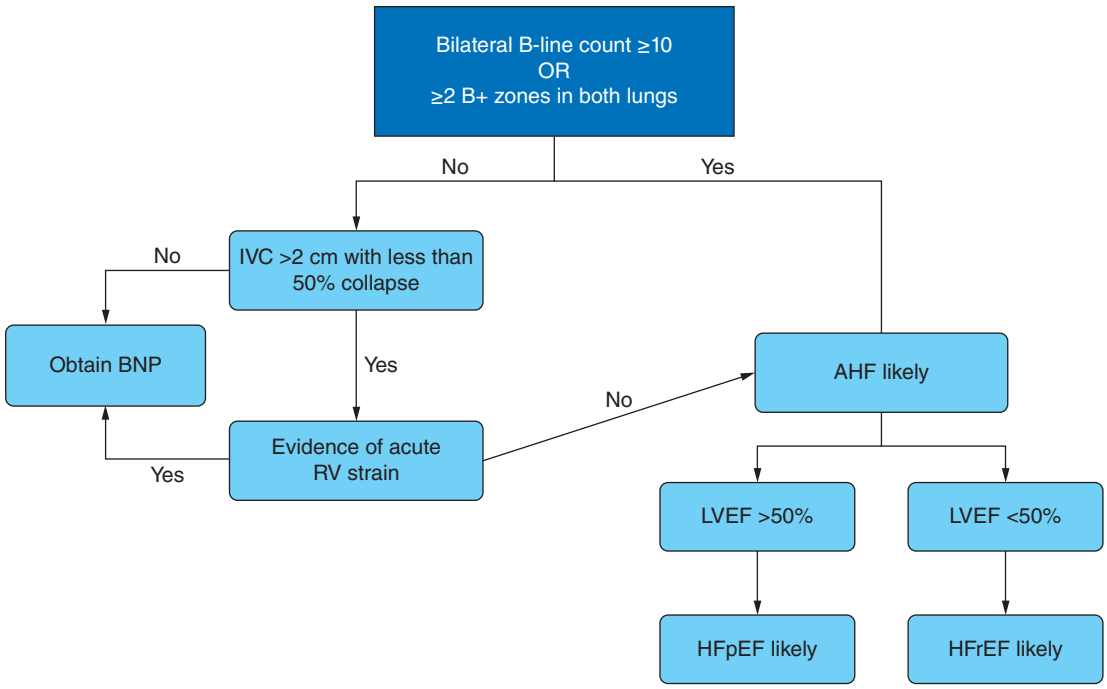

FIGURE 53-1. Bedside US use to identify acute heart failure (AHF) in dyspneic ED patients. BNP = B-type natriuretic peptide; IVC = inferior vena cava; HFpEF = heart failure with preserved ejection fraction; HFrEF = heart failure with reduced ejection fraction; LVEF = left ventricular ejection fraction; RV = right ventricle.

compatible with the need for rapid left ventricular ejection fraction determination during the initial ED evaluation of the dyspneic patient. However, with limited training, emergency physicians trained in focused cardiac US have reasonable agreement with expert cardiology interpretations by using a visual estimation of left ventricular ejection fraction into broad categories of normal, moderately reduced, and severely reduced.[37,38] Other markers that have been suggested, such as E-point septal separation and fractional shortening, are less reliable markers and may be more time-consuming.[39]

TREATMENT

The initial approach is driven by the acuity at presentation, hemodynamics, and volume status. In critically ill patients, airway management is the first priority to ensure adequate oxygenation and ventilation. In those less acutely ill, a focused evaluation ensues next, followed by treatment.

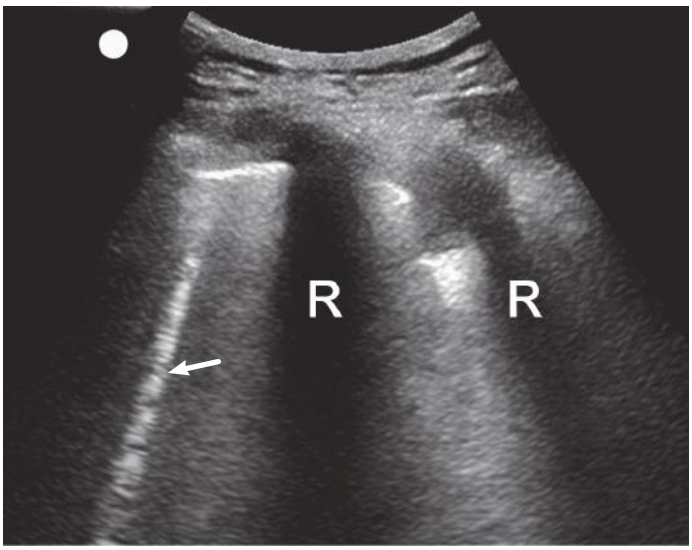

FIGURE 53-2. B lines representing thickened inter-alveolar/interlobular septa. R = rib; arrow = B line. [Reproduced with permission from Ma, Mateer, Reardon, and Joing (eds): *Emergency Ultrasound*, 3rd ed. McGraw-Hill, Inc., 2014. Fig. 7-5, Part C only.]

Supplemental oxygen use is guided by pulse oximetry, seeking saturations above 95%. Because hypoxemia is a greater risk than hypercarbia, do not withhold oxygen even when there is concern about carbon dioxide retention. Capnometry and arterial blood gas measurements can later help titrate therapy in the critically ill or if carbon dioxide retention is likely. In those with extreme findings, endotracheal intubation with mechanical ventilation is indicated.

Noninvasive ventilation may improve the symptoms in patients presenting with heart failure or pulmonary edema.[14,40] Successful noninvasive ventilation requires close monitoring, hemodynamic stability, facial anatomy that allows an adequate facemask seal, and patient cooperation. Using either a facemask or a nasal device, noninvasive ventilation can be delivered with continuous positive airway pressure throughout the respiratory cycle or with bilevel positive airway pressure (see chapter 28, "Noninvasive Airway Management"). Noninvasive ventilation plus standard medical therapy appears to reduce the need for intubation and improves respiratory distress and metabolic disturbance versus standard therapy alone.[14,15] Whether it decreases hospital mortality is unclear.[14]

Acute heart failure with hypotension occurs in approximately 3% of patients.[41] Consider acute coronary syndrome, and management may require reperfusion therapy (see chapters 49, "Acute Coronary Syndromes and 50, "Cardiogenic Shock"). Treatment includes the initiation of inotropic therapy (commonly norepinephrine, dopamine, or dobutamine) and admission to an intensive care unit.

Other standard initial measures include cardiac monitoring, pulse oximetry, IV access, and frequent vital sign assessments. A urinary drainage catheter may aid in monitoring fluid status in the severely ill or incontinent, but this is best reserved for those with extreme illness or an inability to void (to avoid catheter-related complications later.).

HYPERTENSIVE ACUTE HEART FAILURE

The failing heart is sensitive to increases in afterload, with some patients developing pulmonary edema with a systolic blood pressure as low as 150 mm Hg. Prompt recognition and afterload reduction with vasodilators can avoid the need for intubation.[42]

TABLE 53-6 Management of Hypertensive Acute Heart Failure*

Stepwise Approach	Comments
Administer oxygen as needed for saturation ≥95%; give sublingual nitroglycerin.	Sublingual nitroglycerin may be repeated up to one per minute.
If severe dyspnea, consider NIV or intubation.	
If BP >150/100 mm Hg, add IV nitroglycerin or nitroprusside; if BP falls below 100 mm Hg, stop nitrates, and monitor for persistent hypotension or symptoms (see chapter 50, "Cardiogenic Shock"). If BP <150/100 mm Hg after sublingual administration and if improved, consider transdermal nitroglycerin.	See chapter 58, "Pulmonary Hypertension"; see text for discussion of these agents.
Start IV loop diuretic (furosemide or bumetanide) in the setting of volume overload.	Initiate nitrates before diuretics.
Assess for severity of illness/high risk: altered mental status persistent, hypoxia despite NIV, hypotension, troponin elevation, ischemic ECG changes, blood urea nitrogen >43, creatinine >2.75, tachycardia, tachypnea, or inadequate urine output.	See chapter 49, "Acute Coronary Syndromes" for ECG criteria.
Admit to intensive care unit if high severity of illness or risk of decompensation.	
Choose discharge or ED observation unit admission if good response to therapy, no high-risk features, and good social support. Admit the rest. Admit to ICU if any ongoing cardiorespiratory compromise or acute ischemia.	Scoring systems may not reliably identify all patients at risk.

*Inclusion: SBP >140 mm Hg.

Abbreviations: BP = blood pressure; ICU = intensive care unit; NIV = noninvasive ventilation; SBP = systolic blood pressure.

Nitroglycerin A short-acting, rapid-onset, systemic venous and arterial dilator, **nitroglycerin** decreases mean arterial pressure by reducing preload and, at high doses initially, afterload. Nitroglycerin may have coronary vasodilatory effects, decreasing myocardial ischemia and improving cardiac function. The routes chosen—IV, sublingual, or transdermal—are often based on severity of symptoms. Sublingual nitroglycerin is easily administered, rapidly bioavailable, and can be given as often as needed to reach a desired clinical end point provided there is adequate blood pressure. An initial approach is repeated sublingual administration of nitroglycerin, 0.4 milligrams, at a rate of up to one per minute, until relief or replacement with IV nitroglycerin. When using the latter (often for those most symptomatic), a starting dose of 0.5 to 0.7 micrograms/kg/min is common and titrated every few minutes up to 200 micrograms/min based on the blood pressure (avoiding large drops) and symptoms (**Table 53-6**; see also Table 53-8). High doses may be beneficial in the acute setting, and adverse events are uncommon.[43] Apply transdermal nitroglycerine (0.5–2 inches to the chest wall based on blood pressure) **only** after initial therapy has improved conditions, or if symptoms are minor, because of the slow onset of action by this route.

The most important nitroglycerin complication is hypotension, often only lasting transiently and at times even seen with overall clinical improvement. Hypotension usually resolves after cessation of nitroglycerin. If persistent, think of concomitant volume depletion or right ventricular infarct, and deliver a normal saline fluid bolus (250 to 1000 mL). Headache is frequent, but acetaminophen usually is adequate therapy. Methemoglobinemia is a theoretic possibility but not a concern unless high doses are used for extended intervals. Despite broad uptake into regular clinical practice, nitroglycerin has been subject to surprisingly little prospective study.

Nitroprusside If further afterload reduction is required (i.e., continued high systemic vascular resistance usually manifested by persistent elevated blood pressure and continued symptoms despite nitroglycerin doses >200 micrograms/min), use IV **nitroprusside**. This drug is a more potent arterial vasodilator than nitroglycerin; its hemodynamic effects include decreased blood pressure, left ventricular filling pressure reduction, and increased cardiac output. The initial dose of nitroprusside is 0.3 micrograms/kg/min, titrated upward every 5 to 10 minutes based on blood pressure and clinical response (maximum 10 micrograms/kg/min). The major complication is hypotension. It is also associated with thiocyanate toxicity, especially with high doses, prolonged (longer than 3 days) use, and hepatic or renal impairment.

The critical end point is rapidly lowering filling pressure to prevent the need for endotracheal intubation. Give IV vasodilators as soon as vascular access is established if the blood pressure remains elevated.

Loop Diuretics After vasodilator therapy, some patients may require diuretics (see Table 53-8 and next section) based on continued symptoms after blood pressure is controlled. Diuretics (**furosemide** most commonly used) administered alone without vasodilators for hypertensive heart failure may increase mortality[44] and worsen renal dysfunction. Ultimately, successful management of blood pressure and cardiac filling pressure creates marked improvement in respiratory status long before any diuresis.

Contraindications and Alternatives to Vasodilation in Select Settings Because all vasodilators exert hypotensive effects, do not use if there are signs of hypoperfusion or existing hypotension. **Flow-limiting, preload-dependent states such as right ventricular infarction, aortic stenosis, hypertrophic obstructive cardiomyopathy, or volume depletion increase the risk of vasodilator-associated hypotension (Table 53-7).** Combined with acute pulmonary edema, the latter preload-dependent states are very difficult to manage. Therapy is aimed at decreasing the outflow gradient by slowing heart rate and cardiac contractility. Although this can be accomplished with IV β-blockers, treatment is best done in the intensive care unit with invasive hemodynamic guidance. If there is coexistent shock in the setting of hypertrophic obstructive cardiomyopathy, phenylephrine (40 to 100 micrograms/min IV) is a good choice because it creates peripheral vasoconstriction without increasing cardiac contractility.

NORMOTENSIVE HEART FAILURE

Shortness of breath, orthopnea, jugular venous distension, rales, and possibly an S_3 may still be evident even in the presence of normal vital signs, oxygenation, and ventilation. In this situation, treat with diuresis first, with further treatment based on response to therapy (**Table 53-8**).

Diuretics Loop diuretics provide rapid symptomatic relief of congestive symptoms and improve the effects of angiotensin-converting enzyme inhibitors by decreasing intravascular volume. Most ED patients require IV dosing, because bowel wall edema may prevent proper GI absorption. Dosing is guided by symptoms and prior usage (Table 53-8). In general, dose loop diuretics at the lowest possible dose that relieves congestion. Once congestion is resolved, a fixed maintenance dose is continued to prevent recurrence.

Loop diuretics promote water and sodium excretion and are effective except in severe renal dysfunction. Furosemide is inexpensive and effective. Alternatives are bumetanide (1 milligram equivalent to 40 milligrams of furosemide) or torsemide (20 milligrams equivalent to 40 milligrams of furosemide). All trigger rapid diuresis after an IV dose, often within 10 to 15 minutes.

TABLE 53-7 Causes of Hypotension after Vasodilator Use

Excessive vasodilation
Hypertrophic obstructive cardiomyopathy
Intravascular volume depletion
Right ventricular infarction
Cardiogenic shock/myocardial infarction
Aortic stenosis
Anaphylaxis
Unsuspected sepsis

TABLE 53-8 Medications for Acute Heart Failure

Vasodilators for Acute Heart Failure

Vasodilator	Dose	Titration End Point	Complications
Sublingual NTG	0.4 milligram every 1–5 min	Blood pressure	Hypotension
IV NTG	0.2–0.4 microgram/kg/min (starting dose)	Symptoms	Headache, hypotension
Nitroprusside	0.3 microgram/kg/min (starting dose), 10 micrograms/kg/min (maximum)	Blood pressure	Hypotension, cyanide/thiocyanate toxicity, coronary steal
		Symptoms	

Diuretics for Heart Failure

Diuretic	Dose (IV)	Effect	Complications
Furosemide	No prior use: 20–40 milligrams IVP	Diuresis starts within 15–20 min	↓ K^+, ↓ Mg^{2+}, hyperuricemia, hypovolemia
	If prior use: total daily IV dose 1 to 2.5 times the patient's previous total daily oral dose, divided in half and given IV bolus every 12 h	Duration of action is 4–6 h	Ototoxicity, prerenal azotemia
	If no effect by 20–30 min, increase subsequent dose		
Bumetanide	1–3 milligrams IV	Diuresis starts within 10 min	Same as above
		Peak action at 60 min	
Torsemide	10–20 milligrams IV	Diuresis starts within 10 min	Same as above
		Peak action in 1–2 h	

Abbreviations: IVP = IV push; NTG = nitroglycerin; ↓ = decreased.

The DOSE trial suggests a total daily IV dose 1 to 2.5 times the patient's previous total daily oral dose, divided in half and administered by IV bolus every 12 hours.[45] For example, if the patient is on furosemide 80 milligrams PO twice a day, then an initial ED dose is 80 to 200 milligrams IV bolus. Higher doses are associated with more rapid symptom improvement but a slight decrease in renal function. For patients who are loop diuretic naïve, a reasonable starting dose is furosemide 40 milligrams IV. Bolus and continuous infusion therapy are equivalent, but the latter is more challenging in the ED and hence often eschewed. Ethacrynic acid (0.5 to 1 milligram/kg; maximum 100 milligrams) is another option. Sulfa allergy is generally not a concern with nonantibiotic drugs such as diuretics that contain a sulfa moiety (see chapter 206 "Antimicrobials" for more discussion).

Diuretics may worsen renal function and create hypokalemia. An increasing QT interval should trigger a search for hypocalcemia, hypokalemia, or hypomagnesemia. Ototoxicity is rare but may occur if diuretics are used in conjunction with aminoglycoside antibiotics. Potassium-sparing diuretics, such as spironolactone (25 to 50 milligrams PO), are generally reserved for advanced chronic heart failure; these are used more for their mortality benefit than diuretic effect.

Urinary diuretic response requires monitoring. With greater symptoms or less response to initial IV diuretics, double the dose and repeat in 30 to 60 minutes or as needed based on urine output. Ongoing congestion or dyspnea after a loop diuretic may signal the need for another therapy, such as a vasodilator.

Other Treatments **Ultrafiltration** allows the extracorporeal removal of plasma water from whole blood across a semipermeable membrane with a transmembrane pressure gradient.[46] Ultrafiltration has advantages over diuresis including more precise regulation of fluid removal, avoidance of diuretic-associated electrolyte abnormalities, a higher level of sodium removal for a given amount of volume, and attenuation of significant fluctuations in intravascular volume.[47] While initial studies provided promising safety and efficacy data,[48,49] subsequent study in patients with cardiorenal syndrome and persistent congestion did not demonstrate an advantage of ultrafiltration over bolus diuretic therapy.[50] If all diuretic and medical strategies are unsuccessful, consider ultrafiltration for patients with obvious volume overload to alleviate congestive symptoms and excess weight.[2] Ultrafiltration is unlikely to be deployed in the ED given the need to optimize other approaches first.

Morphine (2 to 5 milligrams IV) relieves congestion and anxiety, but it is associated with adverse events, including the need for mechanical ventilation, prolonged hospitalization, ICU admission, and mortality.[51] If desired for its venodilation properties or pain control, use morphine in small, titrated doses (2 to 4 milligrams IV) and with close monitoring. The trial noting harm did not set out to study morphine use, so selection bias may explain some or much of the findings. Only those failing standard therapy or with severe symptoms received the drug, multiplying the negative outcomes. Nonetheless, morphine has a role secondary to nitrates and loop diuretics and is not needed routinely.

Nesiritide is a vasodilator whose formulation uses recombinant human B-type natriuretic peptide. Several small studies suggested a benefit of adding nesiritide to standard therapy on patient-reported relief of dyspnea, but additional studies, including the pivotal mortality trial ASCEND-HF,[8] found no significant difference in the frequency of rehospitalization or mortality. ASCEND-HF reported an increased risk of both symptomatic and asymptomatic hypotension among patients randomized to nesiritide.[8] Nesiritide does not result in substantial clinical improvement when added to standard care and is a second-line agent when nitroglycerin is ineffective or contraindicated.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are given for hypertension and chronic heart failure, but there is little data to recommend use in the ED for acute heart failure.

Oral angiotensin-converting enzyme inhibitors decrease mortality and hospitalizations in patients with reduced ejection fraction[2]; these are often used after observation care if no contraindications exist after contact with a primary care physician or cardiologist. Oral angiotensin receptor blockers are alternatives to or can be added to angiotensin-converting enzyme inhibitors in select heart failure patients with reduced ejection fraction.[2] Their use may also be considered after consultation and the conclusion of treatment. Treatment of angiotensin-converting enzyme inhibitor–induced angioedema is outlined in the chapter 14, "Anaphylaxis, Allergies, and Angioedema."

β-Blockers are not usually initiated in the acute setting, except perhaps to control rate-related heart failure. They are generally reserved for stable patients. The rationale for β-blockers rests on the fact that norepinephrine levels are elevated in heart failure, contribute to myocardial hypertrophy, increase afterload and coronary vasoconstriction, and are associated with mortality. β-Blockers reduce sympathetic nervous system activity and are used for mortality reduction and symptom relief.

Drugs to Avoid in Acute Heart Failure Oral **calcium channel blockers** have myocardial depressant activity and are not routine treatment for acute heart failure, with trials demonstrating either no benefit or

worse outcomes. If necessary, amlodipine may be used for compelling clinical reasons (e.g., as an antianginal agent despite maximal therapy with nitrates and β-blockers).

Avoid selective or nonselective **nonsteroidal anti-inflammatory drugs** in patients with acute heart failure. They can cause sodium and water retention and blunt the effects of diuretics,[2] and may increase morbidity and mortality.

DISPOSITION DECISIONS

While risk-stratification tools are commonplace in other ED disease processes such as chest pain and pneumonia, we lack a readily available and validated ED-based risk-stratification tool that has been compared to physician judgment.

Thus, disposition decisions in ED patients with acute heart failure are often based on physician judgment, a physiologic risk assessment, and an assessment of barriers to successful outpatient care such as caregiver support, access to medications, and timely follow-up (**Figure 53-3**). High-risk physiologic markers in ED patients with acute heart failure associated with morbidity and mortality (**Table 53-9**)[52] include renal dysfunction, low blood pressure, low serum sodium, and elevated natriuretic peptides or cardiac troponin. Unfortunately, high-risk markers are not present in up to 50% of ED patients, limiting the impact in disposition decisions.[53] Prospective testing of four acute heart failure prediction rules suggests they would not be useful in the ED.[54]

The unpredictability of postdischarge behavior and care limits, coupled with the elevated overall risk of harm or repeated care events, limits the ability to discharge patients directly from the ED. Admit patients with high-risk features to the hospital (**Table 53-10**).[55] Those who require invasive monitoring or procedures require intensive care unit admission. Others may be appropriate for non–intensive care unit level care. Observation unit management is an option in others with lower risk features. Many patients do not have high-risk features at initial ED evaluation and experience improvement in dyspnea during their ED stay as a result of standard therapy.[56] Many have complete symptom resolution within 12 to 24 hours of initial therapy, a typical time period of observation. The monitoring of blood pressure, heart rate, urine output, and body weight is easily accomplished in the observation setting, and any diagnostic testing (labs, echocardiography) needed can occur. Finally, an extended observation interval allows patients to receive heart failure education, confirm outpatient medications, and arrange follow-up prior to discharge. Ideally, outpatient follow-up within 5 days can decrease readmissions.[57] Prior studies suggest 75% of patients will respond to therapy, will have no identifiable high-risk features, and will be discharged home. Their rates of readmission

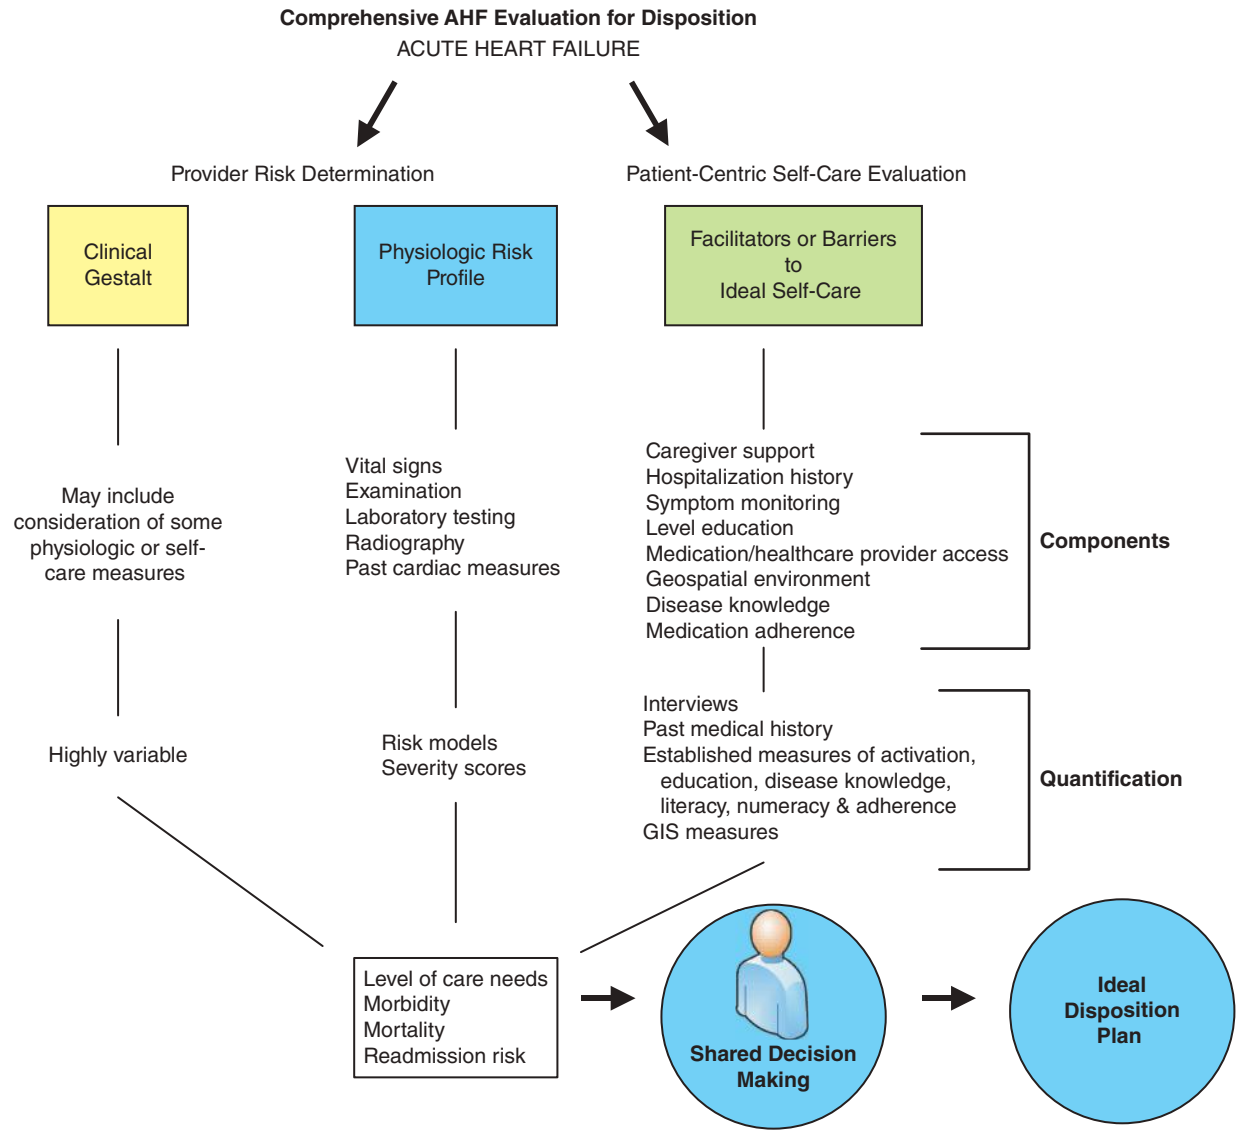

FIGURE 53-3. Factors impacting disposition decisions in ED patients with acute heart failure (AHF).

TABLE 53-9 Selected ED-Based Risk-Stratification Studies from the Last 8 Years that Examine Events within 30 Days or Less of Index ED Presentation

Author/Year	N	Predicted Outcome	Variables in Final Model	Low-Risk Markers
Lassus/2013	441–4450 (pooled analysis, total n varied by biomarker evaluated)	30-d and 1-y mortality	ST2, MR-proADM, CRP, NT-proBNP, BNP, MR-proANP in addition to clinical model (age, gender, blood pressure on admission, estimated glomerular filtration rate <60 mL/min/1.73 m^2, sodium and hemoglobin levels, and heart rate)	No
Stiell/2013	559	30-d death and 14-d serious nonfatal events	History of TIA/CVA, vital signs, ECG and lab findings	No
Lee/2012	15,164	7-d mortality	Creatinine, BP, O_2 saturation, Tn, history of cancer, home metolazone, EMS transport	Yes
Hsieh/2008	8384	Inpatient mortality or serious medical complications, 30-d mortality	pH, pulse, renal function, WBC, glucose, sodium	Yes
Lee/2003	2624/1407	30-d mortality	Age, RR, BP, BUN, sodium, cerebrovascular disease, dementia, COPD, cirrhosis, cancer, hemoglobin	Yes
Auble/2005	33,533	Inpatient mortality or serious medical complications, 30-d mortality and AHF readmission	pH, pulse, renal function, WBC, glucose, sodium	Yes
Fonarow/2005	65,275	In-hospital mortality	BUN, systolic BP, creatinine	No

Abbreviations: AHF = acute heart failure; ANP = atrial natriuretic peptide; BNP = B-type natriuretic peptide; BP = blood pressure; COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; CVA = cerebrovascular accident; RR = respiratory rate; TIA = transient ischemic attack; Tn = troponin.

TABLE 53-10 Heart Failure Observation Unit/Short Stay Exclusion Criteria

Recommended Exclusions
Positive troponin
Blood urea nitrogen >40 milligrams/dL
Creatinine >3.0 milligrams/dL
Sodium <135 mEq/L
New ischemic changes on ECG
New onset of acute heart failure*
IV vasoactive infusions being actively titrated
Significant comorbidities requiring acute interventions
Respiratory rate ≥32 breaths/min and/or requiring noninvasive ventilation at the time of OU consideration
Signs of poor perfusion at the time of OU consideration
Suggested Exclusions
Poor social support
Poor follow-up

*Although part of the published guidelines, many institutions admit patients to OUs with new-onset heart failure.

Abbreviation: OU = observation unit.

are similar to or better than those who are managed in an inpatient setting.[58,59] Patients with an inadequate response to initial therapy or with high-risk features identified during their observation stay are admitted to the hospital for further management. An observation unit strategy can help reduce costs while delivering quality care for select lower risk ED patients with acute heart failure.[58]

CHAPTER 54

Valvular Emergencies

William D. Alley
Simon A. Mahler

INTRODUCTION

In contrast to the dramatic symptoms associated with acute valvular dysfunction, most valvular heart disease encountered in the ED is chronic and incidentally noted on exam. Adaptive responses preserve cardiac function and can delay the diagnosis of chronic valvular disease for decades but contribute to eventual cardiac dysfunction. Compared with the general population, patients with clinically evident valvular heart disease have a 2.5-fold higher death rate and a 3-fold increased rate of stroke.[1]

THE NEWLY DISCOVERED MURMUR

After discovering a new murmur, the first step in the ED is to determine the clinical significance. Benign or physiologic murmurs do not cause symptoms or findings compatible with cardiovascular disease; they are generally soft systolic ejection murmurs that begin after S_1, end before S_2, and are not associated with abnormal heart sounds. Systolic murmurs may be associated with anemia, sepsis, volume overload, or other conditions causing an increased cardiac output. Evaluation and treatment are focused on the underlying trigger rather than the murmur itself. Patients without chest pain, dyspnea, fever, or other signs attributable to valvular disease do not need emergent echocardiography but should be referred for eventual imaging.

Any diastolic murmur or new systolic murmur with symptoms at rest is pathologic and warrants emergent echocardiographic imaging. Patients with syncope from suspected aortic stenosis require admission for monitoring and echocardiography (**Figure 54-1**). **Table 54-1** presents a grading system for murmurs. Another consideration in the newly diagnosed murmur is the possibility of endocarditis, especially in suspected valvular insufficiency (see chapter 155, "Endocarditis").

MITRAL STENOSIS

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Mitral stenosis prevents normal diastolic filling of the left ventricle. Despite declining frequency, rheumatic heart disease remains the most

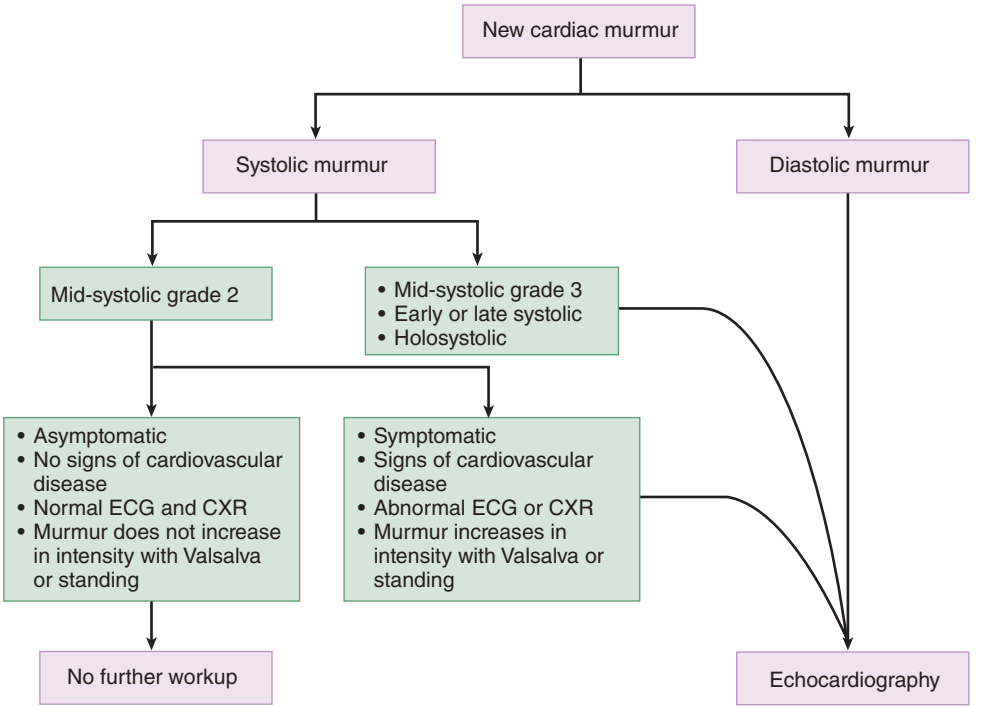

FIGURE 54-1. Algorithm for evaluation of newly discovered systolic murmur. CXR = chest x-ray.

common cause worldwide. Rheumatic carditis causes fusion of valvular commissures, matting of chordae tendineae, and eventual calcification and limited mobility of the valve. Valvular obstruction is slowly progressive, often with 20 to 40 years before onset of symptoms. Mitral valve obstruction causes left atrial pressure to rise, resulting in left atrial enlargement, pulmonary congestion, pulmonary hypertension, and frequently atrial fibrillation. In severe disease, pulmonary hypertension may lead to pulmonic and tricuspid valve incompetence, pulmonary edema, right-sided heart failure, and bronchial vein rupture.

Mitral annular calcification is a slowly progressive nonrheumatic cause of mitral stenosis. It is more common among women, elderly, and those with hypertension or with chronic renal failure.[2] Due to its slow progression, mitral annular calcification rarely causes severe symptoms.

CLINICAL FEATURES

Exertional dyspnea is the most frequent presenting complaint in patients with mitral stenosis. It is often precipitated by anemia or infection, which increases cardiac demand. Orthopnea and premature atrial contractions are also common. Symptoms associated with left- or right-sided heart failure may occur with more severe obstruction. Systemic emboli are a risk, especially when accompanied by atrial fibrillation. Due to earlier recognition and treatment, hemoptysis is a rare presenting symptom, although it can be massive.

Signs of mitral stenosis include a mid-diastolic rumbling murmur with crescendo toward S_2. With the onset of atrial fibrillation, the presystolic accentuation of the murmur disappears. Typically, the S_1 is loud and is followed by a loud opening snap that is high-pitched and best heard to the right of the apex (**Table 54-2**). The apical impulse is small and tapping due to an underfilled left ventricle. Systemic blood pressure is typically normal or low. If pulmonary hypertension is present, signs may include a thin body habitus, peripheral cyanosis, and cool extremities due to compromised cardiac output. Auscultatory findings are less obvious.

TABLE 54-1 A Grading System for Murmurs

Grade	Description
1	Faint, may not be heard in all positions
2	Quiet, but heard immediately with stethoscope placement onto the chest wall
3	Moderately loud
4	Loud
5	Heard with stethoscope partly off the chest wall
6	Heard when stethoscope is entirely off the chest wall

DIAGNOSIS AND TREATMENT

The ECG may demonstrate notched or biphasic P waves and right axis deviation in patients with mitral stenosis (**Figure 54-2**). On chest radiograph, straightening of the left heart border, indicating left atrial enlargement, is a typical and early radiographic finding. Eventually, findings of pulmonary congestion are noted.

The diagnosis is confirmed with echocardiography (**Figure 54-3**). In candidates for surgical repair, transesophageal echocardiography best

TABLE 54-2 Comparison of Heart Murmurs, Sounds, and Signs

Valve Disorder	Murmur	Heart Sounds and Signs
Mitral stenosis	Mid-diastolic rumble, crescendos into S_2	Loud snapping S_1, small apical impulse, tapping due to underfilled ventricle
Mitral regurgitation	Acute: harsh apical systolic murmur starts with S_1 and may end before S_2 Chronic: high-pitched apical holosystolic murmur radiating into S_2	S_3 and S_4 may be heard
Mitral valve prolapse	Click may be followed by a late systolic murmur that crescendos into S_2	Mid-systolic click; S_2 may be diminished by the late systolic murmur
Aortic stenosis	Harsh systolic ejection murmur	Paradoxical splitting of S_2, S_3, and S_4 may be present; pulse of small amplitude with a slow rise and sustained peak
Aortic regurgitation	High-pitched blowing diastolic murmur immediately after S_2	S_3 may be present; wide pulse pressure

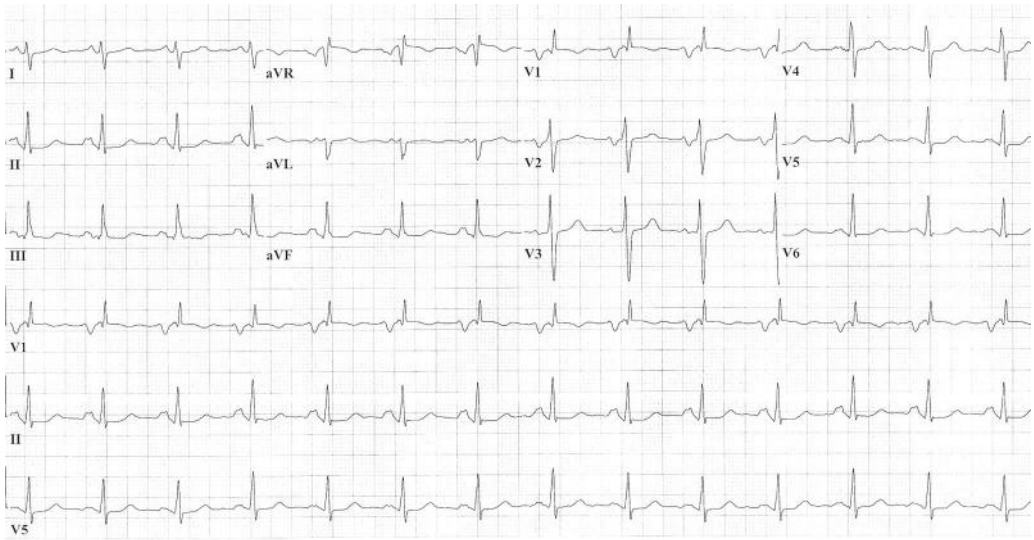

FIGURE 54-2. The ECG in mitral stenosis, demonstrating left atrial enlargement and right axis deviation. Note abnormal P waves in lead V_2.

assesses the degree of mitral regurgitation and the presence of a left atrial thrombus.[3]

Medical management focuses primarily on symptom control and anticoagulation. Patients in atrial fibrillation with rapid ventricular response or with dyspnea on exertion may benefit from heart rate control (see chapter 18, "Cardiac Rhythm Disturbances"). Experts recommend anticoagulation if the left atrial diameter is greater than 55 mm or the patient has atrial fibrillation, a left atrial thrombus, or history of systemic emboli. In patients who present with hemoptysis from mitral stenosis–induced pulmonary hypertension, bleeding may be severe enough to require blood transfusion, emergent bronchoscopy, and consultation with a thoracic surgeon.

The most important ED action for patients with suspected but asymptomatic mitral stenosis is recognition and referral. The primary treatment for symptomatic disease is mechanical intervention, by balloon valvotomy, valve repair, or valve replacement, all optimally performed before the onset of severe pulmonary hypertension.

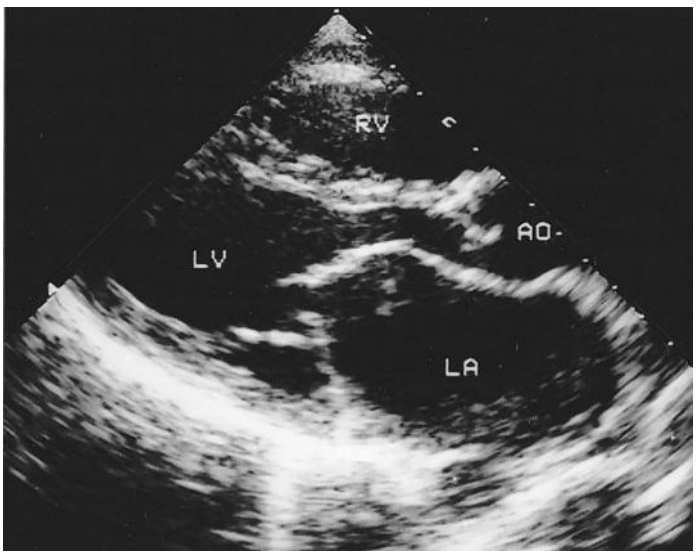

FIGURE 54-3. Parasternal long-axis view of mitral stenosis. The left atrium is enlarged, mitral opening is limited, and doming of the anterior mitral leaflet is present. MITRAL REGURGITATION

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Mitral regurgitation occurs when a dysfunctional valve allows retrograde blood flow from the left ventricle into the left atrium during systole. Most patients with mitral regurgitation follow a chronic and slowly progressive course. The most common cause is fibroelastic deficiency syndrome, seen primarily in the elderly.[4] **Mitral valve prolapse** is another cause of mitral regurgitation and is typically found in younger patients. Secondary mitral regurgitation occurs when a dilated left ventricle causes papillary muscle displacement and valve dysfunction.

In chronic mitral regurgitation, the left atrium dilates to accommodate increasing regurgitant flow to keep left atrial pressure near normal. Stroke volume is augmented, maintaining effective forward flow despite a large regurgitant volume. In contrast, acute mitral regurgitation results in new-onset pulmonary vascular congestion and peripheral edema. Cardiogenic shock may also exist from impaired forward blood flow. **Acute mitral regurgitation** is typically caused by papillary muscle or chordae tendineae rupture from myocardial infarction or valve leaflet perforation from infective endocarditis. Blunt thoracic trauma and spontaneous chordae tendineae rupture are other rare causes.

CLINICAL FEATURES

Symptoms of acute mitral regurgitation are severe dyspnea, tachycardia, and pulmonary edema. Cardiogenic shock or cardiac arrest can develop rapidly. Typical signs include an S_4 gallop and a harsh apical systolic murmur loudest in early or mid-systole, diminishing before S_2 (Table 54-2). Even with severe symptoms, the murmur may not be audible over breath sounds in the noisy ED environment. A hyperactive apical impulse may be apparent. In the setting of ischemia, chest pain may be masked by overwhelming dyspnea.

Chronic mitral regurgitation can be tolerated for years without symptoms. Eventually exertional dyspnea develops, sometimes associated with palpitations or atrial fibrillation. Signs include a late systolic left parasternal lift and lateral displacement of the apical impulse. A high-pitched holosystolic murmur is best heard in the fifth intercostal space and mid-left thorax and radiates to the axilla. The first heart sound is soft and often obscured by the murmur. An S_3 is usually heard and is followed by a short diastolic rumble, indicating increased flow into the left ventricle. Given its slowly progressive course, signs of systemic thromboembolism may be the first suggestion of mitral regurgitation associated with atrial fibrillation.

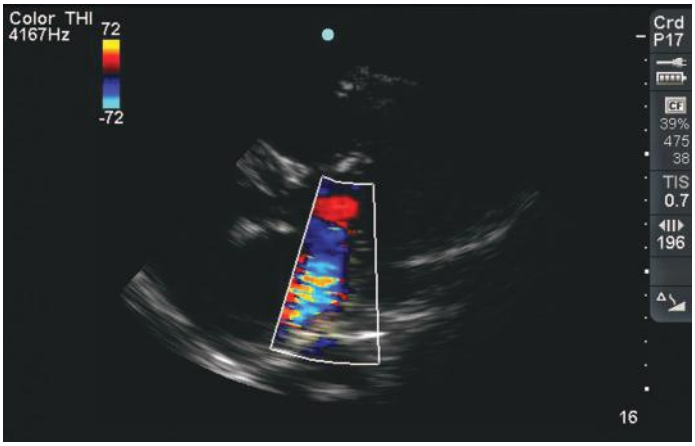

FIGURE 54-4. An echocardiogram demonstrating severe mitral regurgitation. Color flow Doppler shows regurgitant flow back into the left atrium.

DIAGNOSIS AND TREATMENT

Think of acute mitral regurgitation in any patient with new-onset and marked pulmonary edema, especially in patients with near-normal heart size on chest radiograph or in those who do not respond to conventional therapy. Obtain an ECG to look for signs of ischemia, frequently in the inferior or anterior walls. In chronic mitral regurgitation, the ECG may demonstrate left atrial enlargement and left ventricular hypertrophy, and the chest x-ray shows left atrial and ventricular enlargement that is proportional to the severity of the regurgitant volume. Transthoracic echocardiography (**Figure 54-4**) diagnoses mitral regurgitation, but may underestimate the severity of regurgitation. If transthoracic echocardiography is nondiagnostic, cardiac MRI or transesophageal echocardiography may be undertaken.[3] Exercise stress echocardiography may also be useful.

For acute mitral regurgitation due to papillary muscle rupture, emergency surgery is the treatment of choice. In the ED, start therapy with oxygen and positive-pressure ventilation for respiratory failure (see chapter 53, "Acute Heart Failure"). Nitrates provide afterload reduction, which results in increased forward flow into the aorta and partially restores mitral valve competence as left ventricular size diminishes. Inotropic therapy with dobutamine may be necessary. Aortic balloon counterpulsation increases forward flow and mean arterial pressure while diminishing regurgitant volume and left ventricular filling pressure.

Treatment of severe mitral regurgitation from acute myocardial infarction includes emergent revascularization.[5] Endocarditis as a cause of acute mitral valve insufficiency requires specific evaluation and treatment (see chapter 155, "Endocarditis").

Medical therapy may improve regurgitant flow and allow a delay to surgery. The key is emergency cardiology and surgical consultation while medically optimizing care.

In patients with chronic mitral regurgitation, treat acute symptoms. Control atrial fibrillation with rapid ventricular response with β-blockers or calcium channel blockers, and start anticoagulation to avoid embolization. Long-term management is best decided by the primary care provider or a cardiologist.

MITRAL VALVE PROLAPSE

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Mitral valve prolapse is a systolic billowing of one or both leaflets into the left atrium occurring with or without mitral regurgitation. It is characterized by myxomatous degeneration of the valve caused by heritable defects in connective tissue proteins. It is the most common valvular heart disease in industrialized countries, affecting approximately 2.4% of the population.[6] Morbidity and mortality are greatly influenced by the presence of concomitant mitral regurgitation.[7]

CLINICAL FEATURES

Most patients with mitral valve prolapse are asymptomatic. Associated symptoms can include nonclassic chest pain, palpitations, fatigue, anxiety, and dyspnea unrelated to exertion. Signs such as scoliosis, pectus excavatum, and low body weight can also be associated. If exercise induces symptoms, morbidity increases.[8]

The classic auscultatory finding is a mid-systolic click (Table 54-2). Maneuvers that decrease preload, such as Valsalva or standing, will cause the click to occur earlier in diastole. Increasing preload by squatting or afterload by hand grips causes the systolic click to move later in systole. A late systolic murmur that crescendos into S_2 is present in some patients.

DIAGNOSIS AND TREATMENT

The diagnosis is unlikely to be made in the ED. The emergency evaluation focuses on late complications such as atrial fibrillation or heart failure. The ECG is usually normal, as is the chest radiograph unless scoliosis or pectus excavatum is seen. If mitral valve prolapse is suspected, refer the patient to a cardiologist for outpatient echocardiography to confirm the diagnosis and to identify any associated mitral regurgitation.[9]

ED treatment is rarely required. Patients with palpitations attributed to mitral valve prolapse may respond to oral β-blockers, but that treatment is typically left to the cardiologist or primary care physician. Antithrombotic therapy is not routinely recommended unless complicated by transient ischemic attacks, stroke, or atrial fibrillation.[10,11] Patients with mitral valve prolapse *and* concomitant mitral regurgitation require endocarditis prophylaxis (see chapter 155, "Endocarditis").[9]

AORTIC STENOSIS

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Aortic stenosis is a structural abnormality of the aortic valve that prevents left ventricular outflow. In the United States, the most common cause of adult aortic stenosis is degenerative calcification (calcific aortic stenosis), associated with increasing age, hypertension, smoking, elevated cholesterol, and diabetes.[12] Rheumatic heart disease is a major cause of aortic valve disease worldwide. Bicuspid aortic valves and congenital heart disease are causes as well, especially in younger patients. The prevalence of aortic stenosis is about 3% of patients >74 years old.[13]

The typical course involves a long asymptomatic period, during which the left ventricle hypertrophies to preserve ejection fraction. Ventricular hypertrophy eventually impairs diastolic filling and increases myocardial oxygen demand. Slowly, aortic valve obstruction worsens, cardiac output diminishes, and systemic blood flow and coronary blood flow are impaired.

CLINICAL FEATURES

The classic triad of aortic stenosis is dyspnea, chest pain, and syncope. However, many patients with severe stenosis (aortic valve area <1.0 cm^2) are asymptomatic. Often, a long asymptomatic period is followed by stepwise onset of symptoms starting with dyspnea followed by chest pain, then syncope, and finally signs of heart failure. Once symptoms start, mortality increases.[14] Decreased exercise tolerance and exertional dyspnea or dizziness may be unnoticed or unreported prior to more ominous symptoms.

Classic physical examination findings are a late peaking systolic murmur at the right second intercostal space, radiating to the carotids, a single or paradoxically split S_2, an S_4 gallop, and a diminished carotid pulse with a delayed upstroke (pulsus parvus et tardus; Table 54-2). Brachioradial delay may also be a useful early finding. Simultaneously palpate the patient's right brachial artery and right radial artery. Any palpable delay between the brachial and radial pulses is abnormal. A narrowed pulse pressure, with or without hypotension, is another important clinical finding.

Aortic stenosis with atrial fibrillation can have dire consequences. Patients with AS typically have diastolic dysfunction and are dependent on preload from atrial contraction to maintain cardiac output. Without effective atrial contraction, cardiac output drops dramatically, especially if the patient is given nitroglycerin to treat chest pain or dyspnea.

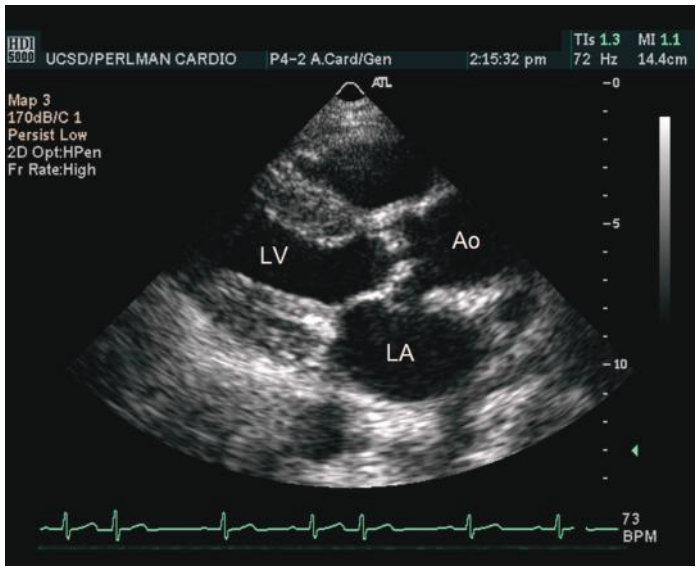

FIGURE 54-5. Parasternal long-axis plane demonstrating a thickened, stenotic aortic valve. Ao = aorta; LA = left atrium; LV = left ventricle. [Reproduced with permission from Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P (eds): *Hurst's the Heart*, 12th ed. © 2008, McGraw-Hill, New York.]

DIAGNOSIS AND TREATMENT

ECG and chest radiograph findings lack sensitivity and specificity. The ECG usually demonstrates left ventricular hypertrophy, and a left or right bundle-branch block may be present in up to 10% of patients. The chest radiograph is normal early in the disease, but eventually signs of left ventricular hypertrophy and congestive heart failure develop. Transthoracic echocardiography confirms the diagnosis and determines severity (**Figure 54-5**). Low-dose dobutamine stress echocardiography may be useful to identify patients with severe aortic stenosis prior to the development of classic symptoms.[3]

Treat pulmonary edema with oxygen and positive-pressure ventilation as necessary. Negative inotropic drugs, such as β-blockers or calcium channel blockers, are often poorly tolerated. **Use nitrates, vasodilators, and diuretics with caution** because reducing preload or afterload may cause significant hypotension. New-onset atrial fibrillation may require cardioversion to maintain cardiac output.

Most patients with newly symptomatic aortic stenosis are admitted. Without surgery, 40% to 50% of patients with classic symptoms die within 1 year.[15,16] Patients discharged from the ED should avoid vigorous physical activity and be seen promptly by a cardiologist. Endocarditis in isolated aortic stenosis is uncommon, and antibiotic prophylaxis is not recommended routinely (see chapter 155, "Endocarditis").[9]

AORTIC REGURGITATION

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Aortic regurgitation occurs when valve leaflets fail to close fully, causing blood to flow from the aorta into the left ventricle during diastole. The course is usually slowly progressive, with many patients remaining asymptomatic for decades. Over time, aortic regurgitation increases left ventricular wall stress, leading to hypertrophy. Increased stroke volume followed by a rapid pressure drop during diastole causes wide pulse pressures. Tachycardia shortens diastole, which decreases regurgitant volume and mutes symptoms early in the disease. In contrast, increased afterload during stress or isometric exercise exacerbates regurgitant flow and may precipitate symptoms. Over time, the combination of increasing left ventricular dilatation and hypertrophy compromises systolic function, and reduced cardiac output results in symptoms of heart failure.

Among patients in the Framingham Heart Study receiving echocardiography, aortic insufficiency was documented in 13% of men and 8.5% of women, mostly of trace or minor severity.[17] Approximately half of cases are due to valvular leaflet problems from bicuspid aortic valves, infective endocarditis, or rheumatic disease. Nonvalvular causes include aortic dissection, Marfan's syndrome, or aortitis.[18] Aortic regurgitation is also frequently associated with aortic stenosis, and at times, associated regurgitation may be severe.

CLINICAL FEATURES

Acute aortic regurgitation generally presents rapidly, with dyspnea and pulmonary edema being the most common presenting symptoms. To maintain cardiac output, tachycardia develops, but is often inadequate, resulting in cardiogenic shock or cardiac arrest. Sudden-onset ripping or tearing interscapular pain suggests **aortic dissection**. Fever or a history of IV drug abuse suggests endocarditis.

On physical exam, aortic regurgitation is associated with a high-pitched blowing diastolic murmur heard immediately after S_2, in the second or third intercostal space at the left sternal border (Table 54-2). In acute disease, the murmur may be inaudible due to tachycardia, tachypnea, and rales. A systolic ejection murmur due to increased stroke volume and an S_3 due to ventricular dilatation may also be heard. In the left lateral decubitus position, a mid-diastolic rumble (Austin Flint murmur) may be appreciated using the bell of the stethoscope at the cardiac apex. Patients often have a widened pulse pressure. The classic "water hammer pulse" (Corrigan pulse) is a peripheral pulse with a quick rise in upstroke due to increased stroke volume followed by collapse from a rapid fall in diastolic pressure. Other classic findings include accentuated precordial apical thrust, pulsus bisferiens, Duroziez sign (a "to-and-fro" femoral murmur), de Musset sign (pulsatile head bobbing), and Quincke sign (capillary pulsations visible at the proximal nail bed while pressure is applied at the tip).

Patients with chronic aortic regurgitation typically present with exertional dyspnea or fatigue. Chest pain may occur from myocardial ischemia due to low diastolic pressures that decrease coronary blood flow. Palpitations may be caused by large stroke volume or premature ventricular contractions. Symptoms of left ventricular failure may occur late in the course of the disease, but greater than one quarter of patients with chronic aortic regurgitation who die or develop left heart dysfunction do so before symptoms occur.[9]

DIAGNOSIS AND TREATMENT

Echocardiography confirms the diagnosis and determines the cause and severity of regurgitation.[3] Unstable patients require bedside transthoracic echocardiography (**Figure 54-6**). Chest x-ray may show acute

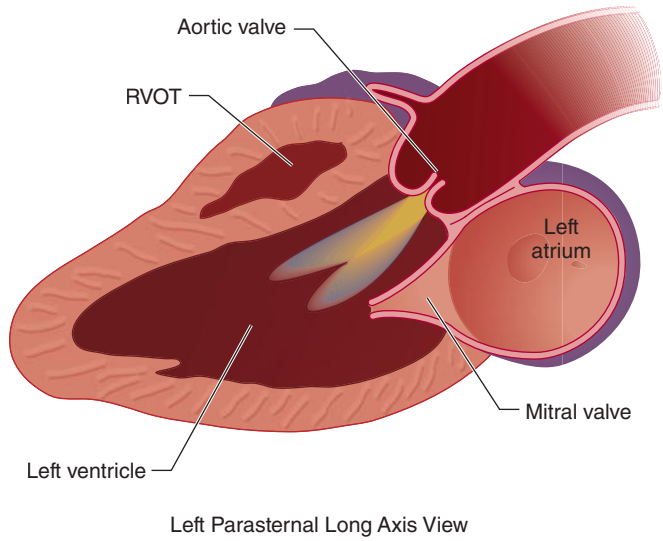

FIGURE 54-6. An illustration of an echocardiogram demonstrating aortic regurgitation. Note regurgitant flow back into the left ventricle. RVOT = right ventricular outflow tract. [Courtesy of P. Lynch, MD, Yale Cardiology Department and Cancer Imaging Program, with permission.]

pulmonary edema without cardiac enlargement. In aortic regurgitation due to aortic dissection, the chest x-ray may have additional findings associated with dissection such as a widened mediastinum (see chapter 59, "Aortic Dissection and Related Aortic Syndromes"). If aortic dissection is suspected, CT with contrast is needed to assess the aorta, and transesophageal echocardiography is needed to assess valvular function. ECG findings in patients include sinus tachycardia and are generally nonspecific. Ischemic changes or ST elevation may be seen from aortic dissection involving the coronary arteries. In chronic aortic regurgitation, the chest x-ray reveals cardiomegaly, aortic dilatation, and, possibly, evidence of congestive heart failure. The most common ECG abnormality is left ventricular hypertrophy.

Acute aortic regurgitation requires immediate surgical intervention. Treat pulmonary edema with oxygen and intubation for respiratory failure. Nitroprusside, combined with inotropic agents such as dobutamine or dopamine, can augment forward flow and reduce left ventricular end-diastolic pressure. Diuretics and nitrates are usually ineffective. **Although β-blockers are commonly used in aortic dissection, avoid these in acute aortic regurgitation** because they block the compensatory tachycardia that is critical in maintaining cardiac output. Intra-aortic balloon counterpulsation is also contraindicated because it worsens regurgitant flow. Despite intensive medical management, death from ventricular dysrhythmias, pulmonary edema, or cardiogenic shock is common. In patients with only mild acute aortic regurgitation due to endocarditis, antibiotics may be adequate treatment without acute surgical intervention (see chapter 155).

Chronic aortic regurgitation is usually treated with vasodilators such as angiotensin-converting enzyme inhibitors or dihydropyridine calcium channel blockers.[3] If acute symptoms such as pulmonary edema or chest pain occur, admit the patient for stabilization and further management. Patients who become symptomatic, have a low ejection fraction, or have significant left ventricular dilatation are candidates for aortic valve replacement.

RIGHT-SIDED VALVULAR HEART DISEASE

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

The incidence of true right-sided valvular heart disease is not known because normal subjects frequently have a small amount of tricuspid and pulmonary valve regurgitation at baseline. Pathologic **tricuspid regurgitation** is usually due to elevated right heart pressure or volume overload, such as from pulmonary hypertension, chronic lung disease, pulmonary embolism, or atrial septal defects. **Tricuspid stenosis** is rare and is generally accompanied by regurgitation. The **pulmonic valve** is the least likely valve to be affected by acquired disease. Most pulmonic valvular disease is congenital (see chapter 126, "Congenital and Acquired Pediatric Heart Disease"), although pulmonary hypertension, rheumatic heart disease, and carcinoid syndrome can rarely cause some degree of pulmonic valve disease. Acute onset of symptomatic tricuspid disease is most often due to endocarditis. Tricuspid valve endocarditis typically involves aggressive organisms, such as *Staphylococcus aureus,* which can cause rapid valve destruction.

CLINICAL FEATURES

Clinically significant right-sided valvular disease causes signs and symptoms of right heart failure such as jugular venous distention, peripheral edema, hepatomegaly, splenomegaly, and ascites. Exertional dyspnea is often the first symptom in patients with right-sided valvular disease associated with pulmonary hypertension. Patients with tricuspid valve regurgitation from endocarditis are often acutely ill with signs of sepsis. The murmur of tricuspid valve regurgitation is soft, blowing, and holosystolic. It is best heard along the lower left sternal border and increases with inspiration. A systolic waveform in the jugular vein, hepatic pulsations, and systolic eyeball propulsion may be seen in severe tricuspid incompetence. Tricuspid valve stenosis is associated with a rumbling crescendo-decrescendo diastolic murmur occurring just before S_1. This murmur is best heard along the lower left sternal border, increases with inspiration, and is often preceded by an opening snap.

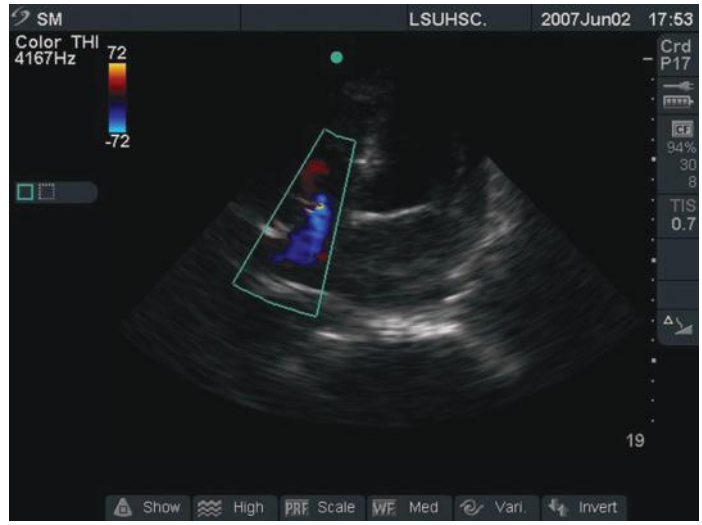

FIGURE 54-7. An echocardiogram demonstrating tricuspid regurgitation. Note regurgitant flow into the right atrium.

Pulmonic stenosis often presents with exertional dyspnea, syncope, chest pain, and the signs and symptoms of right heart failure. There is a harsh systolic murmur, best heard in the left second intercostal space, which increases with inspiration. A loud ejection click may precede the murmur, and an S_4 is often heard. Pulmonic regurgitation is associated with a high-pitched and blowing diastolic murmur (Graham Steell murmur), which increases in intensity during inspiration and is best heard over the left second and third intercostal spaces. An S_3 gallop is often present. Patients with severe right-sided valvular disease typically have a palpable right ventricle thrill or heave.

DIAGNOSIS AND TREATMENT

The diagnosis of right-sided valvular heart disease requires echocardiography (**Figure 54-7**), with transesophageal echocardiography being more sensitive than transthoracic studies. Chest radiography and ECG findings lack sensitivity or specificity. Chest radiography may show signs of right atrial and ventricular enlargement. In pulmonic stenosis, there may be dilatation of the left pulmonary artery. ECG may demonstrate right atrial enlargement and signs of right ventricular hypertrophy.

Treatment of right-sided valvular heart disease is aimed at the underlying cause. Treat those with endocarditis with antibiotics. Patients with functional tricuspid or pulmonic regurgitation should receive treatment aimed at the underlying cause of the pulmonary hypertension or right-sided failure. Diuretics treat the effects of elevated venous pressure, such as lower extremity edema, ascites, and hepatic congestion, but use with caution to avoid volume depletion or electrolyte abnormalities.[19] Patients with symptomatic pulmonic or tricuspid stenosis may be candidates for balloon valvotomy, and those with severe tricuspid regurgitation due to a structural valve abnormality may require valve replacement.

PROSTHETIC VALVE DISEASE

PATHOPHYSIOLOGY

Prosthetic valves are divided into two basic groups: mechanical and bioprosthetic. Mechanical valves are more durable with lower failure rates but have a higher risk for thromboembolic complications. Life-long anticoagulation is necessary to reduce the thrombotic risk. Bioprosthetic valves, from porcine, bovine, or human sources, are less thrombogenic but are more likely to fail and require repeat surgery.

Systemic thromboembolism is a common complication of mechanical heart valves. Without anticoagulation, the risk of valve thrombosis or thromboembolism is about 8%, and falls to 1% to 2% per year with anticoagulation.[20,21] Embolic risk is highest during the first 3 postoperative

months, and emboli are more common from mitral rather than from aortic valves. Antiplatelet therapy is recommended for all patients with prosthetic valves. In all patients with mechanical valves, lifelong anticoagulation is recommended.[10] The rate of bleeding complications is dependent on the type and intensity of anticoagulation. Major bleeding complications from warfarin occur in approximately 1.4% of prosthetic valve patients per year.[22]

Prosthetic valves may malfunction in a number of ways, including thrombosis, dehiscence of sutures, gradual degeneration, or even sudden fracture. Symptoms are often slowly progressive, but in acute failures, severe symptoms and death may occur before corrective surgery can be accomplished.

Prosthetic valve endocarditis occurs in up to 6% of patients within 5 years of surgery.[23] Early cases (within the first year) are more commonly caused by *Staphylococcus epidermidis* and *S. aureus*.[24] Late cases of endocarditis are caused by similar organisms as those affecting native valves.[24] The most frequent organism is *Streptococcus viridans,* but *Serratia* and *Pseudomonas* are also implicated. Regardless of source, prosthetic valve endocarditis carries a high mortality rate.[25]

CLINICAL FEATURES

Although valve replacement relieves valvular obstruction and regurgitation, cardiac remodeling persists, and many patients have persistent cardiac symptoms after valve replacement. Long-standing volume or pressure overload leads to ventricular dysfunction, and many patients continue to have dyspnea and symptoms of heart failure. Patients are also likely to have concomitant coronary artery disease, systemic hypertension, or atrial fibrillation.

Symptoms of prosthetic valve dysfunction depend on the type and location of the valve. Patients with prosthetic valves experience some symptoms specific to the presence of the artificial valve. Thromboembolism may cause systemic symptoms such as transient neurologic symptoms, amaurosis fugax, or self-limited ischemic episodes in the extremities or organs. Major embolic events include stroke, mesenteric infarction, or sudden death. Prophylaxis against thrombotic complications of prosthetic valves with systemic anticoagulation may cause major bleeding, with hemorrhagic stroke being the most common lethal bleeding complication.

Acute onset of respiratory distress, pulmonary edema, and cardiogenic shock may be associated with mechanical valve failure, tearing of a bioprosthesis, or a large clot obstructing the valve or preventing closure. Failures often result in sudden death before corrective surgery can be done. A paravalvular leak also presents with congestive heart failure. The severity of symptoms is dependent on leak size and how rapidly the leak develops. Slowly progressive development of heart failure may occur with gradual accumulation of a prosthetic valve thrombus.

Patients with bioprostheses usually have a normal S_1 and S_2, with no abnormal opening sounds. Mechanical valves normally have a loud, clicking, metallic sound associated with valve closure. Systolic murmurs of prosthetic aortic valves are common, but loud diastolic murmurs should be considered pathologic. A "quiet" mechanical valve is concerning. A loud holosystolic murmur indicates prosthetic mitral valve dysfunction. Aortic bioprostheses usually cause a short mid-systolic murmur, and mitral bioprostheses may cause a short diastolic rumble.

DIAGNOSIS OF PROSTHETIC VALVE DYSFUNCTION OR COMPLICATIONS

Think of potential prosthetic valve dysfunction in any patient with a valve replacement and new or progressive dyspnea, congestive heart failure, decreased exercise tolerance, or chest pain. Suspect thromboembolism, septic embolism, or intracranial hemorrhage in any patient with a prosthetic valve and new focal neurologic deficit. Finally, consider endocarditis in prosthetic valve patients with persistent fever or fever without a clear source.

Echocardiography is the diagnostic test of choice. Chest radiography lacks sensitivity and specificity but may show a change in valve position or signs of heart failure. Obtain a head CT in patients with focal neurologic deficits to evaluate for hemorrhage or embolic stroke. Patients on warfarin may require a complete blood count and coagulation studies. Obtain blood cultures for suspected endocarditis.

TREATMENT AND DISPOSITION

Emergency treatment for acute prosthetic valve dysfunction requires cardiology and cardiothoracic surgery consultation. Emergent surgery and thrombolytic therapy are potential therapies for acute valve thrombosis. Lesser degrees of obstruction should be treated by optimizing anticoagulation. Obtain consultation before discharging a patient with suspected prosthetic valve dysfunction.

REVERSAL OF ANTICOAGULATION WITH PROSTHETIC VALVES

Management of patients with prosthetic valves in the ED requires knowledge of the recommendations on anticoagulation and reversal of excessive anticoagulation. Mechanical mitral valves require an INR of 2.5 to 3.5, whereas bileaflet mechanical valves in the aortic position require an INR of 2.0 to 3.0.[3,10] Aspirin is recommended for all patients with prosthetic valves—mechanical or bioprosthetic.[10]

For the emergency physician, the greatest dilemma regarding anticoagulation is not who should be on anticoagulation, but how to treat supratherapeutic anticoagulation with or without bleeding. An INR >5 poses a significant risk of excess bleeding, but rapid changes in anticoagulation pose an equally ominous risk of valve thrombosis and thromboembolism. Patients with an INR of 5 to 10 without bleeding may be treated by withholding warfarin or administering 1.0 to 2.5 milligrams of oral vitamin K. **Patients with severe bleeding complications are best treated with fresh frozen plasma or prothrombin complex concentrate.[3] Avoid parenteral, high-dose vitamin K due to risk of overcorrection**.[9]

PREGNANT WOMEN WITH VALVULAR DISEASE

The changes in cardiovascular physiology during pregnancy may be poorly tolerated by patients with underlying valvular disease. Increases in cardiac output and blood volume accentuate the murmurs associated with mitral or aortic stenosis. Regurgitant aortic or mitral murmurs may be attenuated due to pregnancy-associated decreases in systemic vascular resistance. In general, asymptomatic mild lesions are well tolerated and pose low maternal and fetal risks. However, more pronounced disease that produces symptoms or is associated with pulmonary hypertension or left ventricular dysfunction is risky and requires high-risk obstetric follow-up. Neonatal complications associated with symptomatic maternal valvular lesions include prematurity, intrauterine growth retardation, respiratory distress syndrome, intraventricular hemorrhage, and death.[26]

Patients with mild valvular heart disease can often be managed medically during pregnancy. Those with moderate or severe stenotic valvular heart disease may require balloon valvotomy or surgery. Patients with aortic or mitral regurgitation who have severe symptoms refractory to medical management may also require surgery. Endocarditis prophylaxis is unnecessary in patients with valvular heart disease when undergoing vaginal or cesarean delivery.[9]

Pregnant women with valvular heart disease may present in extremis, with dyspnea, pulmonary edema, angina, or syncope. These are generally treated in a similar fashion as discussed above. Pregnancy is associated with a hypercoagulable state due to changes in circulating hormone levels as well as venous stasis. Pregnant patients with valvular heart disease or prosthetic valves are at increased risk for thromboembolic events, and anticoagulation is recommended.[3] Warfarin in pregnancy is associated with teratogenic effects, spontaneous abortion, prematurity, and stillbirth. Unfractionated and low-molecular-weight heparins are safe in pregnancy, but require close monitoring. Heparin therapy should be targeted to a partial thromboplastin time ratio of at least twice the control. However, the effectiveness of heparin thromboembolic prophylaxis is not well established in pregnant women despite being a common path.[9,26] Low-dose aspirin (81 to 162 milligrams) once daily is recommended during the second and third trimesters for pregnant patients with mechanical or bioprosthetic valves.

PRACTICE GUIDELINES

Practice guidelines include the 2014 American College of Cardiology/American Heart Association Guidelines for the Management of Patients with Valvular Heart Disease[3] and the Joint Task Force on the Management of Valvular Heart Disease of the European Society of Cardiology and the European Association for Cardio-Thoracic Surgery Guidelines on the Management of Valvular Heart Disease.[19]

CHAPTER 55

Cardiomyopathies and Pericardial Disease

James T. Niemann

INTRODUCTION

The term cardiomyopathy describes a heterogeneous group of diseases that directly alter cardiac structure, impair myocardial function, or alter myocardial electrical properties. Discoveries in molecular genetics and the description of (ion) channelopathies as diseases have prompted new definitions and classification of cardiomyopathies.[1] Primary cardiomyopathies are diseases that solely or predominantly involve the myocardium[1]; the most common disorders are listed in **Table 55-1**. Secondary cardiomyopathies include heart muscle diseases associated with specific systemic disorders. At present, no classification method perfectly distinguishes all forms of cardiomyopathy, and overlap exists between categories.[2,3] Secondary cardiomyopathies often present with hemodynamic findings similar to those of the idiopathic dilated or restrictive forms of cardiomyopathy. The most common causes of secondary cardiomyopathies are listed in **Table 55-2**. As a group, the cardiomyopathies are the third most common form of cardiac disease encountered in the United States, following coronary (ischemic) heart disease and hypertensive heart disease. **Hypertrophic cardiomyopathy** is the second most common cause of sudden cardiac death in the adolescent population and the leading cause of sudden death in competitive athletes.[4]

An in-depth discussion of each of the primary and secondary cardiomyopathies is beyond the scope of this chapter, and one is unlikely to make a specific diagnosis in the ED. This chapter discusses selected cardiomyopathies (**Table 55-3**). The cardiomyopathies usually present with signs of systolic and diastolic ventricular dysfunction. The ED evaluation will generally guide the need for urgent treatment, admission, or referral for further diagnostic evaluation, based on the severity of symptoms.

CARDIOMYOPATHIES WITH SYSTOLIC AND DIASTOLIC DYSFUNCTION

DILATED CARDIOMYOPATHY

Epidemiology and Pathophysiology Dilated cardiomyopathy is the most common cardiomyopathy and is usually idiopathic but may be familial or occur with specific cardiac or systemic disorders (**Tables 55-1** and **53-2**). **Peripartum cardiomyopathy** most commonly manifests as dilated cardiomyopathy and is discussed in chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period." The idiopathic form of dilated cardiomyopathy causes approximately 25% of all cases of congestive heart failure (CHF) and is the primary indication for cardiac transplantation in the United States. The prevalence of **idiopathic dilated cardiomyopathy** is about 36 cases per 100,000 population. Blacks and males have a 2.5-fold increase in risk compared with whites and females. Most patients are diagnosed between the ages of 20 and 50 years, and the majority have advanced symptoms of CHF at the time of initial presentation.[5]

TABLE 55-1 The Primary Cardiomyopathies

Genetic
Hypertrophic cardiomyopathy
Arrhythmogenic right ventricular cardiomyopathy/dysplasia
Left ventricular noncompaction
Conduction system disease
Long QT syndrome
Brugada syndrome
Catecholaminergic polymorphic ventricular tachycardia
Short QT syndrome
Idiopathic ventricular fibrillation
Mixed (genetic and nongenetic)
Dilated cardiomyopathy
Primary restrictive nonhypertrophied cardiomyopathy
Acquired
Myocarditis (inflammatory cardiomyopathy)
Stress (Takotsubo) cardiomyopathy
Peripartum cardiomyopathy

Dilated cardiomyopathy is characterized by systolic and diastolic dysfunction and diminished left ventricular (LV) and, often, right ventricular (RV) contractile force, resulting in a low cardiac output and increased end-systolic and end-diastolic ventricular volumes. A decrease in ventricular compliance leads to an increase in intracavitary pressures. LV and, often, RV dilatation accompanied by normal LV wall thickness are the hallmarks of dilated cardiomyopathy.

Clinical Features As a result of systolic pump failure, the patient presents with signs and symptoms of CHF: dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, bibasilar rales, and dependent edema. Depressed ventricular contractile function and dilatation may result in the formation of mural thrombi, and the patient may develop signs of peripheral embolization (e.g., an acute neurologic deficit, flank pain, and hematuria or a pulseless, cyanotic extremity). Chest pain is felt to be

TABLE 55-3 Features of Selected Cardiomyopathies

Type	Name	Clinical Features	ECG
Systolic and diastolic dysfunction	Dilated cardiomyopathy	Congestive heart failure Chest pain Regurgitant murmurs	LVH Poor R-wave progression
	Myocarditis	Fever Tachycardia Myalgias Chest pain	Nonspecific ST-T wave changes, often with pericarditis
Diastolic dysfunction	Hypertrophic cardiomyopathy	Dyspnea on exertion Chest pain Palpitations Syncope Prominent J wave Pulsus bisferiens Systolic ejection murmur, increases with Valsalva and decreases with squatting	LVH Large septal Q waves
	Restrictive cardiomyopathies	"Square root sign" of left ventricular filling pressures; easily confused with constrictive pericarditis	In some, low voltage of QRS; conduction disturbances; atrial fibrillation

Abbreviations: ECG = electrocardiogram; LVH = left ventricular hypertrophy.

due to limited coronary vascular reserve rather than atherosclerotic coronary artery disease, but the cause cannot be distinguished clinically.

Murmurs do not necessarily indicate primary valvular disease. Annular dilatation and displacement of the papillary muscles of the atrioventricular valves inhibit complete valve closure. Holosystolic mitral or tricuspid regurgitant murmurs are frequently heard at the apex or lower left sternal border. An apical diastolic rumble may be heard and is due either to accentuated, early diastolic atrial-to-ventricular flow (the result of mitral regurgitation and left atrial overload) or to a loud summation gallop. The liver will be enlarged and pulsatile if tricuspid insufficiency is significant.

Diagnosis The diagnosis may be suspected in patients with typical radiographic and electrocardiographic findings, but the diagnosis is typically made at follow-up with echocardiography and additional testing as indicated by individual characteristics. The chest radiograph invariably shows an enlarged cardiac silhouette and increased cardiothoracic ratio. Biventricular enlargement is common. Evidence of pulmonary venous hypertension ("cephalization" of flow and enlarged hila) is also frequent and may serve to differentiate cardiac enlargement due to myocardial failure from that due to a large pericardial effusion.

The electrocardiogram is almost always abnormal. LV hypertrophy and left atrial enlargement are the most common findings. Q or QS waves and poor R-wave progression across the anterior precordium may produce a pseudoinfarction pattern. Atrial fibrillation and ventricular ectopy are common rhythm disturbances.

Echocardiographic studies in a symptomatic patient demonstrate a decreased ejection fraction, increased systolic and diastolic volumes, and ventricular and atrial enlargement.[6] Echocardiography is indicated when the cause of heart failure is uncertain to exclude known causes of heart failure that may be correctable (e.g., pericardial effusion or valvular disease), to estimate ejection fraction, and to rule out other potential complications (e.g., mural thrombi) that may be amenable to therapy. The acuity of the patient's presentation determines the urgency of echocardiography.

Treatment and Disposition For the treatment of acute decompensated heart failure, see chapter 53, "Acute Heart Failure." Chronic therapy may include diuretics and digoxin, but these drugs do not appear to improve survival rates.[7] Guidelines from the American College of Cardiology for the management of heart failure (and other cardiovascular disorders) are available online at http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards.aspx. The use of angiotensin-converting enzyme inhibitors and blockers, specifically carvedilol, improves survival in patients with dilated cardiomyopathy and CHF.[8] Selected patients benefit from cardiac resynchronization therapy.[9-11] Patients with complex ventricular ectopy who are found to be at risk for sudden cardiac death may benefit from amiodarone therapy or an implanted cardioverter-defibrillator.[12]

Patients with a known dilated cardiomyopathy and chronic CHF may present to the ED with a mild to moderate worsening of symptoms.[13] If the cause is noncompliance with medical therapy or diet, ED treatment with nitrates, IV diuretics, reinstitution of prescribed medications, patient counseling, and timely referral to the primary care physician are appropriate. However, life-threatening causes of acute exacerbations, such as cardiac ischemia, should be considered before assuming benign causes. Acutely symptomatic patients require hospitalization for definitive diagnosis and management. Important subsets of patients with dilated cardiomyopathy are treated with left ventricular assist devices while awaiting heart transplantation or as destination therapy.[14,15] Principles of patient assessment and management and device complications are described in **Left Ventricular Assist Devices** (see next page)**.**

MYOCARDITIS (INFLAMMATORY CARDIOMYOPATHY)

Pathophysiology Myocarditis is a common cause of dilated cardiomyopathy but is discussed separately to highlight its acute presentation and individual therapy. Myocarditis is inflammation of the heart muscle and is most frequently characterized pathologically by focal infiltration of the myocardium by lymphocytes, plasma cells, and histiocytes. Varying amounts of myocytolysis and destruction of the interstitial reticulin network are also seen.[16] Because many episodes are mild, they do not always come to medical attention. **Table 55-4** lists some common infectious causes of myocarditis. Myocarditis is frequently accompanied by pericarditis.

TABLE 55-4 Common Infectious Causes of Myocarditis

Viral Agents	Bacteria
Coxsackie B virus	*Corynebacterium diphtheriae*
Echovirus	*Neisseria meningitidis*
Influenza virus	*Mycoplasma pneumoniae*
Parainfluenza virus	β-Hemolytic streptococci (rheumatic fever)
Epstein-Barr virus	Lyme disease
Hepatitis B virus	
Human immunodeficiency virus	

LEFT VENTRICULAR ASSIST DEVICES (LVADs)

Daniel Renner, Heather Heaton, and Jason N. Katz

Left ventricular assist devices (LVADs) augment left ventricular output in patients with severe cardiomyopathy. Right ventricular assist devices and biventricular assist devices also exist, though these are much less common and are used only for temporary circulatory support. There are several models of LVADs in current use which share many similar features.

In all LVADs, the implanted pump transfers blood from the apex of the left ventricle to the proximal aorta (Figure 1). The pump is powered by an external power source (battery or bedside unit), which is connected to a controller. Both the battery and controller reside outside of the body and can be carried or worn by the patient. The controller drives the pump through a driveline, which connects the implanted pump to the external controller through a surgical incision in the abdominal wall.

Most contemporary LVADs use pumps that drive blood through a continuous-flow mechanism (e.g. axial or centrifugal flow), maintaining a normal mean arterial blood pressure in the absence of a palpable pulse. However, many patients may still retain some cardiac contractility; in these individuals the LVAD serves to assist (and not replace) normal physiologic cardiac output, and a pulse may be present. Because the LVAD can (in some patients) maintain systemic perfusion even with minimal cardiac function, an LVAD patient can sometimes be clinically stable even in the setting of ventricular fibrillation. LVAD patients still rely upon reasonable right ventricular function to pump blood to the lungs.

Patients and families are thoroughly trained on the management of the LVAD and its complications, and they should be involved during patient assessment and management. It is important to call the patient's LVAD coordinator as soon as possible to assist with management decisions--this information should be present in the patient's travel bag, along with a spare controller and batteries.

CLINICAL FEATURES

LVAD patients should have a normal mean arterial pressure. Blood pressure can be assessed by a mechanical cuff or by doppler ultrasound. If using a doppler, remember that blood flow can be continuous and not pulsatile. When auscultating the heart, the continuous whirr of the pump is heard.

The ECG should have discernible QRS complexes (Figure 2).

The LVAD is visible on a chest radiograph (Figure 3). Bedside US can be used to assess RV function and to evaluate for pericardial effusion/tamponade. Plain imaging and CT scans are safe, but MRIs are contraindicated.

THE HEMODYNAMICALLY UNSTABLE LVAD PATIENT

NEVER PERFORM CHEST COMPRESSIONS ON AN LVAD PATIENT. Chest compressions can dislodge the LVAD from the heart and aorta, causing LV rupture and intractable hemorrhage.

Immediately auscultate the precordium -- an audible "whirr" indicates that the pump is functioning. If nothing is heard, search for a cause of mechanical LVAD failure. With the help of family or the patient, check and/or change the batteries and/or controller. **Do not disconnect anything.**

If the pump is audible and functioning, obtain a blood pressure (by automatic cuff or manual doppler) and place the patient on a cardiac monitor and continuous pulse oximetry. If the LVAD model does not provide pulsatile flow, it is difficult to obtain a reading by pulse oximetry.

For **hypotension**, give a bolus of normal saline. Assess for bleeding, especially from GI hemorrhage. **If hypotension persists despite adequate fluid resuscitation, or in the presence of right ventricular failure or LVAD malfunction, initiate IV pressors.** Dopamine is a reasonable first line therapy. **Obtain an ECG** to rule out right ventricular myocardial infarction or strain. Obtain standard laboratory studies as clinically indicated. **Bedside US** can assess for right ventricular dilatation or failure. If there is right ventricular strain, consider pulmonary hypertension or pulmonary embolism. Give heparin if **pulmonary embolism or device thrombosis** is suspected and bleeding is excluded.

VF or VT in an unstable patient requires defibrillation/cardioversion, using standard ACLS energy recommendations. Do not place defibrillator pads over the driveline. If the patient is clinically stable, give amiodarone according to ACLS protocols.

MEDICAL COMPLICATIONS

Medical complications include anemia, bleeding, thromboembolism, or infection. **Anemia** can be caused by hemolysis (erythrocyte destruction from the pump) or bleeding. LVAD patients are typically anticoagulated with warfarin to an INR target of 2-3. **Bleeding and coagulopathy** are investigated and treated with standard measures. LVAD patients are also at risk for **thromboembolism**, such as pulmonary embolism, stroke and mesenteric ischemia, especially in the setting of suboptimal anticoagulation. Heparin is safe and indicated for such events once bleeding has been ruled out. **Infection** is a common complication, especially at the driveline exit site. Treat sepsis with volume resuscitation, blood cultures, and antibiotics.

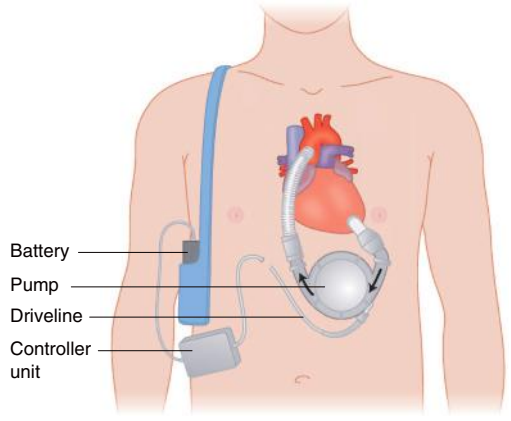

FIGURE 1. LVAD carries blood from the left ventricle to the aorta.

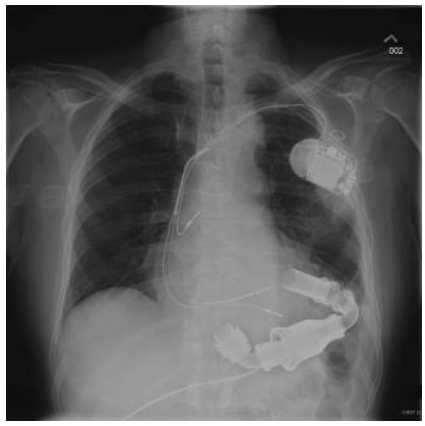

FIGURE 3. Posteroanterior chest radiograph of a patient with an LVAD and an implantable defibrillator. The outflow conduit to the proximal aorta is not radiographically visible. [ECG used with permission of Daniel Renner, MD.]

FIGURE 2. ECG of a patient with an LVAD. QRS is evident and baseline shows some electrical interference from the pump. [ECG used with permission of Daniel Renner, MD.]

Clinical Features Fever, myalgias, headache, and sinus tachycardia usually out of proportion with fever are common signs and symptoms. Other signs and symptoms depend on the extent of myocardial involvement and myocardial depression. In severe cases, heart failure can develop. With less extensive myocardial involvement, pericarditis and the clinical manifestations of systemic illness (fever, myalgias, headache, and rigors) may overshadow clinical signs of myocardial dysfunction, and myocarditis may not be suspected. Retrosternal or precordial angina-type chest pain is frequent and is usually due to pericardial inflammation **(myopericarditis)**. A pericardial friction rub is commonly heard.

Diagnosis The gold standard for diagnosis of myocarditis is endocardial biopsy, but this invasive modality is uncommonly used.[17] The diagnosis is more commonly made clinically based on symptoms with supportive testing. The chest radiograph is usually normal or nondiagnostic. Cardiomegaly and pulmonary venous hypertension or pulmonary edema are present with severe disease. Electrocardiogram changes include nonspecific ST-T–wave changes, ST-segment elevation or PR depression from associated pericarditis, atrioventricular block, and QRS interval prolongation. Cardiac enzymes may be elevated.[18] Echocardiographic studies are also nonspecific, with myocardial depression and wall motion abnormalities in severe cases. Newer imaging modalities include nuclear imaging with gallium-67– or indium-111–labeled antimyosin antibodies and cardiac MRI.[19-21]

Treatment and Disposition Treatment for idiopathic or viral myocarditis is supportive. Antibiotics are needed for myocarditis complicating rheumatic fever, diphtheria, or meningococcemia. Immunosuppressive therapy (e.g., prednisone, azathioprine, and others) may be of value in selected patients, but large trials have not consistently demonstrated benefit.[19] Immunosuppressive therapy is usually reserved for more severe cases and is rarely begun in the ED. Admission is usually indicated if the patient presents with CHF.

CARDIOMYOPATHIES WITH DIASTOLIC DYSFUNCTION

HYPERTROPHIC CARDIOMYOPATHY

Epidemiology and Pathophysiology **Hypertrophic cardiomyopathy** is characterized by LV and/or RV hypertrophy that is usually asymmetric and involves primarily the interventricular septum. The diagnostic hallmarks of the disease remain echocardiographic asymmetric septal hypertrophy and histologic hypertrophy associated with myocardial fiber disarray surrounding areas of increased loose connective tissue.[22] The underlying pathophysiology appears to be microvascular dysfunction with mechanico-energetic uncoupling. The disorder can be familial, with autosomal dominant inheritance, or it can occur sporadically. There is no apparent sex or ethnic predilection. Hypertrophic cardiomyopathy is a heterogeneous disease of the sarcomere with many mutations. The most common mutation involves the beta-myosin heavy chain. Particular genotypes have more rapidly progressive courses. The prevalence in the general population is approximately 1 in 500. The annual mortality rate in the overall hypertrophic cardiomyopathy population is about 1% per annum, but is up to 4% to 6% in childhood and adolescence.

Hemodynamically, hypertrophic cardiomyopathy is characterized by abnormal LV diastolic function due to reduced compliance of the hypertrophied left ventricle. Decreased compliance is reflected by an increase in LV filling pressure. Cardiac output, ejection fraction, and end-systolic and end-diastolic volumes are usually normal. During cardiac catheterization and hemodynamic monitoring, a systolic pressure gradient between the body of the left ventricle and the subvalvular outflow tract can be recorded in some patients at rest or after provocation (e.g., exercise or isoproterenol infusion). Most clinical symptoms are the result of impaired diastolic relaxation and restricted LV filling.

Clinical Features Severity of symptoms in most instances is related to the patient's age; the older the patient, the more severe are the symptoms. Dyspnea on exertion is the most frequent initial complaint and is due to exercise-induced sinus tachycardia, which results in an abrupt elevated LV diastolic pressure and pulmonary venous hypertension. Additional symptoms include chest pain, palpitations, and syncope. A family history of death due to cardiac disease, frequently described as "massive heart attack" or "heart failure," is not uncommon.

Chest pain in hypertrophic cardiomyopathy patients is due to an imbalance between the oxygen demand of the hypertrophied left ventricle and the available myocardial blood flow.[15] In older patients, associated atherosclerotic coronary artery disease may further limit myocardial perfusion. Precordial or retrosternal chest discomfort in hypertrophic cardiomyopathy may mimic angina pectoris or may be "atypical." Response to nitroglycerin administration is poor and highly variable.

The hypertrophic cardiomyopathy patient may be aware of forceful ventricular contraction and complain of an abnormal heartbeat or "palpitations." Atrial fibrillation is poorly tolerated because of the increased importance of the atrial contribution to LV filling.

Jugular venous pressure is usually not elevated. However, a prominent a (atrial) wave may be noted on close inspection of the neck veins. The upstroke of the carotid arterial pulse is rapid and frequently biphasic or bifid (pulsus bisferiens). The apical impulse is sustained and hyperdynamic, and a presystolic lift is common.

The first and second heart sounds are usually normal, with an S_4 heard in most patients. The systolic ejection murmur of hypertrophic cardiomyopathy is heard best at the lower left sternal border or at the apex and rarely radiates to the carotid arteries. Easily performed bedside maneuvers can be used to increase the intensity and duration of the murmur (**Table 55-5**). **Interventions that decrease LV filling and the distending pressure in the LV outflow tract or that increase the force of myocardial contraction accentuate the murmur of hypertrophic cardiomyopathy.** Such interventions include standing and the strain phase of the Valsalva maneuver. The murmur is also louder with the first sinus beat after a premature ventricular contraction. **Maneuvers that increase LV filling (squatting, passive leg elevation, and hand grip) decrease the murmur.** The murmurs of hypertrophic cardiomyopathy and mitral valve prolapse, when associated with murmur, are similar and are compared in **Table 55-5**.

Diagnosis The diagnosis may be suspected in the ED based on symptoms and supportive testing, but typically is confirmed at follow-up with echocardiography or cardiac MRI, frequently followed by genetic testing. The resting ECG is nonspecific in most patients with hypertrophic cardiomyopathy, often demonstrating LV hypertrophy and left atrial enlargement. Evidence of chamber enlargement is most common in patients with large gradients across the LV outflow tract. Q waves >0.3 mV, termed septal Q waves, may be seen in anterior, lateral, or inferior leads. Q waves may mimic those seen after myocardial infarction (pseudoinfarction pattern). The polarity of the T wave can differentiate between hypertrophic cardiomyopathy septal Q waves from Q waves due to myocardial infarction. Upright T waves in those leads with QS or QR complexes are usually found in hypertrophic cardiomyopathy, whereas

TABLE 55-5 Effect of Bedside Interventions on the Murmur of Hypertrophic Cardiomyopathy Compared to Mitral Valve Prolapse

Intervention	Hypertrophic Cardiomyopathy	Mitral Valve Prolapse
Valsalva maneuver (strain phase)	Murmur increased	Click closer to S_1, murmur increased
Standing after squatting	Murmur increased	Click closer to S_1, murmur increased
Passive leg elevation in supine patient	Murmur decreased	Click closer to S_2, murmur decreased
Hand grip	Murmur decreased	Click closer to S_1, murmur increased
Squatting	Murmur decreased	Click closer to S_2, murmur decreased

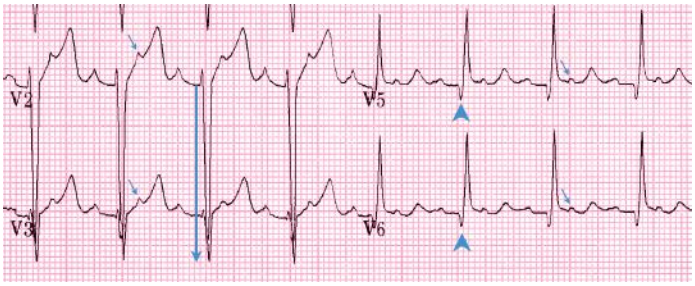

FIGURE 55-1. Deep S-wave voltage (28 mm S in V_2, *large arrow*) signifies LV hypertrophy, and narrow septal Q waves in V_5 and V_6 (*arrowheads*) are noted. T waves are upright in the leads with the septal Q waves, typical of hypertrophic cardiomyopathy. This patient also has atrial flutter with 2:1 block. The additional P waves appear in the ST segments (*small arrows*). [Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine,* 3rd ed. New York: McGraw-Hill, 2010; Fig 23.40B.]

T-wave inversion in such leads is highly suggestive of ischemic heart disease. From a patient with hypertrophic cardiomyopathy, **Figure 55-1** demonstrates evidence of LV hypertrophy as shown by deep S waves in V_2 and septal Q waves with upright T waves in leads V_5 and V_6. The chest radiograph is usually normal or nonspecific.

Echocardiography plays a substantial role in the diagnosis of hypertrophic cardiomyopathy, in the correlation of the auscultatory and hemodynamic events with LV anatomic changes, and in defining inheritance patterns. The characteristic echocardiographic finding is disproportionate septal hypertrophy. Other echocardiographic abnormalities include reduced LV end-diastolic dimensions, systolic anterior motion of the mitral valve, and mid-systolic closure of the aortic valve. Cardiac MRI is recommended when echocardiography is inconclusive in patients clinically suspected of having the disease.[22]

Treatment and Disposition The majority of patients with hypertrophic cardiomyopathy who seek medical care typically do so because of declining exercise tolerance, chest pain, or syncope.[22] The patient who presents complaining of exercise intolerance or chest pain in whom the typical murmur of hypertrophic cardiomyopathy is heard should be referred for echocardiographic evaluation. Syncope in patients with hypertrophic cardiomyopathy typically occurs during or immediately after exercise. **If hypertrophic cardiomyopathy is suspected in a patient with syncope, hospitalization is indicated.** The diagnostic evaluation in such cases is extensive and includes echocardiographic studies as well as extended ambulatory (Holter) monitoring, exercise stress testing to assess blood pressure response, and tilt testing. **Syncope in patients with hypertrophic cardiomyopathy may presage sudden cardiac death.** β-Blockers are the mainstay of therapy for patients with chest pain.[22] Preparticipation screening guidelines for athletes advocated in the United States include personal and family medical history, and careful physical examination.[23] At this time, routine electrocardiography or echocardiography is not recommended in the United States[24,25] because evidence does not yet support universal testing.[25,26]

RESTRICTIVE CARDIOMYOPATHY

Epidemiology and Pathophysiology Restrictive cardiomyopathy may result from systemic disorders (amyloidosis, sarcoidosis, hemochromatosis, progressive systemic sclerosis [scleroderma], carcinoid heart disease, endomyocardial fibrosis, or hypereosinophilic syndrome), but in most cases, it is idiopathic. The idiopathic form is sometimes familial, with autosomal dominant transmission. There has been no clearly demonstrated predilection for gender or ethnicity.

Restrictive cardiomyopathy is heart muscle disease that results in "restricted" ventricular filling, with normal or decreased diastolic volume of one or both ventricles. Systolic function is usually normal, and ventricular wall thickness may be normal or increased, depending on the underlying cause. The hemodynamic hallmarks include (1) elevated LV and RV end-diastolic pressure, (2) normal LV systolic function (ejection fraction >50%), and (3) a marked decrease followed by a rapid rise and plateau in early diastolic ventricular pressure. The rapid rise and abrupt plateau in the early diastolic ventricular pressure trace produce a characteristic "square root sign" or "dip-and-plateau" filling pattern due to increased myocardial stiffness. This pattern is not diagnostic, however, and may be seen in constrictive pericarditis, with which restrictive cardiomyopathy is commonly confused. Differentiation between the two is critical because constrictive pericarditis can be cured surgically. The diagnosis of restrictive cardiomyopathy should be considered in a patient presenting with CHF but no evidence of cardiomegaly or systolic dysfunction.[27]

Clinical Features and Diagnosis Symptoms are typical of CHF and include dyspnea, orthopnea, and pedal edema. Right-sided heart failure may predominate and results in hepatomegaly, right upper quadrant pain, and ascites. Chest pain is uncommon, except in amyloidosis.

Findings on physical examination depend on the stage or severity of myocardial involvement. An S_3 and an S_4 are often heard. Pulmonary rales, jugular venous distention, Kussmaul sign (jugular venous pulse rises during inspiration rather than falling), hepatomegaly, pedal edema, and ascites are also typical findings. On chest x-ray, there may be signs of CHF but a normal heart size. Chamber enlargement due to wall thickening, but not dilatation, and nonspecific ST-T–wave changes are usually noted on the electrocardiogram. Cardiac conduction disturbances are common in amyloidosis and sarcoidosis. Atrial fibrillation may occur in the setting of atrial enlargement. Low-voltage QRS complexes (QRS amplitude <0.7 mV) are frequently described in patients with restrictive cardiomyopathy secondary to amyloidosis and hemochromatosis. The differential diagnosis includes constrictive pericarditis or diastolic LV dysfunction (most commonly due to ischemic heart disease, hypertension, or age-related changes in ventricular diastolic compliance). Doppler echocardiographic studies and cardiac catheterization with hemodynamic assessment are often required for specific diagnosis.

Treatment and Disposition CT and MRI of the heart can differentiate constrictive pericarditis from restrictive cardiomyopathy.[28] Correct diagnosis is important because constrictive pericarditis can be surgically corrected, and diastolic LV dysfunction usually responds well to β-blockers or calcium channel blockers. The medical management of restrictive cardiomyopathy is less effective and symptom directed (diuretics and angiotensin-converting enzyme inhibitors) unless due to sarcoidosis (corticosteroid therapy) or hemochromatosis (chelation therapy). The need for admission is usually determined by the severity of symptoms and the availability of diagnostics.

PERICARDIAL DISEASE

The pericardium consists of a serous or loose fibrous membrane (visceral pericardium) overlying the epicardium and a dense collagenous sac (parietal pericardium) surrounding the heart. The space between the visceral and parietal pericardium may normally contain up to 50 mL of fluid.[28] Because its layers are serosal surfaces and because of its proximity and attachments to other structures, the pericardium may be involved in a number of disease processes (**Table 55-6**). In this section, the clinical manifestations and evaluation of acute and constrictive pericarditis and nontraumatic cardiac tamponade are discussed.

ACUTE PERICARDITIS

Clinical Features The most common symptom of acute pericarditis is sharp or stabbing precordial or retrosternal chest pain. Pain may be of sudden or gradual onset and radiates to the back, neck, left shoulder, or arm, and may be aggravated by inspiration or movement. Referral of pain to the left trapezial ridge (due to inflammation of the joining diaphragmatic pleura) is a particular distinguishing feature. Chest pain due

TABLE 55-6 Common Causes of Acute Pericarditis

Idiopathic
Infectious
Viral (coxsackie virus, echovirus, human immunodeficiency virus)
Bacterial (especially *Staphylococcus, Streptococcus pneumoniae*, β-hemolytic streptococci [acute rheumatic fever], *Mycobacterium tuberculosis*)
Fungal (especially *Histoplasma capsulatum*)
Malignancy (leukemia, lymphoma, metastatic breast and lung carcinoma, melanoma)
Drug induced (procainamide, hydralazine)
Systemic rheumatic diseases (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, polyarteritis nodosa, dermatomyositis)
Radiation induced
Postmyocardial infarction (Dressler's syndrome)
Uremia
Myxedema

to acute pericarditis may be aggravated by inspiration or movement. Typically, chest pain is most severe when the patient is supine and is relieved when the patient sits up and leans forward.[29,30] Associated symptoms include fever, dyspnea due to accentuated pain with inspiration, and dysphagia from irritation of the esophagus by the posterior pericardium.

A pericardial friction rub is the most common and important physical finding in pericarditis but may be difficult to appreciate in a noisy ED. It is best heard with the diaphragm of the stethoscope at the lower left sternal border or apex when the patient is sitting and leaning forward. It may be audible only during a certain phase of respiration and characteristically is intermittent. A pericardial friction rub is most often triphasic, with a systolic component due to ventricular contraction, an early diastolic component during the early phase of ventricular filling, and a presystolic component synchronous with atrial systole. It is less commonly biphasic, with a systolic component with either an early diastolic or presystolic component. A monophasic rub is less common but is most often systolic.

Diagnosis • ***Electrocardiogram*** Serial electrocardiogram changes during acute pericarditis and its convalescence are characterized by four stages (**Table 55-7** and **Figure 55-2**).

If a large pericardial effusion develops during the course of acute pericarditis, low-voltage QRS complexes and electrical alternans may be evident. Pericardial fluid attenuates myocardial electrical signals, and the pendular motion of the heart within the fluid-filled pericardial space results in electrical alternans (see **Figure 55-5** in the Nontraumatic Cardiac Tamponade section of this chapter).

Although serial ECG tracings are of diagnostic value in acute pericarditis, sequential ECG assessment is not a diagnostic luxury afforded the emergency physician. Differentiating pericarditis from the normal variant with "early repolarization" is a common problem and can be difficult when only a single 12-lead electrocardiogram is available. The ST-T–wave changes present in the early repolarization or normal variant electrocardiogram mimic those of pericarditis and have been reported in 2% of healthy young adults. However, the ST-segment/T-wave amplitude ratio in leads V_5, V_6, or I can differentiate pericarditis from early repolarization.[31,32] Using the end of the PR segment as a baseline, or 0 mV, the amplitude or height of the ST segment at its onset is measured in V_5, V_6, or lead I and recorded in millivolts. The height of the T wave in the same lead is measured from the baseline to the T-wave peak. If the ratio of ST amplitude (in millivolts) to T-wave amplitude (in millivolts) is >0.25, acute pericarditis is likely, and if the ratio is <0.25, acute pericarditis is unlikely (**Figure 55-2**). Sensitivity at an ST/T ratio >0.25 for acute pericarditis is >0.85, and the specificity is >0.8 (positive likelihood ratio of about 4 and negative likelihood ratio of about 0.2). Pericarditis alone does not cause significant cardiac rhythm disturbances.

TABLE 55-7 Serial Electrocardiogram Changes of Acute Pericarditis

Stage	PR Segment	ST Segment	T Wave
1 (acute)	Depression, especially in II, aVF, and V_4–V_6	Elevation, especially in I, V_5, and V_6; ST amplitude: T-wave amplitude >0.25	—
2	Isoelectric or depressed	Returns to isoelectric line	Amplitude decreases, inversion rare
3	Isoelectric or depressed	Isoelectric	T-wave inversion, especially in I, V_5, and V_6
4	Isoelectric	Isoelectric	Normal

Radiographic Assessment Chest radiographs are of limited value. The cardiac silhouette may be of normal size and contour in acute pericarditis and, in some instances, the setting of cardiac tamponade. If previous chest radiographs are available for comparison, a recent increase in the size of the cardiac silhouette or an increase in the cardiothoracic ratio without radiographic evidence of pulmonary venous hypertension can distinguish an expanding pericardial effusion from left heart failure. The "epicardial fat-pad sign" is rarely seen on the lateral chest radiograph and has been reported in only 15% of cases of acute pericarditis during fluoroscopy with image intensification. If acute pericarditis is suspected on the basis of history, physical examination, or ECG, a chest radiograph may help establish an underlying cause, such as neoplasm or infection.

Echocardiographic Studies Echocardiography is the procedure of choice for the detection, confirmation, and serial follow-up of patients with acute pericarditis and a pericardial effusion.[33] (See http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards.aspx for more information.)

Normally, the pericardial sac is only a "potential" space, and the myocardium is echocardiographically in direct contact with surrounding thoracic structures. The anterior RV wall is in contact with the chest wall, and the posterior LV wall is in contact with the posterior pericardium and adjacent pleura. When a pericardial effusion is present, the pericardial space fills with echo-free fluid (**Figure 55-3**).

Echocardiographically, a separation is seen between the right ventricle and the chest wall and between the left ventricle and the posterior pericardium. Quantitation of the size of the effusion is arbitrary and is determined by where the echo-free space is seen (anterior or posterior) and when in the cardiac cycle it occurs. For example, when an echo-free space is seen only posteriorly and only during systole, a small effusion is said to be present. The sensitivity of CT for detecting pericardial effusion is similar to that of echocardiography (**Figure 55-4**).

Ancillary Laboratory Evaluation Suggested laboratory studies are listed in **Table 55-8**. **Serum creatine kinase–MB fraction and troponins may be elevated in acute pericarditis due to associated myocarditis.**[11]

Treatment and Disposition Treatment of pericarditis depends on the cause.[34] Most patients with idiopathic or presumed viral pericarditis have a benign course lasting 1 to 2 weeks. Symptoms respond well to nonsteroidal anti-inflammatory agents administered for 7 days to 3 weeks. Ibuprofen, 300 to 800 milligrams orally every 6 to 8 hours, may be preferred because of fewer side effects, limited impact on coronary artery blood flow, and large dose range. Colchicine, 0.5 milligram orally twice a day, may be a beneficial adjuvant and may prevent recurrent episodes.[35,36] Hospitalization is not necessary in most cases, unless there is associated myocarditis, and follow-up or repeat echocardiography is not needed unless symptoms fail to resolve or reappear or new symptoms are noted.[37] Indicators of a poor prognosis include temperature >38°C (100.4°F), subacute onset over weeks, immunosuppression, history of oral anticoagulant use, associated myocarditis (elevated cardiac biomarkers, symptoms of CHF), and a large pericardial effusion (an echo-free space >20 mm).[38] In general, patients with these risk factors or with an enlarged cardiac silhouette on chest radiograph should be admitted for echocardiography to assess the extent of the effusion and degree of hemodynamic compromise and cardiac dysfunction.

FIGURE 55-2. This series of three electrocardiograms (ECGs) shows the typical progression of changes associated with acute pericarditis. **A.** In stage I pericarditis, the ECG shows diffuse ST-segment elevation and PR depression in leads I, II, III, and avF. The ST-segment to T-wave amplitude ratio measured in V_6 is 2 mm/4 mm, or 0.50, thus meeting criteria for pericarditis rather than early repolarization (see the text under Diagnosis, Electrocardiogram). **B.** In stage II pericarditis, ST segments are returning toward the isoelectric point in most leads in which they had been elevated. **C.** In stage III pericarditis, we see resolution of ST changes and the appearance of diffuse T-wave inversion. These evolutionary changes are typical of and diagnostic for pericarditis and usually occur over several weeks.

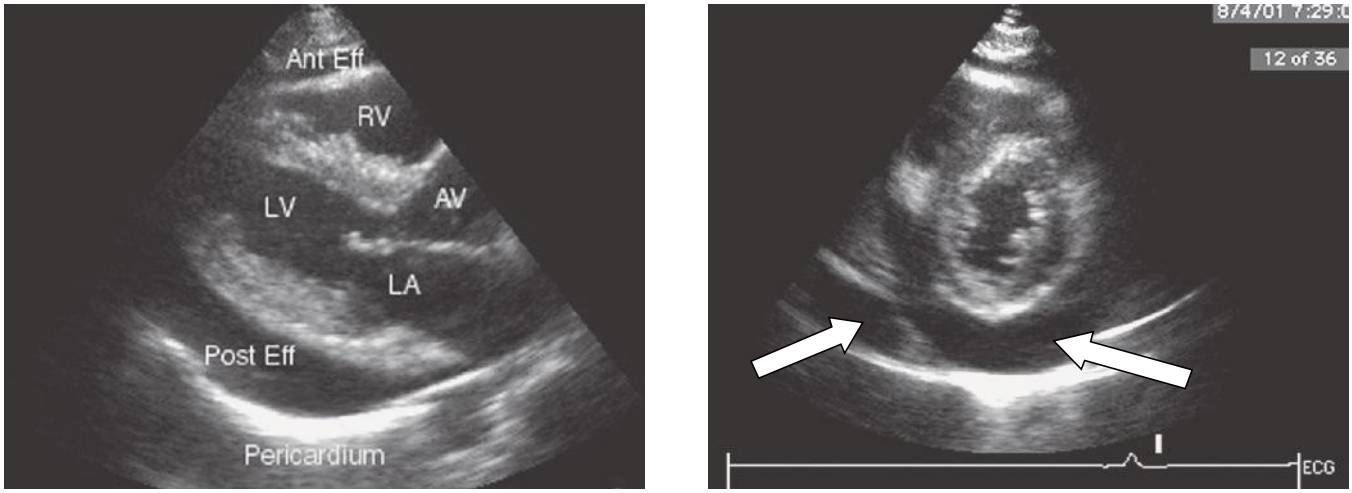

FIGURE 55-3. **A.** Pericardial effusion on parasternal long-axis view. Ant Eff = anterior effusion; AV = aortic valve; LA = left atrium; LV = left ventricle; Post Eff = posterior effusion; RV = right ventricle. **B.** Pericardial effusion on (*arrows*) parasternal short-axis view. NONTRAUMATIC CARDIAC TAMPONADE

Pathophysiology An increase in the amount of fluid within the pericardial sac results in an increase in intrapericardial pressure. The normal fibrocollagenous parietal pericardium has elastic properties and stretches to accommodate increases in intrapericardial fluid. The initial portion of the pericardial volume-pressure curve is flat: Relatively large increases in volume result in comparatively small changes in intrapericardial pressure. The curve becomes steeper as the parietal pericardium reaches the limits of its distensibility.[39] If fluid continues to accumulate, intrapericardial pressure rises to a level greater than that of the normal filling pressures of the right heart chambers. When this occurs, ventricular filling is restricted and results in cardiac tamponade. The point at which this occurs is determined by the rate of fluid accumulation, pericardial compliance (a thickened parietal pericardium is less distensible), and intravascular volume (hypovolemia lowers ventricular filling pressure). Common causes of cardiac tamponade in nontrauma patients are listed in **Table 55-9**.

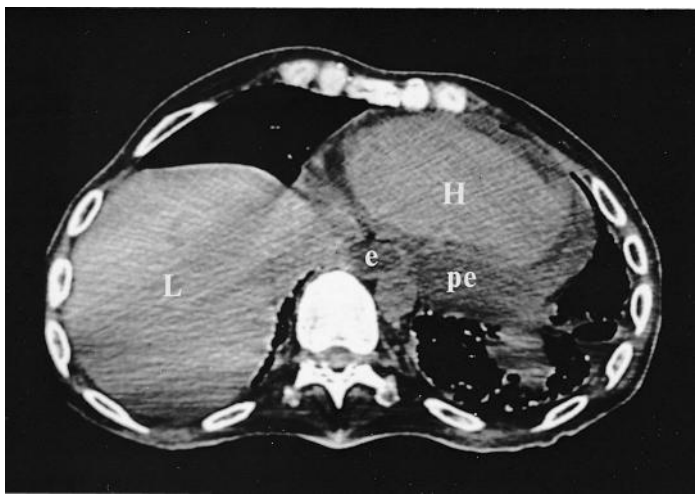

FIGURE 55-4. This CT scan of the chest shows a large pericardial effusion (pe) predominantly posteriorly located in a patient with scleroderma and pericarditis. No pericardial thickening or calcification was detected. Esophageal (e) dilatation is noted. Cardiac function cannot be evaluated. H = heart; L = liver. TABLE 55-8 Ancillary Diagnostic Studies in Acute Pericarditis

Diagnostic Study	Considerations
Cardiac markers	Indicate myocardial involvement
CBC and differential WBC count	May suggest infection or leukemia
BUN/creatinine	May suggest a diagnosis of uremic pericarditis
Streptococcal serologic testing (antistreptolysin O, anti-DNAse, antihyaluronidase)	Particularly in patients with a history of rheumatic heart disease or pharyngitis
Blood cultures	If bacterial infection suspected
Serologic studies	Antinuclear antibodies, anti-DNA titers, or rheumatoid factor in patients with systemic symptoms
Erythrocyte sedimentation rate	Will not determine specific diagnosis, but can confirm clinical suspicion of pericarditis and can be followed serially to assess response to therapy
Acute and convalescent viral antibody titers	Measuring viral titers would not be expected to change the course of treatment
Thyroid function studies	Thyrotoxicosis is a rare cause of pericarditis; thyrotoxicosis can cause pericardial effusion without the typical electrocardiogram changes and symptoms of pericarditis

TABLE 55-9 Common Causes of Cardiac Tamponade in Medical (Nontrauma) Patients

Cause	Approximate Frequency (%)
Metastatic malignancy	40
Acute idiopathic pericarditis	15
Uremia	10
Bacterial or tubercular pericarditis	10
Chronic idiopathic pericarditis	10
Hemorrhage (anticoagulant)	5
Other (systemic lupus erythematosus, postradiation, myxedema, etc.)	10

FIGURE 55-5. This rhythm strip (lead II, top tracing) and plethysmograph (bottom tracing) were recorded in a patient who presented with dyspnea, hypotension, and clinical and echocardiographic evidence of cardiac tamponade. A paradoxical pulse was noted on palpation of the radial artery. The amplitude of the R waves varies from beat to beat (electrical alternans).

Clinical Features Symptoms are nonspecific, and patients most commonly complain of dyspnea at rest and with exertion. Additional symptoms may be due to the underlying disease (e.g., uremia or tuberculous pericarditis).

Physical examination may reveal tachycardia and low systolic arterial blood pressure with a narrow pulse pressure. **Pulsus paradoxus** may also be present. A paradoxical arterial pulse is said to be present when the cardiac rhythm is regular and there are apparent dropped beats in the peripheral pulse during inspiration. There is usually a <10 mm Hg decrease in systolic blood pressure during inspiration in the supine position. A value >10 mm Hg usually separates true tamponade from lesser degrees of restricted cardiac filling.[28,40] Pulsus paradoxus is not diagnostic of cardiac tamponade and may be noted in other cardiopulmonary processes. In cardiac tamponade, the neck veins may be distended with an absent "y" descent. The apical impulse is indistinct or tapping in quality. Cardiac auscultation may reveal "distant" or soft heart sounds. Pulmonary rales are usually absent, and there may be right upper quadrant tenderness from hepatic venous congestion.

Diagnosis The chest radiograph may or may not reveal an enlarged cardiac silhouette because this finding depends on the amount of intrapericardial fluid accumulation. The pulmonary vasculature typically appears normal. An epicardial fat-pad sign may occasionally be seen within the cardiac silhouette.

The ECG usually shows low-voltage QRS complexes (<0.7 mV) and ST-segment elevation (due to the inflammation of the epicardium) with PR-segment depression, as in pericarditis. Electrical alternans (beat-to-beat variation in the amplitude of the P and R waves unrelated to the respiratory cycles; **Figure 55-5**) is a classic but uncommon finding.

The diagnosis should be suspected based on the clinical examination and chest radiograph findings. Echocardiography is the diagnostic test of choice. In addition to a large pericardial fluid volume, typical echocardiographic findings described in cardiac tamponade are right atrial compression, RV diastolic collapse, abnormal respiratory variation in tricuspid and mitral flow velocities, and dilated inferior vena cava with lack of inspiratory collapse.

Treatment and Disposition Volume expansion with a bolus of normal saline solution (500 to 1000 mL) will increase intravascular volume, facilitate right heart filling, and increase cardiac output and arterial pressure. However, it is a temporary measure. Pericardiocentesis is necessary for definitive therapy and for specific diagnosis.

If there is hemodynamic instability, emergency pericardiocentesis is indicated in the ED. The technique is described in Section 4, Resuscitative Procedures, chapter 34, Pericardiocentesis. However, pericardiocentesis is optimally performed in the cardiac catheterization laboratory using echocardiographic guidance to avoid cardiac perforation and coronary artery laceration. In addition, a pigtail catheter can be inserted to allow continuous fluid drainage and prevention of reaccumulation.

CONSTRICTIVE PERICARDITIS

Pathophysiology Constrictive pericarditis results from pericardial injury and inflammation, resulting in fibrous thickening of the layers of the pericardium, which prevents passive diastolic filling of the cardiac chambers.[16] Some causes include postcardiac trauma with intrapericardial hemorrhage, after pericardiotomy (open-heart surgery, including coronary revascularization), in fungal or tuberculous pericarditis, and in chronic renal failure (uremic pericarditis), but in most cases, a specific cause is not determined.

Clinical Features The symptoms of constrictive pericarditis usually develop gradually and may mimic those of CHF and restrictive cardiomyopathy. However, clinical signs may occur early if fluid also accumulates within the thickened, noncompliant pericardial sac (effusive constrictive pericarditis).

Common signs and symptoms include exertional dyspnea, pedal edema, hepatomegaly, and ascites. Examination of the neck veins with the patient at a 45-degree angle from horizontal will reveal jugular venous distention and a rapid "y" descent of the cervical venous pulse. Elevated venous pressure is also seen in CHF, but a rapid "y" descent is infrequently encountered. The Kussmaul sign (inspiratory neck vein distention) is frequent in constrictive pericarditis but rare in CHF. A paradoxical pulse is uncommon, and its absence does not exclude constrictive pericarditis. On cardiac auscultation, an early diastolic sound, a pericardial "knock," may be heard at the apex 60 to 120 milliseconds after the second heart sound. The pericardial knock sounds like a ventricular gallop but occurs earlier than the S_3 of CHF, which it may mimic. The knock is due to accelerated RV inflow in early diastole and early myocardial distention, followed by an abrupt slowing of further ventricular expansion.

Diagnosis • ***Electrocardiogram*** Low-voltage QRS complexes and inverted T waves are common, but there are no specific diagnostic electrocardiogram signs.

Radiographic Assessment Chest radiographs most commonly demonstrate a normal or slightly enlarged cardiac silhouette, clear lung fields, and little or no evidence of pulmonary venous congestion. Pericardial calcification may be seen. Thoracic CT and MRI may also demonstrate a thickened pericardium.

Echocardiographic Studies On occasion, two-dimensional echocardiography may demonstrate pericardial thickening and abnormal ventricular septal motion in a patient with suspected constrictive pericarditis. However, its diagnostic utility is much less than that in a patient with acute pericarditis. Doppler echocardiography, cardiac CT, and MRI are preferred.

Cardiac Catheterization In many instances cardiac catheterization with measurement of intraventricular pressures will be required to confirm the diagnosis. A characteristic dip and plateau (the "square root sign") of the right ventricular pressure trace is characteristic of the disease.[41]

Treatment and Disposition In cases of significant constriction and impaired ventricular filling, admission for pericardiectomy is the treatment of choice.

CHAPTER 56

Venous Thromboembolism

Jeffrey A. Kline

INTRODUCTION AND EPIDEMIOLOGY

Pulmonary embolism (PE) occurs when clotted blood enters the pulmonary arterial circulation. Most PEs result from deep vein thrombosis (DVT) in the legs, arms, or pelvis and occasionally from the jugular vein or inferior vena cava. The term *venous thromboembolism* (VTE) includes PE and DVT.

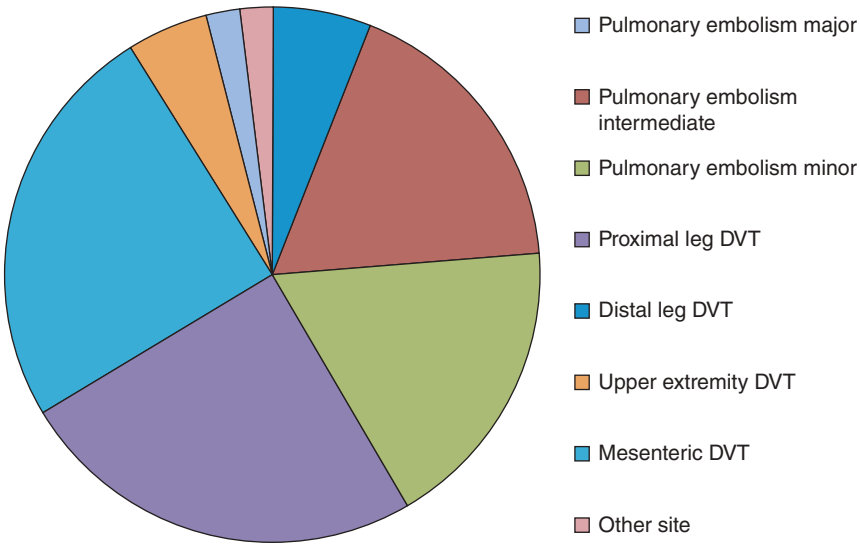

FIGURE 56-1. Distribution of the frequency of clots diagnosed by emergency physicians by severity and location. Major refers to pulmonary embolism (PE) with hypotension, intermediate is PE with right ventricular dysfunction, and minor is small PE without hemodynamic effect. Distal deep vein thrombosis (DVT) refers to calf vein and saphenous vein thrombosis, and other sites include inferior vena cava, pelvic, jugular, ovarian, cerebral, and retinal veins.

In the United States, approximately 200,000 people will have new or recurrent PE diagnosed each year, and twice that many will have DVT without confirmed PE.[1] VTE collectively affects about 1 in 500 persons per year in North America, and about 1 in every 300 adult ED patients receive the diagnosis (**Figure 56-1**). The incidence of VTE increases with age, peaking at 1 in 100 per year at age 80. Based on autopsy data, PE is the second leading cause of sudden, unexpected, nontraumatic death in outpatients.[2] The case fatality rate from PE depends on the hemodynamic severity of the PE, age, and comorbid conditions; the case fatality rate is 45% for PE with circulatory shock, but only about 4% to 5% of patients with PE have shock. In patients with hemodynamically stable PE who are less than 50 years old and without other comorbidities, the case fatality rate is 1%.[3]

Morbidity from DVT includes PE and the postthrombotic syndrome. The latter is manifested as chronic leg swelling and pain and occurs in about 20% of all ED patients with proximal DVT.[4] Both DVT and PE present across a spectrum of severity, with recognition of minor forms of the disease, including distal PE (called subsegmental) and distal DVT, usually in the calf or saphenous veins.[5]

PATHOPHYSIOLOGY

Blood clots occur when coagulation exceeds the removal by fibrinolysis. *Thrombophilias* are conditions that tip the balance of coagulation-fibrinolysis toward excessive clotting. Most guidelines categorize VTE as provoked (or secondary) or unprovoked (idiopathic).[6] Provoked VTEs are *acquired* and often time-limited conditions, generally often following recent surgery, trauma, or any condition associated with limb or body immobility; active cancer is a VTE provoker that often persists. Other provoking factors generally include diseases or conditions that impede venous blood flow, infection, chronic disease, estrogen use, pregnancy or initial postpartum interval, and age >50 years (each year after 50 increases the risk). Unprovoked VTE patients have no known risk factors, suggesting an increased tendency to clot.

Most VTEs diagnosed in the ED are unprovoked.[3,7] Patients with unprovoked VTE have a 15% chance of recurrence in the next year compared with 5% for those with a provoked episode. For this reason, those with unprovoked VTE usually receive longer treatment than patients with provoked VTE.[8] Those with provoked VTE have a higher 1-year death rate, likely from the comorbid conditions (notably cancer).[9]

Venous thrombi that are large enough to cause clinically important PE can form in the popliteal, common femoral, superficial femoral, pelvic, axillary, jugular, and great veins. At least one third of patients with DVT have concomitant PE, even when the patient lacks symptoms of PE.[10] Although 75% to 80% of hospitalized patients with PE have image-demonstrated DVT, only 40% of ambulatory ED patients with PE have concomitant DVT.[11]

Blood clots that form in the large veins of the legs, especially the femoral and iliofemoral veins, usually begin on the valves, leading to scarring and poor function of the venous valves. This causes pooling of venous blood in the legs, leading to varicose veins, pain, swelling, skin hyperpigmentation, and ulcers, known as the postthrombotic syndrome.[4] With PE, the correlation between the degree of initial pulmonary vascular obstruction and clinical severity is weak, but patients without prior heart or lung disease generally begin to experience symptoms from PE when approximately 20% of lung vasculature becomes occluded.[12] With larger clot burden, the pulmonary arterial pressure increases, leading to right ventricular dilation and myocardial damage, causing the release of troponin and B-type natriuretic peptide. Right ventricular dilation or injury, as evidenced on CT or echocardiography or suggested by elevated troponin or B-type natriuretic peptide, indicates right heart failure and increased risk of circulatory shock and death.[13] The two principle mechanisms of death from PE appear to be abrupt near-total pulmonary artery occlusion that leads to pulseless electrical activity and asystole from ischemic effect on the His-Purkinje conduction system. Approximately one third of survivors of large PEs go on to have persistent right heart dysfunction and severe symptoms.[14] Approximately 5% of patients with PE go on to experience chronic pulmonary vascular obstruction, leading to progressive damage to the lung vessels and right heart with disabling dyspnea and pulmonary hypertension, called *chronic thromboembolic pulmonary hypertension*.

Inherited thrombophilias increase risk of first-time VTE, although most of these patients are unaware of this condition until a clot occurs. The risk of recurrent VTE in those with a known thrombophilia is the same as in those who have had a prior unprovoked VTE absent that condition.[15]

With limb immobility, the risk *increases* depending on joint, as follows: elbow (least), shoulder, ankle, knee, and hip (most). Acute immobilization of the hip and knee in one leg with non–weight bearing causes the greatest risk for VTE, whereas immobilization of the wrist alone probably causes no risk. In addition to the presence of limb immobility, risk of VTE increases with whole-body immobility or neurologic immobility, but not by travel, even if >8 hours.[16]

Over half of patients with postoperative PE receive the diagnosis after hospital discharge, and the average time from surgery to PE diagnosis is >10 days. Risk increases with patient age, longer surgery, open surgery, and surgery in which thromboprophylaxis is not used. The highest-risk surgeries include abdominal surgery to remove cancer, joint replacement surgery, and surgery on the brain or spinal cord in the setting of neurologic deficits. However, the risk of recurrence after surgery-provoked VTE is generally lower than for unprovoked VTE, although

the 4-year risk of recurrence ranges from 5% to 11% per year depending on the surgical procedure.[17]

Thrombogenic potential of cancer varies with host factors, tumor stage, and tumor type. In general, the more undifferentiated the cell type and the larger the tumor burden (especially distant metastasis), the higher is the risk. Cancers that are particularly thrombogenic include adenocarcinoma, glioblastoma, metastatic melanoma, lymphoma, and multiple myeloma.[18] Pancreatic, stomach, ovarian, and renal cell cancers carry notoriously high risk.

Cancers with minimal risk of VTE include localized breast, cervical, prostate, and nonmelanomatous localized skin cancers such as squamous cell carcinoma and basal cell carcinoma not treated with chemotherapy. However, about 10% of patients with advanced-stage breast cancer or with breast cancer undergoing chemotherapy develop symptomatic VTE. VTE risk is high during the induction phase of chemotherapy, especially if treated with L-asparaginase and bolus fluorouracil or tamoxifen. Concomitant treatment with red blood cell growth factors such as erythropoietin increases risk of thrombosis, regardless of tumor type or stage.[18] Similarly, multiple myeloma patients treated with lenalidomide or thalidomide are at high risk of VTE.[19]

A family history of VTE increases longitudinal risk of VTE,[20] although this has no impact on outcomes.[7] Although sex does not play a role in first-time VTE, men have more recurrent VTE.[8]

Table 56-1 presents a list of risk factors for VTE relevant to ED practice.

Although smoking causes conditions that increase risk (e.g., cancer) and acts synergistically with obesity and possibly oral contraceptive use, smoking is not an independent risk factor for VTE.[7]

TABLE 56-1 Risk Factors for Venous Thromboembolism (VTE) That are Generally Relevant to Emergency Medicine

Factor	Comment
Age	Risk becomes significant at 50 y and increases with each year of life until age 80 y.
Obesity	In the general population, VTE risk starts at BMI >35 kg/m^2 and increases with increasing BMI.
Pregnancy and postpartum state	70% of all peripartum PEs occur postpartum. Risk increases with trimester (but overall risk remains low throughout pregnancy).
Prior VTE	Highest risk of recurrence is for unprovoked VTE in men, particularly if D-dimer remains elevated
Solid cancers	Risk greatest with adenocarcinomas and metastatic disease. A history of remote, inactive cancer probably does not increase risk.
Hematologic cancers	Acute leukemias and myeloma confer the greatest risk, particularly when treated with L-asparaginase and the thalidomide derivatives.
Thrombophilias	Non-O blood type, lupus anticoagulant, shortened aPTT, factor V Leiden, and familial protein C and S and antithrombin deficiency have the strongest risk.
Recent surgery or major trauma	Risk increased with endotracheal intubation or epidural anesthesia and continues at least 4 weeks after exposure. Risk varies with type of surgery.
Immobility	Acute limb immobility of two contiguous joints confers the highest risk.
Bed rest	Becomes a risk factor at approximately 72 h.
Indwelling catheters	Cause approximately one half of arm deep venous thromboses.
Long-distance travel	Published data are controversial. In general, risk becomes significant after 6 h of continuous travel.
Smoking	A population risk factor, but not a factor that increases probability of VTE in the ED setting. May increase risk of other factors such as obesity.
Congestive heart failure	Related primarily to severity of systolic dysfunction.
Stroke	Risk greatest in first month after deficit.
Estrogen	Highest-risk period is in the first few months. All contraceptives containing estrogen increase risk of VTE including transdermal and transvaginal preparations.
Noninfectious inflammatory conditions	Examples are inflammatory bowel disease, lupus, and nephrotic syndrome. Risk of VTE increases roughly in proportion to severity of underlying disease.

Abbreviations: aPTT = activated partial thromboplastin time; BMI = body mass index; PE = pulmonary embolism.

CLINICAL FEATURES OF PULMONARY EMBOLISM

PE symptoms range from none to sudden death. Patients with similar comorbidities and clot burden may have drastically different clinical presentations. **Table 56-2** lists factors that affect symptoms.

The hallmark of PE is dyspnea unexplained by auscultatory findings, ECG changes, or clear alternative diagnosis on chest radiograph. Chest pain with pleuritic features is the second most common symptom of PE, although about one half of all patients diagnosed with PE in the ED have no complaint of chest pain.[7] The classic PE pain is in the thorax between the clavicles and the costal margin that increases with cough or breathing; it is not purely substernal and not manifested from the skin or muscle. Pulmonary infarction can inflict severe focal pain, although most patients with PE and pleuritic chest pain have no radiographic evidence of pulmonary infarction. Pulmonary infarction in basilar lung segments can manifest as referred pain to either shoulder or mimic biliary or ureteral colic. Proximal PE without infarction can also cause pleuritic chest pain without focal pain.

HISTORY

In addition to the common symptoms of chest pain and dyspnea, approximately 3% to 4% of ED patients with PE have syncope, and another 1% to 2% present with new-onset seizure (or convulsion-like activity) or confusion.[3] Because about 20% of people have a patent foramen ovale, PE that increases right-sided pressures can lead to right-to-left transit of thrombotic material in the atria and showers into the brain circulation, producing stroke-like symptoms called the **paradoxical embolism syndrome**. Neurologic symptoms can vary widely, from classic localized findings to staring spells, transient altered mental status, and atypical myelopathy symptoms (e.g., numbness below the waist), all of which can fluctuate.[21] Presence of a patent foramen ovale worsens the prognosis in PE.

PHYSICAL EXAMINATION

On physical examination, abnormal vital signs suggest acute cardiopulmonary stress in a patient with PE: tachycardia, tachypnea, a low pulse oximetry reading, and sometimes mild fever. Unfortunately, PE does not predictably alter any vital sign; approximately one half of patients with proven PE have a heart rate of <100 beats/min at diagnosis, and approximately one third have abnormal early vital signs that normalize in the ED.[22] The mechanism of altered vital signs results in obstruction to blood flow and clot-derived autacoids, which together stimulate adrenergic efferent fibers to the heart and cause ventilation–perfusion mismatch on the lungs. The amount of clot burden does not predict vital sign changes reliably, with no clear correlation between measured clot and initial heart rate or oximetry. Although approximately 10% of patients with PE have an oral temperature of >38°C (100.4°F), <2% of patients with PE have a temperature of >39.2°C (102.5°F).

Most patients with PE have clear lungs on auscultation. Wheezes or bilateral rales make an alternative diagnosis of bronchospasm or pneumonia possible but do not exclude PE. For example, pulmonary infarction may produce rales over the affected lung segment. On heart

TABLE 56-2 Factors That Can Affect the Clinical Presentation of Patients with Pulmonary Embolism (PE)

Cofactor	Clinical Impact	Comment
Previously healthy and young age	Less severe signs and symptoms	One half of previously healthy patients with first-time PE have normal vital sign values at diagnosis.
Prior cardiopulmonary disease	Can either amplify or obscure history and findings	Most patients with PE complicating baseline cardiopulmonary disease describe dyspnea with PE as "worse than usual."
Patient cognitive dysfunction	Causes the history to be less reliable	Approximately 20% of patients with PE missed by ED clinicians had baseline dementia.
Clot size and location	Affects severity of dyspnea, pain, and signs	Proximal clots cause ventilation–perfusion mismatch and dyspnea; distal clots cause infarction with pain.
Gradual loading of PE over time	Gradual onset of dyspnea on exertion and fatigue	Has symptom overlap with left ventricular dysfunction. Fewer than one half of patients with PE describe symptom onset as sudden.

examination, one may hear a right ventricular S_3 or a split S_2 with a loud second sound. The presence of a percutaneous indwelling catheters in the arm increases the probability of axillary vein thrombosis, although it is less clear whether these lines, dialysis catheters, or pacemaker wires also increase the risk of symptomatic PE.

CLINICAL FEATURES OF DEEP VEIN THROMBOSIS

Patients with DVT complain of extremity pain, swelling, or cramping. A difference of ≥2 cm between right and left leg diameter at 10 cm below the tibial tubercle doubles the likelihood of DVT. Patients presenting with upper extremity catheter-related DVT often complain of hand swelling or tightness around finger rings. About one quarter of patients with DVT have tenderness and redness in the swollen extremity, findings that are similar to those of cellulitis. Calf or saphenous vein clots are more likely to cause thrombophlebitis, defined formally as inflammation (pain, tenderness, redness, and swelling) over a vein secondary to the presence of thrombotic material in the vein. Signs and symptoms of thrombophlebitis can persist after the vein has recannulated and the clot has dissolved entirely. Calf vein thrombosis may cause **Homan's sign**, which is calf pain elicited by passive foot dorsiflexion; this test has such low sensitivity and specificity that it has no predictive value.

Proximal DVT that causes complete venous obstruction leads to increased compartmental pressures, manifested as an extremely painful, swollen extremity. A swollen, painful, and pale or white limb with a proximal venous thrombosis is termed **phlegmasia alba dolens**, whereas a limb with a dusky or blue color is called **phlegmasia cerulea dolens**. Either condition poses the threat of limb loss, demanding aggressive treatment that can include thrombolysis or catheter-directed thrombectomy.

DIAGNOSIS

Routine cardiopulmonary testing in the ED generally demonstrates nonspecific findings in patients with PE. The mean pulse oximetry reading is lower in patients with proven PE than in those without PE (93 ± 2% vs 95 ± 3%), although this one signal may be absent in those with PE. Similarly, the mean partial pressure of oxygen in arterial blood (Pa_{O_2}) is lower (73 ± 19 mm Hg vs 80 ± 21 mm Hg), and the difference between the estimated partial pressure of oxygen in the alveoli (PA_{O_2}) and the measured Pa_{O_2}, the alveolar-arterial gradient [$P(A\text{-}a)O_2$], is increased. The arterial partial pressure of carbon dioxide (Pa_{CO_2}) is usually low, reflecting a 20% to 50% increase in minute ventilation to compensate for loss of lung efficiency secondary to the increased dead space. Spontaneously breathing patients with PE also demonstrate a lower end-tidal carbon dioxide compared with healthy individuals.[23]

Most patients with PE have a chest radiograph with one or more abnormalities, including cardiomegaly, basilar atelectasis, infiltrate, or pleural effusion; all are nonspecific for PE. In <5% of patients, a wedge-shaped area of lung oligemia (Westermark sign—usually from complete lobar artery obstruction) or peripheral dome-shaped dense opacification (Hampton hump—always indicative of pulmonary infarction) exists. **The presence of hypoxemia or dyspnea with clear lungs on physical exam and imaging suggests PE.**

The 12-lead ECG is usually nonspecific, with sinus tachycardia or nonspecific ST- and T-wave changes. When PE causes the right ventricular systolic pressure to exceed 40 mm Hg, the ECG can be more specific, including T-wave inversion in leads V_1 to V_4, incomplete or complete right bundle-branch block, and the classic but uncommon $S_1\text{-}Q_3\text{-}T_3$ pattern (**Figure 56-2**).[24] A clinical ECG score allows severity assessment in those with diagnosed PE (higher score equates to higher mortality, **Table 56-3**).[25]

DIAGNOSTIC TESTING FOR VENOUS THROMBOEMBOLISM

DECISION RULES AND CLINICAL ASSESSMENT

Estimating the pretest probability for VTE in a patient is the first step in selecting a diagnostic pathway. **Figure 56-3** shows one diagnostic algorithm; **no singular diagnostic test or algorithm perfectly excludes or diagnoses VTE**. Aggressive diagnostic searches can cause harm disproportionate to benefit from hemorrhage associated with anticoagulation for a false-positive result or self-limited small clot diagnosis or from contrast nephropathy. One approach is to test further only in those with pretest probabilities of >2.5%[26]; those with a pretest probability of PE <2.5% are more likely to be harmed than helped by a diagnostic test, even a D-dimer assay.

The PE rule-out criteria (**Table 56-4**) reliably forecast a probability of PE that is below the 2.0% test threshold in patients *with a gestalt low clinical suspicion*.[27,28] The American College of Emergency Physicians' Clinical Guidelines committee provided a 2b recommendation for the PE rule-out criteria rule.[29] The PE rule-out criteria rule had an apparently high failure rate in one secondary analysis done in a European population with a prevalence of disease of 27% in conjunction with a low-risk Geneva score.[30] However, the subsequent published erratum to the work showed that the PE rule-out criteria rule had 100% sensitivity in the same population *when combined with low gestalt pretest probability* as designed, which was also the case in other studies.[28,31] Thus, taken together, the weight of the available information indicates that PE can be reliably excluded by the combination of a low gestalt pretest probability plus a negative PE rule-out criteria rule. However, not all patients who have any positive PE rule-out criteria must undergo an objective test for PE, since anyone over 50 years old would be tested with any finding even if suspicion was low. The key is generating a clinical gestalt first and, if low, using the PE rule-out criteria to guide further testing.

Most validated PE prediction systems categorize the patient into one of two (low or above low probability) or three (low, moderate, or higher probability) categories.[33] One method uses a computerized database-derived method based on the method of attribute matching to estimate a discrete numerical percentage probability of PE.[26] The **Wells' score** is the most robust scoring system for categorizing the pretest probability for both PE (**Table 56-5**) and DVT (**Table 56-6**).

The Wells' original rules separate patients into low-, moderate-, and high-probability groups. The Wells' DVT and PE scoring systems both reliably produce a stepwise increase in probability of clot presence with higher scores. The Wells' scoring system has been modified to classify patients being evaluated for possible PE into a low-risk (score ≤4) or a non–low-risk group (score >4), which has become a mainstream method of use.[34] The **Charlotte rule** is designed to categorize patients into either a low-risk or non–low-risk group (designated "safe" or "unsafe" in **Figure 56-4**).

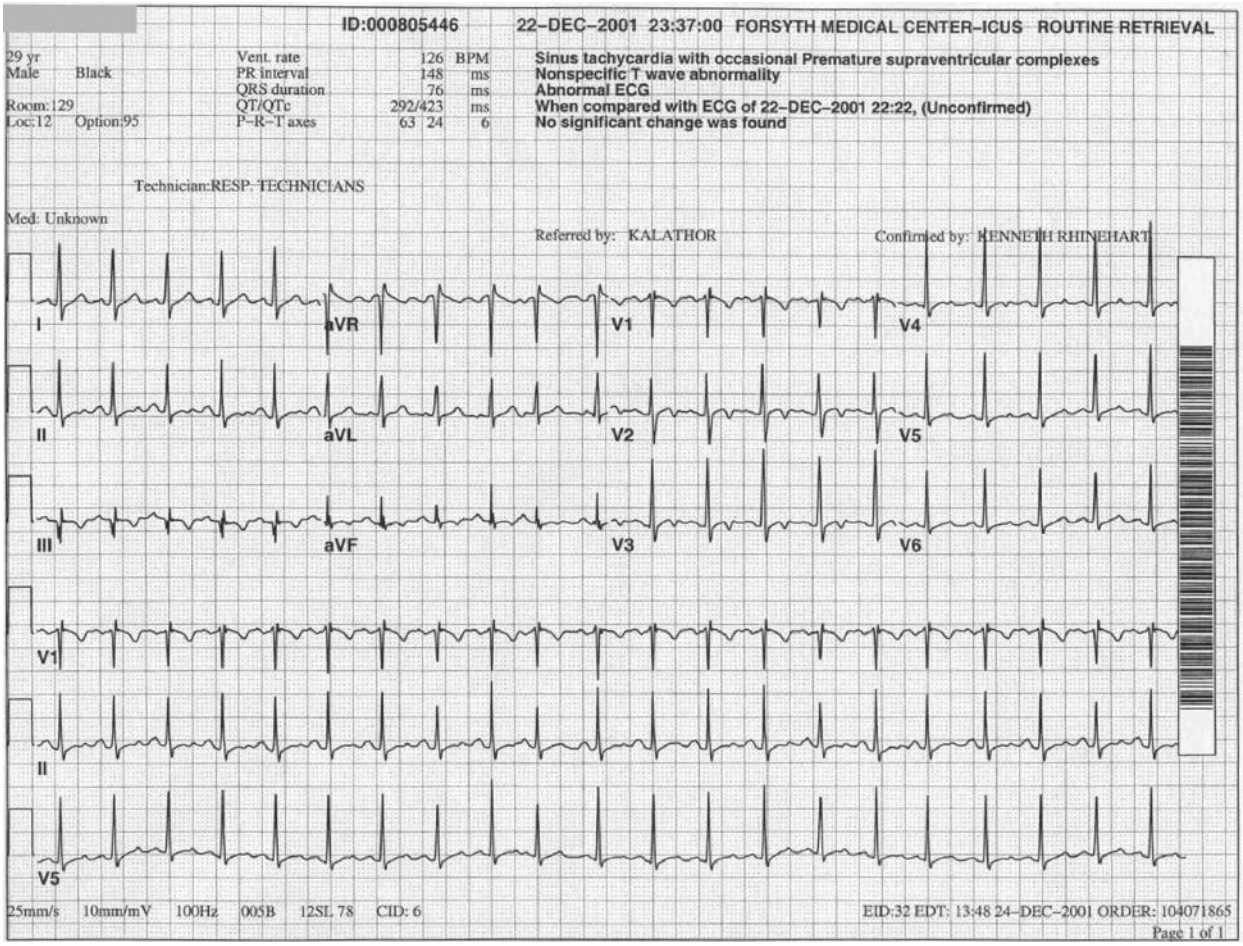

FIGURE 56-2. This 12-lead ECG shows many features of a severe PE: tachycardia, an incomplete right bundle-branch block, an S_1-Q_3-T_3 pattern, and T-wave inversion in the anterior leads.

TABLE 56-3 ECG Scoring Method to Assess Severity of Pulmonary Embolism

Characteristics	Score
Tachycardia (>100 beats/min)	2

If all S_1-Q_3-T_3 pattern, add	2
Total score (maximum: 21)	

*If present, check maximum only.

The Wells' rule has a subjective component—clinical judgment of the likelihood of an alternative diagnosis. Both the Charlotte rule and the revised **Geneva score** (**Table 56-7**) exclude subjective assessments.

Runyon et al[35] studied the accuracy of unstructured, gestalt estimation of pretest probability for PE, grouping patients into low-, moderate-, and high-risk categories (where the cutoffs suggested to the clinicians were <15%, 15% to 40%, and >40%); the measured frequencies of PE were similar when stratified by Wells' or Geneva scores.[33] Moreover, the interobserver agreement for gestalt classification was good ($\kappa = 0.60$), and gestalt estimation did not show a decrease in sensitivity based on training level.[35] Gestalt estimation is a viable method to estimate pretest probability and is preferred over no estimation.

D-DIMER TESTING

The D-dimer assay is the best blood test to exclude VTE, working on the principle that clots contain fibrin that is degraded naturally through the action of plasmin. Fibrin breakdown liberates the D-dimer protein into the blood. Multiple manufacturers each produce a slightly different assay, but the D-dimer test can be broadly classified as either qualitative or quantitative. Qualitative tests generally have lower diagnostic sensitivity but higher specificity compared with quantitative tests. Quantitative tests are usually done in the central hospital laboratory and require a turnaround time of at least 1 hour. Different D-dimer assays have different thresholds for normal because of different capture antibodies and optical methods of detection. Some laboratories report results in D-dimer mass concentration (e.g., nanograms per milliliter or micrograms per milliliter), and others report fibrinogen equivalent units. Two fibrinogen molecules produce one D-dimer unit, so that the fibrinogen equivalent unit number is twice the D-dimer number for the same measurement. For PE and DVT, the diagnostic sensitivity of automated

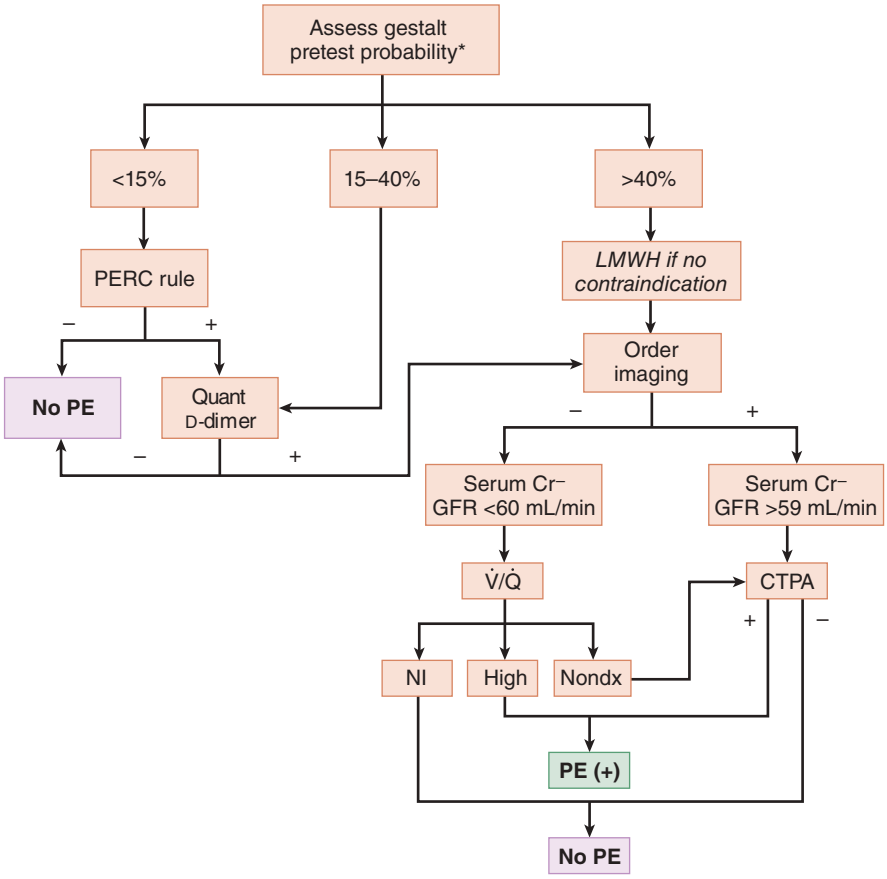

FIGURE 56-3. Pulmonary embolism rule-out criteria (PERC) rule—diagnostic algorithm for pulmonary embolism (PE). *Some physicians prefer to start with a clinical decision rule such as the Wells' score (where <2, 2–6, and >6 are used instead of <15%, 15%–40%, and >40%, respectively). Note: Determine renal function by clinical picture (healthy, no risk factors for reduced glomerular filtration rate [GFR]) or calculated GFR. Nondiagnostic ventilation–perfusion (V̇/Q̇) scan findings require confirmation from results of another test, such as CT pulmonary angiography (CTPA), if benefits outweigh risks. + = positive for PE; – = negative for PE; Cr = creatinine; High = high probability scan findings; LMWH = low-molecular-weight heparin; NI = normal; Nondx = nondiagnostic (any reading other than normal or high probability); quant = quantitative.

TABLE 56-4 Pulmonary Embolism Rule-Out Criteria Rule (all nine factors must be present to exclude pulmonary embolism)[32]

Clinical low probability (<15% probability of pulmonary embolism based on gestalt assessment)
Age <50 years
Pulse <100 beats/min during entire stay in ED
Pulse oximetry >94% at near sea level (>92% at altitudes near 5000 feet above sea level)
No hemoptysis
No prior venous thromboembolism history
No surgery or trauma requiring endotracheal or epidural anesthesia within the last 4 weeks
No estrogen use
No unilateral leg swelling, defined as asymmetrical calves on visual inspection with patient's heels raised off the bed

TABLE 56-5 Wells' Score for Pulmonary Embolism

Factor	Points*
Suspected deep venous thrombosis	3
Alternative diagnosis less likely than PE	3
Heart rate >100 beats/min	1.5
Prior venous thromboembolism	1.5
Immobilization within prior 4 wk	1.5
Active malignancy	1
Hemoptysis	1

*Risk score interpretation (probability of PE): >6 points = high risk (78.4%); 2–6 points = moderate risk (27.8%); and <2 points = low risk (3.4%).

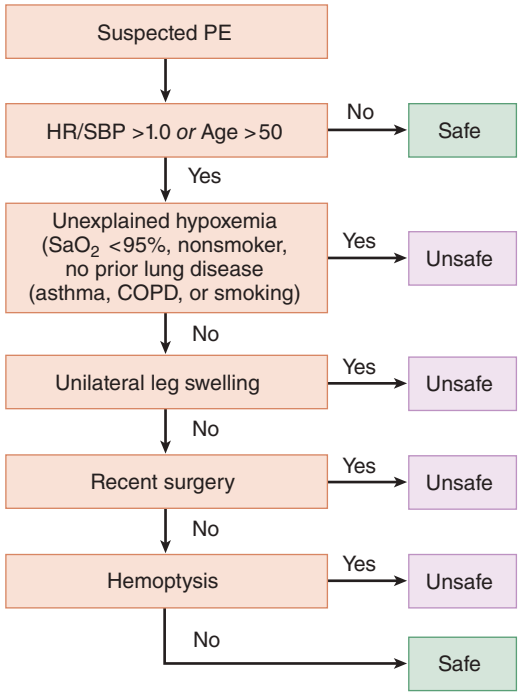

FIGURE 56-4. Charlotte rule for patients with suspected pulmonary embolism (PE). Patients for whom the decision tree leads to the "safe" boxes have a sufficiently low pretest probability to permit PE to be ruled out solely on the basis of a normal quantitative D-Dimer test result. COPD = chronic obstructive pulmonary disease; HR = heart rate; Sa_{O_2} = arterial oxygen saturation; SBP = systolic blood pressure.

quantitative D-dimer assays ranges from 94% to 98% and the specificity ranges from 50% to 60%. **The D-dimer has a half-life of approximately 8 hours and can be elevated for at least 3 days after symptomatic VTE.**

The most common causes of a false-negative or positive D-dimer result are listed in **Table 56-8**; notably, all risk factors for VTE may elevate the D-dimer level. D-Dimer increases with age and should be adjusted upward for age to maintain adequate exclusionary ability. The most common formula studied is age × 10 nanograms/mL (e.g., an 80-year-old patient would have an adjusted threshold for abnormal at 800 nanograms/mL).[34] This assumes the conventional D-dimer cutoff of 500 nanograms/mL; in a large multicenter study, this adjusted approach resulted in a very low false-negative rate (0.3%) when used in conjunction with a Wells' score ≤4 or a simplified revised Geneva score <5.[34]

TABLE 56-7 Revised Geneva Score for Pulmonary Embolism

Clinical Variable	Points*
Age >65 y	1
Previous venous thromboembolism	3
Surgery requiring anesthesia or fracture of lower limb in past month	2
Active malignancy	2
Unilateral leg pain	3
Hemoptysis	2
Unilateral leg edema	4
Heart rate	
75–94 beats/min	3
>95 beats/min	5

*Total score of 0–3 indicates low probability, score of 4–10 indicates moderate probability, and score of >10 indicates high probability of pulmonary embolism.

TABLE 56-8 Factors Known to Alter the D-Dimer Level from Expected Values

Potential False-Positive Levels	Potential False-Negative Levels
Age >70 y	Warfarin treatment
Pregnancy	Symptoms lasting over 5 d
Active malignancy or metastasis	Presence of small clots
Surgical procedure in previous week	Isolated small pulmonary infarction
Liver disease	Isolated calf vein thrombosis
Rheumatoid arthritis	Lipemia
Infections	
Trauma	

IMAGING

Chest CT Angiography **Chest CT angiography** is the most common imaging modality for PE, identifying a clot as a filling defect in contrast-enhanced pulmonary arteries (**Figure 56-5**). Equipment with more detector heads (e.g., 64- or 128-head scanners) allows better resolution and observation of filling defects in subsegmental pulmonary arteries. The diagnostic sensitivity and specificity of a technically adequate mutidetector CT scan are about 90%.[36] Most CT pulmonary angiography protocols require the patient to lie supine and hold their breath for a few seconds, and the scan requires injection of approximately 120 mL of contrast by a computer-controlled injection device. In most centers, the patient must have a peripheral IV catheter (20 gauge or larger) or an approved indwelling line to allow injection of the contrast, and a central catheter cannot be used for injection.

In addition to clot recognition, a CT scan can detect alternative diagnoses, often pneumonia (8% to 22% of cases).[37] Interobserver agreement in identifying segmental or larger filling defects is very good, but interobserver agreement for subsegmental clots is poor. In practice, approximately 10% of CT scans are inadequate from secondary motion artifact or poor pulmonary artery opacification, commonly in obese or

FIGURE 56-5. Axial image from a chest CT angiogram demonstrating a filling defect consistent with acute pulmonary embolism. Two *white arrowheads* outline a circular filling defect in the right middle lobar pulmonary artery. The *long white arrow* projecting in the left lung points to a filling defect in a segmental artery in the posterior medial segmental artery.

very tachypneic patients. Acute life-threatening contrast-triggered anaphylaxis or pulmonary edema is very rare, occurring in about 1 in 1000 patients.[38] About 15% of patients undergoing contrast-enhanced chest CT scan develop contrast nephropathy, defined as a 25% or greater increase in the serum creatinine concentration within 2 to 7 days of the examination.[39,40] **At present, the only clearly helpful prophylactic measure to reduce contrast nephropathy is hydration with intravenous balanced crystalloid solutions.**[41] Other complications from CT scanning include contrast extravasation into a limb that can cause pain or compartment syndrome, and creation of a secondary thrombophlebitis.

Ventilation-Perfusion Lung Scanning **Ventilation–perfusion ($\dot{V}/\dot{Q}$) lung scanning** can identify a perfusion defect when ventilation is normal. $\dot{V}/\dot{Q}$ scanning measures scintillation produced from a gamma ray–emitting atom and yields an image that plots the density of scintillations emitted from the chest using two phases. The perfusion images are usually obtained first and require a peripheral IV catheter for injection and the ability of the patient to sit up and lie down during the procedure. The ventilation component requires the patient to breathe into a nebulizer to inhale an aerosol that contains the isotope. A $\dot{V}/\dot{Q}$ scan with homogeneous scintillation throughout the lung in the perfusion portion has nearly 100% sensitivity in excluding PE, regardless of the appearance of the ventilation portion. A $\dot{V}/\dot{Q}$ scan with two or more apex central wedge-shaped defects in the perfusion phase (**Figure 56-6**) with normal ventilation in these regions indicates >80% probability of PE. All other $\dot{V}/\dot{Q}$ scan findings are nondiagnostic; taken alone, these cannot exclude or diagnose PE.

PULMONARY ANGIOGRAPHY Direct **pulmonary angiography** identifies a clot as a filling defect within the pulmonary artery. This test requires placement of a catheter into the pulmonary artery, usually through the femoral vein, followed by injection of 150 to 300 mL of contrast material. Advantages of direct pulmonary angiography include the ability to demonstrate filling defects in 3-mm or smaller vessels; the ability to measure pulmonary artery pressures; and the potential to treat PE with intrapulmonary catheter–directed modalities or to deploy a vena caval filter. Disadvantages of pulmonary angiography include lack of availability, radiation exposure, and the possibility of contrast-related complications, cardiac dysrhythmias, and rare cardiac or pulmonary arterial perforation.

Venous US **Venous US** is the imaging test of choice in DVT; it can be done quickly and does not use ionizing radiation. When performed by experienced ultrasonographers, it has a diagnostic sensitivity of 90% to 95% and a specificity of 95% for DVT, and venous US has a sensitivity of about 40% as a surrogate method to diagnose PE. The mean sensitivity for DVT of US performed by a trained emergency physician compared with the reference imaging test is 96.1% (95% CI, 90.6% to 98.5%), with a weighted mean specificity of 96.8% (95% CI. 94.6% to 98.1%).[42] However, the details of test performance and training remain important, as two-point compression US may miss some clots and new users require experience with at least 10 examinations before gaining adequate skill.

Compression ultrasonography operates on the principle that normal veins compress but thrombosed veins do not. A 7.5-MHz probe is used to visualize the common femoral, superficial femoral, and popliteal veins for comparison with the adjacent femoral and popliteal arteries. The sonographer manually compresses the probe and compares the flattening of the vein with that of the artery. If the vein compresses completely whereas the artery remains patent, this finding indicates "normal compressibility," and the absence of a thrombus is inferred (**Figure 56-7**). Conversely, if the vein does not compress, the examination is considered positive for a thrombus. The practice of examining the saphenous, tibial, and peroneal veins varies among centers.

The disadvantages of formal US include the need for specialized equipment and a qualified sonographer and radiologist. The examination can be difficult to perform in obese patients, and the probability of an indeterminate result increases with higher patient body mass index. The compression component of the examination causes pain in some patients and could promote clot embolization. Prior history of DVT can make it difficult to determine if venous noncompressibility represents an old or new clot. Color flow Doppler US can help identify recannulization, suggesting a chronic clot, which may not need anticoagulation.

Venography Indirect **CT venography** acquires axial images of the leg veins during the venous return phase minutes after the contrast is injected for chest CT angiography. At present, the low rate of clinical utility, increased gonadal radiation, poor technical resolution, and low interobserver reliability for distal DVT all point away from the value of routine CT venography in the workup of an ED patient with suspected PE.[43]

Planar venography requires injection of contrast material into a small vein in the foot with a proximal venous tourniquet. Subsequent images detail the entire leg venous system, identifying filling defects

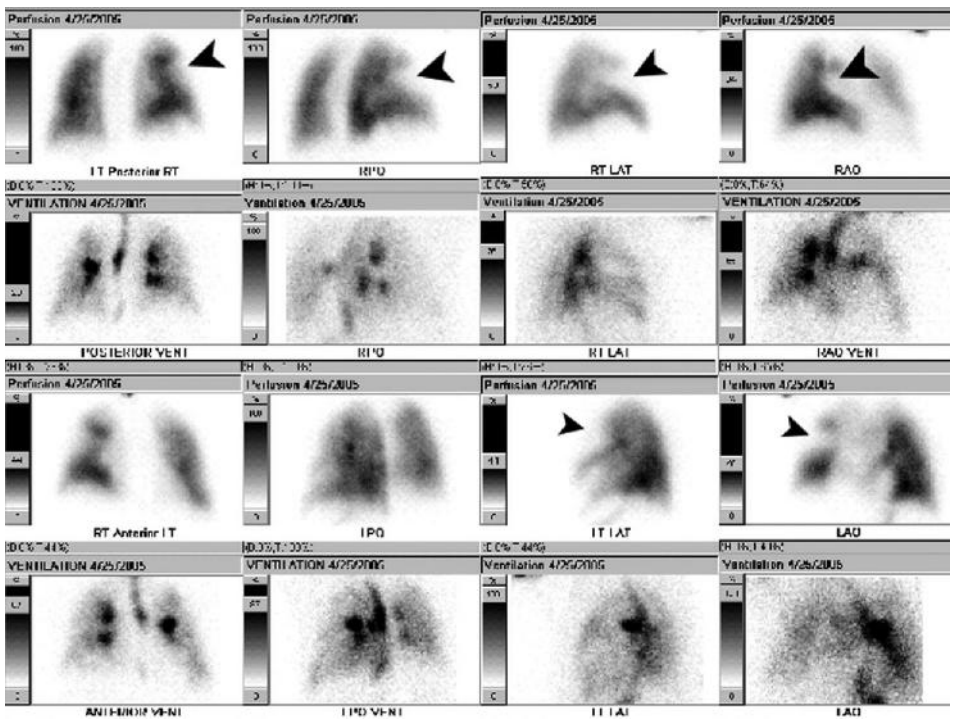

FIGURE 56-6. Ventilation–perfusion lung scan series consistent with a high probability of acute pulmonary embolism (PE) using standard criteria. The first and third rows project the perfusion phases of the examination, and the second and fourth rows show the ventilation phases. The *black arrowheads* point to wedge-shaped defects in the perfusion images. Comparison with the corresponding ventilation view immediately below shows relatively homogeneous scintillation activity in the anatomic segments that lack perfusion. These defects are consistent with an acute PE.

FIGURE 56-7. Compression venous US images showing normal findings and findings indicating deep venous thrombosis. **A.** Compression venous US of the common femoral vein and femoral artery. The left view shows a sonographic image of the right femoral artery (A) and common femoral vein (V) obtained immediately inferior to the inguinal ligament. The image on the right shows the same view after manual compression by the operator. The image demonstrates obliteration of the vein while the artery remains open. This is a normal US finding for the vein. **B.** Venous US image showing evidence of common left femoral vein thrombosis after compression (right panel). The common femoral vein (V) does not compress. Echogenic thrombolytic material can be observed within the vein.

anywhere from the distal calf up to the iliac vein. Because alternative diagnostic imaging is readily available and a contrast-induced leg clot can result from the test in 10% to 15% of uses, venography is now rarely performed.

INTEGRATED APPROACH TO DIAGNOSIS AND TREATMENT

STEP ONE

For a patient to enter a PE testing regimen, he or she should have at least one physiologic manifestation of PE. This may be a symptom (e.g., pain in the chest or torso, a breathing problem, or altered mental status) or a finding (e.g., an abnormal vital sign) that could be produced by a clot in the lung. The physiologic manifestation must be placed in the context of the given patient—an untreated asthmatic patient with shortness of breath and wheezing should be treated first for bronchospasm and reevaluated and not immediately tested for PE. A risk factor for PE in the absence of a known sign or symptom ***does not*** mandate testing for PE or DVT.

STEP TWO

After finding a physiologic manifestation of PE, the next step is to ask, "Do I have more than a low initial suspicion for PE?" Low suspicion means that the physician's gestalt interpretation of the overall clinical picture is PE presence of <15%. If the answer to this question is yes, then a diagnostic test is needed. If the answer is no, then it remains possible that PE can be excluded using the PE rule-out criteria rule. If all eight criteria of the PE rule-out criteria rule are met in the setting of a gestalt-based low suspicion, then no further testing is necessary.[27] In general, if any one of the eight criteria is not met or a prominent finding exists, order a diagnostic test for PE.

STEP THREE

If PE cannot be excluded with the PE rule-out criteria rule, choose a diagnostic test result that can produce a posttest probability of <2.0%. An age-adjusted quantitative D-dimer assay is the best diagnostic test in patients for whom clinical suspicion is low or moderate based on either gestalt estimation, a Wells' score of ≤4, or a "safe" designation according to the Charlotte rule. Before ordering a D-dimer assay, consider factors could separately elevate the D-dimer concentration and impair the utility (**Table 56-9**).

STEP FOUR

Test further only those with a positive D-dimer result; base the choice of the next test on patient and facility factors. The algorithm presented in Figure 56-2 is one path. In general, the next best step for a patient with suspected PE and a positive D-dimer result is chest CT angiography. $\dot{V}/\dot{Q}$ scan is an option in a pregnant patient or a patients with renal insufficiency or prior adverse reaction to contrast material. Performing lower extremity venous US is another option; it lacks ionizing radiation and its ability to diagnose DVT in a patient with PE symptoms is tantamount to diagnosing PE directly. However, **the diagnostic sensitivity of lower extremity US for PE is <40%,** so all patients suspected of having PE for whom US findings are negative require pulmonary vascular imaging.

To diagnose VTE, the clinical assessment and diagnostic tests usually must have a probability of 80% or greater, which is achievable with

TABLE 56-9 Likelihood Ratios (LRs) of Diagnostic Tests and Pretest Probabilities Required to Diagnose or Exclude Pulmonary Embolism (PE)

Test	LR for PE if Test Result Is Negative	LR for PE if Test Result Is Positive*	Examples of Scores on Published Methods That Would Allow Pretest Probability to Rule Out VTE if Test Result Is Negative
Qualitative D-dimer	0.25	2	Wells' score <2, all pulmonary embolism rule-out criteria negative
Quantitative D-dimer†	0.1	2	Gestalt estimate low, Wells' score ≤4, or Charlotte rule negative ("safe") Age-adjustment of the D-dimer cutoff using the formula age × 10 nanograms/mL
CT angiography	0.12	12	Gestalt estimate low, Wells' score ≤4, or Charlotte rule negative ("safe")
$\dot{V}/\dot{Q}$ scan: normal	0.05	NA	Any
$\dot{V}/\dot{Q}$ scan: high probability	NA	12	NA

Abbreviations: NA = not applicable; $\dot{V}/\dot{Q}$ = ventilation–perfusion; VTE = venous thromboembolism.

*A positive D-dimer result should not be used to rule in VTE.

†Assumes a US Food and Drug Administration–cleared assay with cutoff of 500 nanograms/mL as threshold.

positive CT findings or high-probability V̇/Q̇ scan results or venous US with findings indicative of DVT. Lesser probability means VTE may be present but is still clinically uncertain.

A low-risk patient with a CT scan demonstrating a large filling defect in the main pulmonary artery surely has a PE. In contrast, a low-risk patient with a CT image that is partially obscured by motion artifact and an eccentric filling defect in a segmental artery with lung consolidation needs more testing. With an indeterminate CT scan, options are venous US and a quantitative D-dimer assay. If the venous US results are positive, assume and treat for PE. If the US results are negative but the D-dimer concentration is eightfold higher than the upper limit of normal, the likelihood of acute VTE is high and supports therapy.

If the patient has no image-detected DVT or PE and has a normal or marginally elevated D-dimer concentration, then further imaging before anticoagulation is started is an option, especially if the patient has any increased risk of bleeding complications. The combination of a small, irregular filling defect on a suboptimal-quality CT angiogram, together with evidence of no DVT, a normal or even marginally elevated D-dimer concentration (<150% of the threshold), and a low-probability V̇/Q̇ scan result, supports a decision not to initiate anticoagulation in a patient with normal or near-normal vital signs and oxygenation. Commonly, a repeat venous US within 2 to 7 days can help exclude VTE.

Patients with PE detected until after admission from the ED have a higher frequency of altered mental status and preexisting heart or lung diseases.[44-47] Of those discharged home with PE detected later, the clinical features often are a lack of dyspnea, sharp chest pain or hemoptysis with a pulmonary infiltrate on imaging (an infarct masquerading as infection), or a lower D-dimer concentration and a small distal clot seen on pulmonary vascular imaging.[46] More evidence is needed to determine if these patients actually benefit from systemic anticoagulation absent concomitant DVT.

Figure 56-8 is one algorithm describing the diagnostic decision making for DVT. Evaluate first using the Wells' criteria for pretest probability of DVT (Table 56-6). Patients with a low pretest probability (score <1) or patients without cancer, a modified Wells DVT score ≤1, and a normal D-dimer result are safely considered negative for DVT; any positive result requires US in this group. Patients with moderate to high Wells' scores or DVT likely (modified Wells DVT score) should undergo US testing, assessing D-dimer only if the US result is negative. In these subjects, assume no clot exists if both US and D-dimer tests are negative; if they have negative US findings and positive D-dimer results, repeat the US 2 to 7 days later.

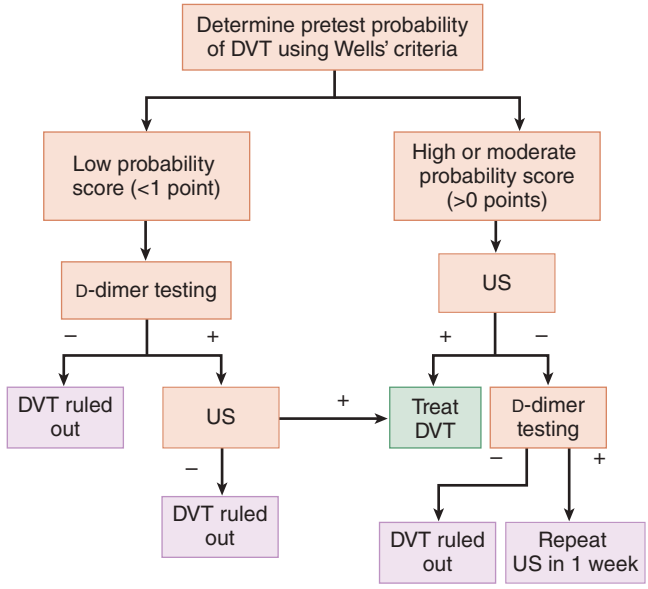

FIGURE 56-8. Diagnostic algorithm for deep vein thrombosis (DVT), applied in patients with leg symptoms compatible with DVT. + = positive test result; – = negative test result.

VENOUS THROMBOEMBOLISM TREATMENT

TREATMENT OF PULMONARY EMBOLISM AND DEEP AND SUPERFICIAL EXTREMITY THROMBOSES

Treatment of VTE requires systemic anticoagulation to prevent further clot formation and allow endogenous fibrinolysis to proceed. In many cases, the initial treatment for VTE is heparin or heparin-like drug. The two most common options are unfractionated heparin or a low-molecular-weight heparin (**Table 56-10**).[6] Initial anticoagulation treatment for VTE can also include oral rivaroxaban.[6] It is anticipated that apixaban will soon have US Food and Drug Administration approval for VTE. Dabigatran can also be used but requires anticoagulation with heparin for several days.

Current data favor the use of low-molecular-weight heparins over unfractionated heparin for treatment of both PE and DVT in terms of composite outcomes (bleeding and death) and cost, although the magnitude of benefit is not large.[6] If uncertain about PE presence, the likelihood can guide anticoagulation therapy; the benefit of empiric anticoagulation for 24 hours exceeds the risks (bleeding and heparin-induced thrombocytopenia) for any patient with a pretest probability of PE of >20%.[48] Delay in administration of heparin to patients with PE is associated with increased mortality, but no study has found that heparin, administered early and prior to imaging, improves morbidity or mortality.

In patients with severe renal insufficiency and acute DVT or PE, most experts recommend unfractionated heparin over low-molecular-weight heparin.[6] **Treat upper extremity DVT the same as lower extremity DVT**, and remove any indwelling catheters associated with clot. Heparin interferes with a few of the assays of enzymatic activity (lupus anticoagulant and endogenous proteases) used to diagnose thrombophilia; however, **do not delay unfractionated heparin for any added**

TABLE 56-10 Antithrombotic Therapy for Deep Venous Thrombosis (DVT) and Pulmonary Embolism (PE)

	Dosage	Comments
Unfractionated heparin	80 units/kg bolus, then 18 units/kg/h infusion	Recommended if outpatient therapy not appropriate or in cases of severe renal failure
LMWHs		Outpatient treatment with LMWH preferred
Dalteparin	100 IU/kg SC every 12 h or 200 IU/kg SC every day	
Enoxaparin	1 milligram/kg SC every 12 h or 1.5 milligrams/kg SC every day	
Tinzaparin	175 IU/kg SC every day	
Factor Xa inhibitors		
Fondaparinux	<50 kg, 5 milligrams SC every day; 50–100 kg, 7.5 milligrams SC every day; >100 kg, 10 milligrams SC every day	Do not use in renal failure
Target-specific anticoagulants		
Rivaroxaban (Xarelto®)	15 milligrams BID for 21 d, then 20 milligrams every day with food	No heparin requirement; good choice for outpatient treatment
Apixaban (Eliquis®)	10 milligrams BID for 7 days then 5 mg BID	No heparin requirement; good choice for outpatient treatment
Dabigatran (Pradaxa®)	150 milligrams BID	Requires run in of heparin for 5–10 d; renal excretion
Thrombolytic therapy	Tissue plasminogen activator or alteplase (Activase®), 10-milligram IV bolus followed by 90 milligrams infused over 2 h	For PE with hemodynamic compromise; after infusion, begin unfractionated heparin or LMWH

Abbreviations: BID = twice a day; FDA = Food and Drug Administration; LMWH = low-molecular-weight heparin; VTE = venous thromboembolism.

thrombophilia testing when VTE is clearly present, because the evaluation can be postponed to the future. No evidence demonstrates any clinical benefit to a thrombophilia evaluation in guiding the intensity or duration of anticoagulation.[49]

DVT that causes **phlegmasia cerulea dolens** requires rapid action to reduce the venous pressure. In addition to initiating anticoagulation, place the affected limb at a neutral level; remove constrictive clothing, cast, or dressing; and arrange for consultant-delivered catheter-directed thrombolysis. If no such service is available and emergency transfer cannot be arranged within 6 hours, consider systemic fibrinolytics if there are no absolute contraindications. One regimen is 50 to 100 milligrams of alteplase infused IV over 4 hours.

TREATMENT FOR SUPERFICIAL THROMBOPHLEBITIS

Treatment for localized superficial thrombophlebitis is an oral nonsteroidal anti-inflammatory drug or topical diclofenac gel until symptoms resolve; there is no need for systemic anticoagulation. For extensive superficial vein involvement, full-dose anticoagulation is recommended.[6] Compression stockings do not aid this condition.[50]

TREATMENT FOR ISOLATED CALF VEIN THROMBOSIS

There are no universally accepted treatment guidelines for thromboses isolated to the calf veins (soleal or gastrocnemius) or the saphenous vein, although many use 3 months of oral anticoagulation. Alternatives include no acute treatment with repeat US in 1 week to identify progression of clot, or outpatient treatment with low-molecular-weight heparin (Table 56-10). Patients with a history of VTE or risk factors for VTE (Table 56-1) should receive 3 months of full-dose anticoagulation when calf thrombosis exists unless contraindications are present.[6]

OUTPATIENT TREATMENT OF PULMONARY EMBOLISM

Patients with DVT diagnosed in the ED are typically discharged after receiving the first dose of low-molecular-weight heparin (Table 56-10) and with anticoagulation continued as an outpatient. More recently, many centers have begun the same practice for carefully selected low-risk patients with PE. Patients with PE and a low risk of death plus adequate home support can qualify for outpatient anticoagulation. The incidence of short-term mortality and the bleeding risk are very low with outpatient treatment, the overall cost of care is less, and the experience is preferred by patients.[51,52] Select low-risk patients using either the Hestia criteria or the Simplified PE Severity Index criteria (**Table 56-11**).[13,53] If low risk, assess the patient's wishes and ability to comply; if no high-risk features exist (elevated troponin, a B-type natriuretic peptide >100 picograms/mL, pulmonary arterial hypertension on ECG, or bleeding risks), outpatient care after an ED stay (up to 23 hours) is an option; otherwise, short-term hospitalization is a good choice.

In practice, the biggest barrier to ED discharge of any VTE patient is ensuring access to anticoagulation. If warfarin is the long-term anticoagulant, the patient must receive low-molecular-weight heparin until the prothrombin time is adequately prolonged *and* for at least 5 days.[6] For low-molecular-weight heparin, patients or their families must learn how to administer subcutaneous injections, have access to drug, have a follow-up appointment where the prothrombin time can be monitored, and have dosing advice given, which are all challenges in some EDs. At this time, only one newer oral anticoagulant, rivaroxaban (Xarelto®), is approved for both DVT and PE. This drug does not require blood monitoring or dosing adjustment for body size. The primary limitation to rivaroxaban is cost, although the manufacturer offers a patient assistance program, and it is on Medicaid and Medicare formularies.

FIBRINOLYSIS FOR PULMONARY EMBOLISM

PE is classified into three categories based on severity: massive, submassive, and less severe PE. **Massive PE** patients have a systolic blood pressure of <90 mm Hg for >15 minutes, a systolic blood pressure of <100 mm Hg with a history of hypertension, or a >40% reduction in baseline systolic blood pressure. **Submassive PE** patients have normal or near-normal blood pressure, but with other evidence of cardiopulmonary stress (**Table 56-12**).

All other PE cases are classified as "less severe." Patients with low-risk PE should not receive fibrinolysis; those with massive PE (defined as a systolic blood pressure <90 mm Hg or an observed decrease of 40 mm Hg) benefit from fibrinolysis. Patients with more severe submassive PE (i.e., causing right ventricular dilation or hypokinesis, elevated troponin or B-type natriuretic peptide, or persistent hypoxemia with distress) may also benefit from fibrinolysis, including higher survival and better quality of life although at a higher bleeding risk.[54-55]

Systemic Fibrinolysis The best evidence suggests **considering systemic fibrinolysis in patients with no contraindications to fibrinolysis**

TABLE 56-11 Two Prognostic Systems That Can Select Low-Risk Patients for Outpatient Treatment

Simplified PE Severity Index Score
0 = low risk; 1 = high risk
Age >80
History of cancer
History of heart failure or chronic lung disease
Pulse >110 beats/min
SBP <100 mm Hg
O_2 saturation <90%
Hestia Criteria
Identifies low-risk PE if:
SBP >100 mm Hg
No thrombolysis needed
No active bleeding
No O_2 required >24 h to maintain saturation >90%
Not already anticoagulated
Absence of severe pain requiring IV narcotics for >24 h
Absence of other medical or social reasons to admit
Creatinine clearance >30 mL/min
Not pregnant, no severe liver disease or HIT

Abbreviations: HIT = heparin-induced thrombocytopenia; PE = pulmonary embolism; SBP = systolic blood pressure.

TABLE 56-12 Modalities to Risk-Stratify Pulmonary Embolism (PE)

Test	Less Severe PE	More Severe PE (massive and some submassive PE)
Hestia criteria	All negative	Any positive
PE Severity Index score	<80	>120
Simplified PE Severity Index criteria	All negative	Any positive
Shock index (heart rate/systolic blood pressure)	<1.0	≥1.0
Pulse oximetry reading	>94%	<95%
Echocardiography	Normal RV systolic function Normal RV size No tricuspid regurgitation	RV hypokinesis RV dilation RVSP >40 mm Hg
Troponin I or T level	Normal	Elevated
B-type natriuretic peptide level	<90 picograms/mL	≥90 picograms/mL
N-terminal pro-B-type natriuretic peptide	<900 picograms/mL	≥900 picograms/mL
D-Dimer level	<4000 nanograms/mL	>8000 nanograms/mL
Serum sodium concentration	<125 mEq/L	≥125 mEq/L

Abbreviations: RV = right ventricular; RVSP = right ventricular systolic pressure.

and any of the following: cardiac arrest; hypotension; respiratory failure, evidenced by severe hypoxemia (pulse oximetry reading <90%) despite oxygen administration, together with evidence of increased work of breathing; or evidence of right-sided heart strain on echocardiography or elevated levels of troponin T or I, or both (**Table 56-12**). **Major contraindications to thrombolytic therapy** include intracranial disease, uncontrolled hypertension at presentation, recent major surgery or trauma (past 3 weeks), and metastatic cancer. Any patient with head trauma from syncope should have a CT scan prior to therapy to detect hemorrhage. **Alteplase** (tissue plasminogen activator) is the only currently approved agent for PE, dosed 100 milligrams IV over 2 hours. Either enoxaparin (1 milligram/kg SC) or unfractionated heparin (80 units/kg IV bolus followed by 18 units/kg/h) is the anticoagulant, with the activated partial thromboplastin time kept at <120 seconds for unfractionated heparin. Heparin or low-molecular-weight heparin is typically started after the thrombolytic infusion. For further discussion of fibrinolytic agents, see the chapter 239, "Thrombotics and Antithrombotics."

Catheter-Directed Thrombolysis Two randomized trials have tested the utility of catheter-directed, intrapulmonary delivery of tissue plasminogen activator and found better outcomes than heparin alone, but not better than systemic tissue plasminogen activator.[56] In view of these study results, as well as the risks of pulmonary arterial catheterization and associated drug delivery delay due to the need to activate the vascular intervention suite, intrapulmonary fibrinolytic delivery is not used in most patients with massive PE.[57] However, catheter-directed thrombolysis for PE requires a far lower dose of alteplase (approximately 10 milligrams total), which may confer a lower bleeding risk. Thus, catheter-directed thrombolysis is an option for patients over 65 years old, where intracranial bleeding risk is highest.[54] Alternatively, 50 milligrams of systemic IV alteplase—half of the Food and Drug Administration–approved dose—is an option with safety advantages.[58] Tiered-dose tenecteplase (TNKase®: <60 kg: 30-milligram dose; ≥60 to <70 kg: 35-milligram dose; ≥70 to <80 kg: 40-milligram dose; ≥80 to <90 kg: 45-milligram dose; ≥90 kg: 50-milligram dose) appears to offer similar effectiveness as alteplase, although it is not yet approved by the Food and Drug Administration for PE.

Surgical Embolectomy If available, surgical embolectomy is an option in young patients with large, proximal PE accompanied by hypotension. Because surgical embolectomy is often delayed, the reported mortality rate is approximately 30%. The amount of clot that can be extracted is often extensive, and removal may help limit later cardiopulmonary complications.

DISPOSITION AND FOLLOW-UP

Patients with severe PE or receiving any thrombolysis/extraction generally are placed in an intensive care unit (**Table 56-13**). Outpatient treatment of DVT and PE is favored in low-risk patients who can adhere to therapy. Indications for admission in patients with DVT are listed in Table 56-13.

TABLE 56-13 Indications for Hospital Admission in Patients with Deep Venous Thrombosis[59]

An extensive iliofemoral deep venous thrombosis with circulatory compromise
An increased risk of bleeding (coagulopathy, active peptic ulcer disease, liver disease) that requires close monitoring of therapy
A limited cardiorespiratory reserve that suggests need for additional care such as monitoring for hypoxemia
A risk of poor compliance with home therapy regimen or inadequate support (i.e., community, social, or medical), or concern with ability to arrange follow-up
A contraindication to use of low-molecular-weight heparin, and inability to use an oral target-specific anticoagulant, which would necessitate IV heparin therapy
Known or suspected coexistent pulmonary embolism with a Simplified Pulmonary Embolism Severity Index score >0 or Hestia criteria positive
A high suspicion of heparin-induced thrombocytopenia without or with thrombosis
Renal insufficiency requiring monitoring of anti–factor Xa level, or use of unfractionated heparin

SPECIAL POPULATIONS

PREGNANCY

If the general patient has a high pretest probability by Wells' or the revised Geneva score, then proceed to pulmonary vascular imaging.[60] However, in pregnant women, limiting fetal exposure to radiation and iodinated contrast is preferred.[61] One study measured D-dimer levels in 228 pregnant women with suspected DVT and found a prevalence of DVT in the study population of 6.6%.[62] See chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period" especially the section on thromboembolic disease of pregnancy.

ISOLATED SUBSEGMENTAL PULMONARY EMBOLISM

Isolated subsegmental PE refers to a filling defect seen in one small pulmonary artery, usually <3 mm in diameter and in the absence of DVT; radiologists often do not agree when viewing these images separately. The incidence of subsegmental PE identification has increased sharply with increased resolution of multidetector-row CT scanning, but the clinical significance is unclear.[63] This raises concern that subsegmental PE may be a radiographic artifact rather than a true disease. Most experts agree that treatment is best in those with subsegmental PE and active cancer; no strong data support the safety of withholding anticoagulation in others with this finding; most still receive standard anticoagulation for 3 to 6 months.[6] It is best to discuss the risks and benefits of treatment of subsegmental PE with patients and their physicians to help make the best decision about anticoagulation.

CANCER PATIENTS WITH VENOUS THROMBOEMBOLISM

Current data and guidelines recommend treatment of patients with active cancer with low-molecular-weight heparin for at least 6 months.[64] Some patients cannot give themselves injections for prolonged periods of time, forcing the choice between oral warfarin versus an oral newer anticoagulant. Pooled data from four newer agent trials in cancer-related VTE (dabigatran, rivaroxaban, and edoxaban) show better outcomes with thrombin or factor Xa inhibitors compared with warfarin.[65] About 2% of cancer patients undergoing staging and surveillance CT scanning have incidental PE detected. These patients are treated with anticoagulation, often at home if low risk.[66,67]

CHAPTER 57

Systemic Hypertension

Brigitte M. Baumann

INTRODUCTION AND EPIDEMIOLOGY

Hypertension affects approximately 30% of the U.S. population, and 1% to 6% of all ED patients will present with severe hypertension.[1-5] Of the latter, between a third and one half will have end-organ damage.[2-5] Risk factors for the development of hypertensive crisis include obesity, cigarette smoking, and older age.[6]

Chronic hypertension is categorized into three classifications: prehypertension, stage 1 hypertension, and stage 2 hypertension[7] (**Table 57-1**).

Hypertensive emergency is an acute elevation of blood pressure (≥180/120 mm Hg) associated with end-organ damage; the targeted end organs include the brain, heart, aorta, kidneys, or eyes[7] (**Table 57-2**). Acute hypertensive emergencies are more common in

TABLE 57-1 JNC7 Classification of Hypertension

Class	Systolic BP (mm Hg)		Diastolic BP (mm Hg)
Normal	<120	and	<80
Prehypertension	120–139	or	80–89
Stage 1	140–159	or	90–99
Stage 2	≥160	or	≥100

Abbreviations: BP = blood pressure; JNC7 = Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

TABLE 57-2 Hypertensive Emergencies

Diagnostic Category	Signs and Symptoms	Evidence of Acute End-Organ Damage
Acute aortic dissection	Chest pain, back pain Unequal blood pressures (>20 mm Hg difference) in upper extremities	Abnormal CT angiogram of chest and abdomen/pelvis or transesophageal echocardiogram of the aorta
Acute pulmonary edema	Shortness of breath	Interstitial edema on chest radiograph
Acute myocardial infarction	Chest pain, nausea, vomiting, diaphoresis	Changes on ECG or elevated levels of cardiac biomarkers
Acute coronary syndrome	Chest pain, nausea, vomiting, diaphoresis	Clinical diagnosis, changes on ECG, or elevated levels of cardiac biomarkers
Acute renal failure	May have systolic or diastolic abdominal bruit	Elevated serum creatinine level, proteinuria
Severe pre-eclampsia, HELLP syndrome, eclampsia	Seizures	Proteinuria, hemolysis, elevated liver enzyme levels, low platelet counts
Hypertensive retinopathy	Blurred vision	Retinal hemorrhages and cotton-wool spots (**Figure 57-1**), hard exudates, and sausage-shaped veins
Hypertensive encephalopathy	Altered mental status, nausea, vomiting, headache	May see papilledema or arteriolar hemorrhage or exudates on funduscopic examination, may note cerebral edema with a predilection for the posterior white matter of the brain on MRI
Subarachnoid hemorrhage	Headache, focal neurologic deficits	Abnormal CT of the brain; red blood cells on lumbar puncture
Intracranial hemorrhage	Headache, new neurologic deficits	Abnormal CT of the brain
Acute ischemic stroke	New neurologic deficits	Abnormal MRI or CT of the brain
Acute perioperative hypertension	Bleeding unresponsive to direct pressure	Clinical diagnosis; manifestations of other hypertensive emergencies
Sympathetic crisis*	Anxiety, palpitations, tachycardia, diaphoresis	Clinical diagnosis in the setting of sympathomimetic drug use (i.e., cocaine or amphetamines) or pheochromocytoma (24-h urine assay for catecholamines and metanephrine or plasma fractionated metanephrines)

Abbreviation: HELLP = hemolysis, elevated liver enzymes, low platelets.

*In this syndrome, acute end-organ dysfunction may not be measurable, but complications affecting the brain, heart, or kidneys may occur in the absence of acute treatment.

FIGURE 57-1. Hypertensive retinopathy. Scattered flame (splinter) hemorrhages and cotton-wool spots (nerve fiber layer infarcts) in a patient with headache and a blood pressure of 234/120 mm Hg.

chronic hypertensive patients who fail to adhere to their antihypertensive therapy regimens and those who are unable to access outpatient health care.[6]

Hypertensive urgency is a term for profound elevations in blood pressure without acute target organ dysfunction.[7] An arbitrary blood pressure of ≥180/120 mm Hg is often cited as an urgency and an indication for rapid pharmacologic intervention (often parenteral) to reduce blood pressure within hours; however, no clear clinical benefit of such treatment exists, and risk can occur from precipitous drops in blood pressure.[8,9] Hypertensive urgency is better seen as another form of severe hypertension where prompt therapy with oral agent(s) is the best path, seeking reduction in blood pressure over days to weeks.

PATHOPHYSIOLOGY

At baseline, chronic hypertensive patients have biochemical and structural changes in the arterial walls that shift the vascular autoregulatory curve, requiring higher arterial pressures to maintain end-organ blood flow, notably in the brain.[10-12] Eventually, the ability to adapt is passed. The resultant mechanical wall stress and endothelial injury lead to increased permeability, and excessive perfusion of the cerebral, cardiac, and renal vascular beds results. This can be followed by activation of the coagulation cascade and platelets, and deposition of fibrin results in fibrinoid necrosis of the arterioles. Clinically, this is manifested by hematuria (involvement of the renal vasculature) or arterial hemorrhages or exudates on funduscopic examination. Further contributing to the damage are prostaglandins, free radicals, cytokines, and mitogenic, chemoattractant, and proliferation factors, which result in endothelial damage, smooth muscle proliferation, and thrombosis.[10,12] The renin-angiotensin system may also be activated, which leads to vasoconstriction. Pressure natriuresis occurs, leading to volume depletion, prompting additional release of vasoconstrictors from the kidney. These combined effects produce hypoperfusion, ischemia, and dysfunction of end organs. Endothelial dysfunction from such crises can persist for years after the acute event.[13]

CLINICAL FEATURES

Measure blood pressure in both arms quickly and consecutively, while the patient is quietly resting. Check blood pressure several times before starting antihypertensive therapy. Blood pressure differences can result from aortic dissection, coarctation, peripheral vascular disease, and some unilateral neurologic and musculoskeletal abnormalities.

TABLE 57-3 Specific Diseases Associated with Elevated Blood Pressures

Disease	Threshold Value Raising Risk	% of Patients with Elevated Pressures
Subarachnoid hemorrhage[20]	≥140 mm Hg SBP	100%
Ischemic stroke[20,21]	≥140 mm Hg SBP ≥160 mm Hg SBP	77%–82% 47%–54%
Intracerebral hemorrhage[20]	≥140 mm Hg SBP ≥160 mm Hg SBP	75% 27%
Type B aortic dissection[22,23]	≥140 mm Hg SBP or ≥90 mm Hg DBP	67%–77%
Type A aortic dissection[24]	>150 mm Hg SBP	36%–74%
Acute heart failure[25]	>140 mm Hg SBP	54%
NSTEMI-ACS[25,26]	≥140 mm Hg SBP ≥160 mm Hg SBP	57%–59% 31%

Abbreviations: BP = diastolic blood pressure; NSTEMI-ACS = non-ST-segment elevation myocardial infarction acute coronary syndrome; SBP = systolic blood pressure.

However, interarm blood pressure differences are also reported in "normal" individuals. The most important factor in blood pressure difference is increasing age, with the thought that loss of vascular elasticity or asymmetrical atheromatous narrowing of subclavian or brachial arteries might be causative. Although there are no guidelines or standards for determining the significance of blood pressure measurement disparities, a between-arm difference >10 to 20 mm Hg is suggested as meaningful,[14,15] and each 10-mm Hg difference carries an increasing mortality hazard. **When a blood pressure difference is detected, treat the higher blood pressure and make sure that subsequent measurements are made on the same arm.**[15] Blood pressure measurements with wrist oscillometric devices give lower readings than arm measurements, so arm measurements are preferred.[16] Use the same device for repeat blood pressure measurements.

After careful blood pressure measurement, the next question in a patient with severely elevated blood pressure is whether this constitutes a hypertensive crisis. Although a modest drop (4 to 12 mm Hg) in systolic and diastolic blood pressures can be expected in patients presenting with elevated blood pressures,[17-19] do not discount a diagnosis of hypertensive emergency simply because the patient has no prior history of hypertension. Up to 16% of patients presenting with hypertensive emergency have no known history of hypertension.[4] The key is to seek acute end-organ involvement.

Table 57-3 lists the proportion of patients who present with elevated blood pressure by stroke subtypes, aortic dissection subtypes, heart failure, and acute coronary syndrome. Although elevations in blood pressure accompany the majority of these presentations, note that **severe** elevations of blood pressure are far less common in presentations typically labeled as hypertensive emergencies (Table 57-2).

CHEST PAIN AND SEVERE HYPERTENSION

Rapid diagnosis and treatment of acute aortic dissection are critical because delays increase mortality. Differentiating the relatively uncommon aortic dissection from the more common acute coronary syndromes is important because blood pressure management is different in these two disorders, and anticoagulation can prove catastrophic in a patient with acute aortic dissection.[27]

Acute aortic dissection presents with abrupt, sudden onset of pain, usually in the chest, often described as tearing or ripping, and radiating to the interscapular region[23,28] (see chapter 59, "Aortic Dissection and Related Aortic Syndromes"). Less than a quarter of patients with acute aortic dissection have a neurologic deficit or pulse deficits based on blood pressure differentials ≥20 mm Hg, and only about a third have a diastolic murmur. Chest radiograph is abnormal in most but usually nonspecific, and only 25% of radiographs demonstrate the classic widened mediastinum,[24] so CT of the chest is needed for the diagnosis. ECG changes are nonspecific, but <10% demonstrate findings consistent with a myocardial infarction.[24] D-Dimer testing cannot be used in isolation to exclude the diagnosis, but elevated D-dimer and C-reactive protein levels are associated with higher in-hospital mortality.[29,30]

FIGURE 57-2. Intracerebral hypertensive hemorrhage. Noncontrast head CT scan with acute intraparenchymal hemorrhage, mass effect, midline shift, and intraventricular extension. [Image used with permission of Todd Siegal, MD.]

ACUTE NEUROLOGIC SYMPTOMS AND SEVERE HYPERTENSION

Elevated blood pressure, headache, and focal neurologic deficits are associated with either ischemic or hemorrhagic strokes. Acute ischemic strokes may be diagnosed with MRI, and cerebral hemorrhage is identified on head CT (see chapter 167, "Stroke Syndromes") (**Figure 57-2**).

Hypertensive encephalopathy is a clinical diagnosis after excluding focal ischemia or bleeding. It is characterized by altered mental status, headache, vomiting, seizures, or visual disturbances, and most patients will have papilledema. When MRI findings demonstrate reversible edema that is primarily focused posteriorly (occipital vs frontal regions), this is referred to as **posterior reversible encephalopathy syndrome** (**Figure 57-3**).

ACUTE RENAL FAILURE, PERIPHERAL EDEMA, AND SEVERE HYPERTENSION

Patients with new-onset renal failure may have peripheral edema, oliguria, loss of appetite, nausea and vomiting, orthostatic changes, or confusion. However, some patients have few or no specific symptoms (see chapter 88, "Acute Kidney Injury"). Elevated serum creatinine confirms the diagnosis, and urinary sediment is also abnormal.

Pre-eclampsia is associated with hypertension, peripheral edema, and proteinuria. These patients may also develop hemolysis, elevated liver enzyme levels, and low platelet counts (HELLP syndrome) (see chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period").

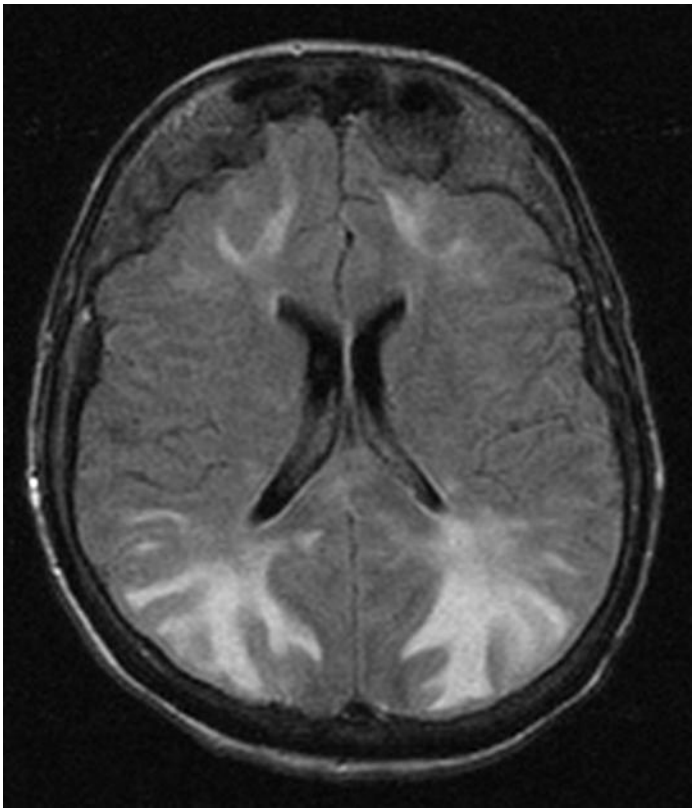

FIGURE 57-3. Axial fluid-attenuated inversion recovery MRI showing white matter hyperintensity in the occipital lobes bilaterally consistent with posterior reversible encephalopathy syndrome. The patient's confusion improved with blood pressure control. Repeat MRI after several days of therapy demonstrated remarkable improvement. [Image used with permission of Michael Farner, MD.]

SYMPATHETIC CRISIS AND SEVERE HYPERTENSION

There are four settings in which an excess of catecholamines can result in a hypertensive emergency. An acute catecholaminergic syndrome may occur with abrupt discontinuation of oral or transdermal **clonidine**. The withdrawal syndrome is potentiated by concomitant β-blocker therapy due to unopposed α-mediated vasoconstriction.

Pheochromocytoma is rare, and between 5% and 20% of tumors are malignant. Patients may experience life-threatening hypertension.[31] Signs of pheochromocytoma include headache, alternating periods of normal and elevated blood pressure, tachycardia, and flushed skin, punctuated by asymptomatic periods.

Sympathomimetic drugs such as cocaine, amphetamines, phencyclidine hydrochloride (PCP), and lysergic acid diethylamide (LSD), can precipitate a hypertensive emergency, with tachycardia, diaphoresis, chest pain, and, depending on the agent, mental status changes.[32] Patients receiving **monoamine oxidase inhibitor** therapy who consume tyramine-containing foods may develop a hyperadrenergic state.[33] **Autonomic dysfunction** due to spinal cord or severe head injury or abnormalities such as spina bifida may also present as a hypertensive emergency, with the diagnosis made clinically based on the existing injury.

ASYMPTOMATIC PATIENTS WITH SEVERE HYPERTENSION

Formal recommendations for the evaluation of an ED patient presenting with asymptomatic but severe hypertension do not exist.[9] Commonly ordered tests include basic metabolic panel (73%), ECG (53%), chest radiograph (46%), and urinalysis (43%).[3] In a prospective study of over 100 ED patients with asymptomatic severe hypertension, clinically meaningful results existed in only 6% of patients, with only 5% of patients thought to have abnormal results attributable to acute hypertensive target organ injury.[34] Until more data are available, base ED evaluation on the patient complaint, history, and review of systems, and perform selected testing.

TREATMENT

Table 57-4 lists agents for the management of hypertensive emergencies categorized by diagnosis. Hypertensive emergencies in pregnancy are discussed in chapter 100. In selecting therapy, be familiar with the use of the selected agent, and establish a target range for blood pressure reduction. The goal is to minimize end-organ damage by initial blood pressure reduction while avoiding hypoperfusion of cerebral, coronary, and renovascular beds. **Acute aortic dissection is the exception, because the risk of morbidity and mortality due to inadequate blood pressure and heart rate control outweighs the risk of hypoperfusion syndromes.**

AORTIC DISSECTION

The therapeutic goal in acute aortic dissection is a systolic blood pressure between 100 and 140 mm Hg and a heart rate ≤60 beats/min.[23,35-37] The resultant reduction in tachycardia decreases the shearing forces and aortic wall stress, limiting the progression of the dissection.[37] Pain control with opioids helps to decrease sympathetic tone.

ACUTE HYPERTENSIVE PULMONARY EDEMA

The treatment of hypertensive pulmonary edema is tailored to the underlying pathophysiology, which could be due to transient left ventricular systolic or diastolic dysfunction, acute dyssynchrony, or ischemic mitral regurgitation. Occasionally, the left ventricular ejection fraction may be normal during the acute episode with only a decrease in systolic function and increased diastolic stiffness and filling pressures, suggesting decreased myocardial capacity to adapt to changes in loading.[39,67] For these reasons, there are no clear evidence-based guidelines for the single best treatment of hypertensive pulmonary edema.

The mainstay of therapy is vasodilators and intravenous diuretics.[39] Intravenous, sublingual, and topical nitrates reduce blood pressure, decrease myocardial oxygen consumption, and improve coronary blood flow.[39,40,68] Diuretics improve symptoms within 6 hours of administration but may not ultimately affect mortality. Be careful using loop diuretics in combination with **nesiritide**, or to a lesser degree **nitroglycerin**, because together these might worsen renal function.[40,69] In patients with systolic dysfunction, intravenous **nicardipine** is an option that increases both stroke volume and coronary blood flow, a potential benefit.[70] When hypertensive pulmonary edema is a result of acute coronary syndrome or atrial fibrillation with rapid ventricular response, **β-blockers** are an appropriate choice.[71]

ACUTE MYOCARDIAL INFARCTION

Patients presenting with severely elevated blood pressure and ischemic changes on ECG should be treated with sublingual or intravenous **nitrates**.[42-44] Routine intravenous β-blockade has fallen out of favor due to conflicting reports of mortality benefits. Currently, intravenous β-blockade is only recommended for patients presenting with severe hypertension. Oral β-blockade in patients presenting with ST-segment elevation myocardial infarctions and non–ST-segment elevation myocardial infarctions remains part of early care, but this route may not provide sufficient or rapid enough blood pressure control in a hypertensive emergency.[42,44]

ACUTE SYMPATHETIC CRISIS

Patients in acute sympathetic crisis due to either cocaine or amphetamines should initially be managed with an IV benzodiazepine, such as lorazepam or diazepam, to decrease adrenergic stimulation.[32,45]

TABLE 57-4 Treatment of Hypertensive Emergencies by Diagnosis

Diagnosis	Therapy Goals	Agents	Risks	Comments
Aortic dissection	Reduce shear forces by ↓ BP and PR; lower SBP to 100–120 mm Hg[35-37]; or lower SBP to <140 mm Hg[23]; ↓ PR <60 beats/min			Measure BP in both arms and treat higher BP
		Labetalol[35-37] IV continuous infusion or **esmolol**[35-37] IV bolus, then continuous infusion	Respiratory distress in COPD, asthma patients; test dose of esmolol recommended, switch to diltiazem if esmolol intolerant[36]	
		Nicardipine[38] IV continuous infusion (after β-blocker)		Always use β-blocker prior to vasodilators
		Nitroprusside[36,37] continuous infusion (after β-blocker)		Always use β-blocker prior to vasodilators; nitroprusside alone increases wall stress from reflex tachycardia; cyanide and thiocyanate toxicity in patients with reduced renal function or therapy >24–48 h
Acute hypertensive pulmonary edema	Reduce BP by 20%–30%; diuresis through vasodilation; symptomatic relief			
		Nitroglycerin SL, topical, or IV continuous infusion[39,40]		IV nitrates dilate capacitance vessels at low doses; higher doses dilate arterioles and lower BP
		Enalaprilat IV[40]	ACE inhibitor, can worsen renal function	Avoid hypotension
		Nicardipine IV continuous infusion		Use with caution; some patients experience a negative inotropic effect
		Nitroprusside IV continuous infusion[39,40]		Cyanide and thiocyanate toxicity in patients with reduced renal function or therapy >24–48 h
		Nesiritide IV[39,40]	Mixed outcomes (favorable and unfavorable) with nesiritide, with most recent ASCEND-HF trial showing no difference in dyspnea and mortality when compared to placebo[41]	Nesiritide lowers PCWP more than nitroglycerin[39]
Acute myocardial infarction	Reduce ischemia; avoid ≤25% reduction of MAP[42]		BP >180/110 mm Hg is a relative contraindication for thrombolytics[43,44]	
		Nitroglycerin SL, topical, or IV continuous infusion[42-44]	Do not give nitrates in patients who have taken phosphodiesterase inhibitors for erectile dysfunction ≤24 h (48 h for tadalafil)[43]	
		Metoprolol or **labetalol** IV bolus[42-44]	Do not give β-blockers in CHF, low-output states, or other contraindications to β-blockers	Monitor for hypotension; consider RV infarct and volume depletion
Acute sympathetic crisis (cocaine, amphetamines, MAOI toxicity)	Reduce excessive sympathetic drive and symptomatic relief			Labetalol is controversial; if given, administer along with a nitrate[42]
		Benzodiazepine[32,45] IV bolus		Benzodiazepines are first-line agents; observe for respiratory depression
		Nitroglycerin SL, topical, or IV continuous infusion[42,45]		
		Phentolamine[45] IV or IM		
		Nicardipine IV continuous infusion[42,45]		
Acute renal failure	Reduce BP by no more than 20% acutely[11]			Do not give nitroprusside, as it results in cyanide and thiocyanate toxicity; avoid ACE inhibitor acutely (some authors contradict this caution)[11]
		Nicardipine[46] IV continuous infusion		

(*Continued*)

TABLE 57-4 Treatment of Hypertensive Emergencies by Diagnosis (*Continued*)

Diagnosis	Therapy Goals	Agents	Risks	Comments
		Clevidipine IV continuous infusion		
		Fenoldopam[46] IV continuous infusion		
Hypertensive encephalopathy	Decrease MAP 20%–25% in the first hour of presentation[47]; more aggressive lowering may lead to ischemic infarction			Autoregulation of cerebral perfusion may be significantly impaired, so avoid rapid BP lowering; do not give nitroglycerin[48] as it may worsen cerebral autoregulation
		Nicardipine[49] IV continuous infusion		
		Labetalol[50] IV continuous infusion		Avoid in sympathetic crisis from drugs
		Fenoldopam[50] IV continuous infusion		
		Clevidipine IV continuous infusion[51]		
Subarachnoid hemorrhage	SBP <160 mm Hg to prevent rebleeding[52]; avoid hypotension to preserve cerebral perfusion; BP parameters have not yet been defined[52]			Nimodipine is used to decrease mortality. BP control is not its primary goal, but some decrease in BP may be seen.[52] Clazosentan is used with success in lieu of nimodipine and has similar hypotensive effects.[53]
		Nicardipine[54-56] IV continuous infusion		
		Labetalol[52,56] IV bolus, 10–20 milligrams IV, or continuous infusion		
		Esmolol IV bolus, then continuous infusion		
		Clevidipine[52] IV continuous infusion		
Intracerebral hemorrhage	If SBP >200 or MAP >150 mm Hg, consider aggressive management, IV infusion.[57] If SBP >180 or MAP >130 mm Hg and possibly elevated ICP*, use infusions or IV boluses while maintaining CPP ≥60 mm Hg.[57] If SBP >180 or MAP >130 mm Hg and no elevated ICP, goal MAP is 110 mm Hg (160/90 mm Hg).[57]			Drops in SBP <150 mm Hg are not associated with increased morbidity.[58] Early hemorrhage growth often occurs in first 6 h. Recent data suggest that during this time, aggressive BP control (SBP 120–160 mm Hg) diminishes hematoma growth, morbidity, and mortality.[58-60]
		Labetalol[56,61] IV bolus or continuous infusion		
		Nicardipine[56,61-63] IV continuous infusion		
		Esmolol[64] IV bolus, then continuous infusion		
Acute ischemic stroke, rtPA candidate (BP ≤185/110 mm Hg)	If fibrinolytic therapy planned, treat if BP remains >185/110 mm Hg after 3 measurements[65]; SBP goal is between 141 and 150 mm Hg[66]		Excess BP Lowering may worsen ischemia	Elevated BP spontaneously decreases within 90 min after onset of acute stroke symptoms
		Labetalol[65] 10–20 milligrams IV bolus; may repeat one time		
		Nicardipine[65] IV continuous infusion 5 milligrams/h, titrate up by 2.5 milligrams/h every 5–15 min; maximum 15 milligrams/h; adjust when desired BP is reached		
		Nitroprusside[65] **may be used if BP is not controlled with above agents or DBP >140 mm Hg**		

(*Continued*)

TABLE 57-4 Treatment of Hypertensive Emergencies by Diagnosis (*Continued*)

Diagnosis	Therapy Goals	Agents	Risks	Comments
Acute ischemic stroke, hypertension excludes rtPA (BP >185/110 mm Hg)	Treat if >220/120 mm Hg on third of 3 measurements, spaced 15 min apart[65]			Do not lower SBP by >10%–15% in first 24 h.[65] BP that is lower during the acute ischemic stroke than the premorbid pressure could be considered hypotension. Be careful with BP control efforts in patients taking oral β-blockers or clonidine; antihypertensive withdrawal syndrome may occur.
		Labetalol[65] 10 milligrams IV bolus, followed by IV continuous infusion 2–8 milligrams/min		
		Nicardipine[65] 5 milligrams/h IV continuous infusion, titrate up to desired effect by 2.5 milligrams/h every 5–15 min; maximum 15 milligrams/h		

Abbreviations: ACE = angiotensin-converting enzyme; BP = blood pressure; CCP = cerebral perfusion pressure; CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; DBP = diastolic blood pressure; ICP = intracranial pressure; MAP = mean arterial pressure; MAOI = monoamine oxidase inhibitor; PCWP = pulmonary capillary wedge pressure; PR = pulse rate; rtPA= recombinant tissue-type plasminogen activator; RV = right ventricular; SBP = systolic blood pressure; SL = sublingual.

*Clinical and CT predictors of elevated ICP include decreased level of consciousness, evidence of midline shift, and hematoma volume >30 mL.

Monitor for respiratory depression and sedation. If benzodiazepines are not effective, nitroglycerin or phentolamine may be used next. A calcium channel blocker can serve as a third-line agent.[42,45,72] β-Blockers can result in unopposed α-blockade, which then can worsen coronary vasoconstriction and increase blood pressure.[45] If a β-blocker is used, labetalol is the adrenergic blocking agent in conjunction with a vasodilator.[42]

In patients with pheochromocytoma and a hypertensive emergency, intravenous phentolamine is recommended (intramuscular if venous access is impaired).[73,74] In the preoperative setting, patients who are hypertensive but not in crisis may be managed and prepared for resection with oral phenoxybenzamine, a long-acting adrenergic α-receptor blocker. Another option before resection is urapidil, a selective α_1-receptor antagonist and 5-HT_{1a} receptor agonist that is available in Europe but is not yet approved by the U.S. Food and Drug Administration.[75]

Patients with monoamine oxidase inhibitor toxicity often respond to an intravenous benzodiazepine; if more therapy is needed, use phentolamine, nitroglycerin, or nitroprusside. Nitroglycerin is indicated for associated chest pain or cardiac ischemia. Monitor closely after reaching a targeted blood pressure, because the hypertensive phase is often followed by a hypotensive phase.

ACUTE RENAL FAILURE

Fenoldopam, nicardipine, and clevidipine are all suitable for acute hypertension-induced renal failure, because they reduce systemic vascular resistance while preserving renal blood flow.[46] Nitroprusside is an alternative, although cyanide toxicity with high or prolonged use dampens enthusiasm in practice. Fenoldopam is considered by some to be a first-line agent because it improves natriuresis and creatinine clearance in patients with elevated blood pressure and impaired renal function.[46]

ECLAMPSIA AND PRE-ECLAMPSIA

Obstetrical hypertensive emergencies can occur well below the blood pressure threshold for other hypertensive emergencies. Treatment is discussed in detail in Section 11, "Obstetrics and Gynecology," in chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period."

NEUROLOGIC EMERGENCIES

Hypertensive encephalopathy (defined as a change in sensorium or seizure from the blood pressure elevation) is a clear indication for rapid blood pressure reduction, once other neurologic emergencies, notably ischemic or hemorrhagic stroke, are excluded.[47,76]

Appropriate agents for the management of hypertensive encephalopathy include intravenous nicardipine, labetalol, fenoldopam, and clevidipine.[49-51,77] Do not use nitroglycerin because it dilates cerebral arteries and alters both global and regional blood flow, which may worsen the autoregulation failure.[48]

The ideal targets for blood pressure control in subarachnoid hemorrhage and ischemic stroke are not clear and should be balanced to avoid worsening ischemia or rebleeding. For **subarachnoid hemorrhage**,[78] recommended agents include intravenous nicardipine, labetalol, and clevidipine[54-56] without one superior agent to date.[52] Oral nimodipine is a good choice for those with modest blood pressure elevations because it lowers blood pressure and reduces vasospasm and subsequent cerebral infarction rates, improving neurologic outcomes.[52,79,80] Clazosentan can also decrease the incidence of vasospasm-related delayed ischemic neurologic deficits and has similar blood pressure–lowering effects as nimodipine.[53] If an anticonvulsant is used and an agent that may further reduce blood pressure is selected, such as intravenous phenytoin (rate dependent) or a benzodiazepine, caution must be exercised with additional blood pressure reduction attempts.

The treatment of hypertension in patients with **intracerebral hemorrhage** includes labetalol, nicardipine, and esmolol.[56,57,61-64] Enalaprilat may also be used, but due to concerns of precipitous blood pressure drop, start with a smaller test dose (0.625 mg).[64] Lowering systolic blood pressures from >180 mm Hg to 120 to 160 mm Hg may improve clinical outcomes.[58-60]

In **ischemic stroke**, moderately elevated blood pressure may be beneficial in preserving cerebral perfusion of ischemic areas. Conversely, it may also worsen edema and contribute to hemorrhagic transformation. It is likely that ideal blood pressure ranges exist for ischemic stroke subtypes, but at this time, such ranges have not yet been determined. For the treatment of ischemic stroke, labetalol and nicardipine are the recommended agents; however, the route and degree of blood pressure reduction depend on whether the patient is a candidate for reperfusion therapy (Table 57-4).[65] **Fibrinolytic therapy is contraindicated in patients who maintain a blood pressure >185/110 mm Hg *after* antihypertensive therapy**. In patients

who maintain blood pressures ≤185/110 mm Hg (with or without antihypertensive therapy) and undergo fibrinolytic therapy, blood pressure goal is at or below 180/105 mm Hg. Blood pressure should be monitored every 15 minutes for 2 hours from the start of recombinant tissue plasminogen activator therapy, then every 30 minutes for 6 hours, and then every hour for 16 hours. Specific antihypertensive agents and blood pressure recommendations for severely hypertensive patients presenting with ischemic stroke are presented in Table 57-4.

PHARMACOLOGIC AGENTS

Parenteral agents used for hypertensive emergencies, including dosage, mechanisms, and warnings, are listed in **Table 57-5**. Refer to Table 57-4 for indications. Other considerations for drug choice include ability to monitor the patient and comorbidities, including respiratory and vascular disease.

β-BLOCKERS

Labetalol is unique among commonly used β-blockers because it also has modest selective α_1-inhibitory effects, with an α- to β-blocking ratio of 1:7.[82] It recommended for nearly all hypertensive emergencies with the exception of cocaine intoxication and systolic dysfunction in association with decompensated heart failure. In the latter, nicardipine is preferred when nitroglycerin fails. Oral **metoprolol** is indicated in the majority of patients presenting with acute coronary syndromes: Oral β-blockers have a clear benefit in terms of survival, whereas mortality data are conflicting with intravenous formulations.[42,44] However, if blood pressure control is needed in a patient with acute coronary syndrome, the intravenous formulation should be used. Esmolol has a short duration of action and is titrable, an advantage in patients at risk for the adverse effects of β-blockers, such as those with severe asthma and chronic obstructive pulmonary disease.

CALCIUM CHANNEL BLOCKERS

Clevidipine is a third-generation dihydropyridine calcium channel blocker with ultra-short-acting selective arteriolar vasodilator properties.[82] It has been studied in the perioperative setting and in patients with renal dysfunction.[83-85] Its advantage is its ability to be titrated with a half-life less than a minute. **Nicardipine** has an onset of action of 5 to 15 minutes and can be titrated at 15-minute intervals. It has been found to be safe and effective in neurologic hypertensive emergencies and has a favorable effect on myocardial oxygen balance increasing both stroke index and coronary blood flow. When compared to labetalol, patients were more likely to reach physician-specified target blood pressure goal in the initial 30 minutes of therapy.[81] **Nifedipine** use (10 milligrams PO) is discouraged in hypertensive emergencies except in peripartum patients.[86,87]

VASODILATORS

Nitroglycerin is a potent venodilator, showing arterial dilatation only at very high doses. Use may cause hypotension and reflex tachycardia, both worsened by the volume depletion characteristic of hypertensive emergencies. **Nitroglycerin is recommended as a first-line agent only in the treatment of heart failure and acute coronary syndromes** due to its favorable effects on coronary blood flow and cardiac workload. Its hypotensive effects are due to its reduction of preload and cardiac output, which makes it a poor choice in other hypertensive emergencies.

S**odium nitroprusside** is best used when other agents fail. It requires more titration than nicardipine in hypertensive neurosurgical patients[88] and has higher mortality rates in cardiac surgery patients when compared to clevidipine.[89] Concerns about cyanide toxicity, heightened in patients with renal or hepatic insufficiency, and the need for invasive monitoring further curtail its use.[90] Combination therapy is the most common current use, as in aortic dissection patients who also receive esmolol to achieve blood pressure targets at lower doses.

OTHER AGENTS

Fenoldopam is a unique peripheral dopaminergic-1 receptor agonist, and due to its ability to promote diuresis, natriuresis, and creatinine clearance, its primary application is in renal hypertensive emergencies.[82] **Phentolamine** is used successfully in cocaine-, amphetamine-, and pheochromocytoma-related hypertensive emergencies.[73,74,82] **Enalaprilat**, the only available IV angiotensin-converting enzyme inhibitor, has special application in patients with heart failure or acute coronary syndrome, but caution should be exercised because of common first-dose hypotension.[64]

Clonidine, a central α_2-agonist, generally does not have a role in the treatment of patients with hypertensive emergencies with the exception of those who have recently stopped taking the drug. An abrupt cessation of clonidine can induce a rebound hypertension, which may be difficult to control with other agents. It can be given orally, at 0.2 to 0.3 milligram initially, with blood pressure reduction starting within 30 to 60 minutes and peaking at 2 to 4 hours.[82] In patients who are unable to take oral medications, a clonidine patch for dermal delivery may be used. However, the onset action may be delayed by 2 to 3 days, and titration is challenging. For maximum absorption, apply the patch to the chest or upper arm.[82,91] Although abrupt cessation of either clonidine or a β-blocker may result in rebound hypertension, clonidine withdrawal tends to be more severe and often will not respond to therapy without reinstitution.

TREATMENT OF ASYMPTOMATIC SEVERE HYPERTENSION

Acute treatment of asymptomatic severe hypertension does not prevent or reduce short-term patient morbidity or mortality.[8] Nevertheless, a small study demonstrated increased risk of cardiovascular events within 4 years of ED presentation in hypertensive urgency patients (systolic blood pressure >220 mm Hg and/or diastolic blood pressure >120 mm Hg) compared to control patients with systolic blood pressures between 135 and 180 mm Hg and diastolic blood pressures between 85 and 110 mm Hg.[92] These data, combined with the evidence that uncontrolled blood pressure is a major risk factor for cardiovascular disease, renal failure, and cerebrovascular accidents, are reasons to initiate outpatient blood pressure reduction regimens prior to discharge. **Table 57-6** lists oral agents commonly used for hypertension. The drugs listed are chosen for their relatively rapid onset of action and their potential use for ongoing control of chronic hypertension. Choosing an agent that can be used once daily and is inexpensive is often an ideal plan (e.g., generic lisinopril, started at 10 milligrams daily). If choosing an angiotensin-converting enzyme inhibitor or angiotensin II receptor antagonist, check the creatinine and potassium first.

DISPOSITION AND FOLLOW-UP OF ASYMPTOMATIC HYPERTENSION

Table 57-7 provides consensus-based and the newer, focused Eighth Report of the Joint National Committee recommendations.[9,93-95] Many ED patients who present with elevated blood pressure have a reduction after approximately 90 minutes; however, patients whose blood pressures remain persistently elevated (systolic blood pressure >140 mm Hg or diastolic blood pressure >90 mm Hg, age <60 years, no medical problems **or** systolic blood pressure >150 mm Hg or diastolic blood pressure >90 mm Hg, age ≥60 years or a history of diabetes or chronic kidney disease) should have clear follow-up and can benefit from starting oral therapy, because only 6% have normal blood pressure values later.[93] Reinforce the need for outpatient follow-up, with or without ED-initiated oral therapy, even if elevated blood pressure was not part of the chief complaint.[95]

Initial therapy recommendations for nonblack individuals are a thiazide diuretic (e.g., hydrochlorothiazide, 25 milligrams daily), an angiotensin-converting enzyme inhibitor (e.g., lisinopril, 10 milligrams daily), or

TABLE 57-5 Intravenous Agents Used for Hypertensive Emergencies

Drug	Dosage	Mechanism/Comments	Warnings
β-Blockers			
Labetalol	Bolus: 10–20 milligrams (0.25 milligram/kg for an 80-kg patient) IV over 2 min; may administer 40–80 milligrams at 10-min intervals, up to 300 milligrams total dose. Continuous infusion: initially, 2 milligrams/min; titrate to response up to 300 milligrams total dose, if needed.	Combined selective α_1-adrenergic and nonselective β-adrenergic receptor blocker with an α- to β-blocking ratio of 1:7.[81] Effect in 2–5 min, peaking by 15 min, duration 2–4 h. Renal, cerebral, and coronary blood flow maintained; minimal placental transfer. **Pregnancy category C**	Avoid use in patients with bradycardia, >first-degree heart block, uncompensated cardiac failure, or active bronchospasm, and in patients receiving IV verapamil or diltiazem. Caution in patients with liver impairment (effects may be prolonged); the elderly have a less predictable response and more toxicity.
Esmolol	Loading dose: 250–500 micrograms/kg infused over 1–3 min IV, follow with: Maintenance infusion: 50 micrograms/kg/min IV over 4 min; if adequate effect not observed, repeat loading dose and increase infusion rate using increments of 50 micrograms/kg/min IV (for 4 min). This regimen can be repeated ×4 bolus doses and to an infusion rate of 300 micrograms/kg/min.	Ultra-short-acting, cardioselective, β-adrenergic receptor blocker. Onset within 60 s, duration 10–20 min. Ideal for use in patients at risk for complications from β-blockers, especially patients with mild to moderately severe left ventricular dysfunction or peripheral vascular disease. Duration 10–20 min; easily stopped. **Pregnancy category C**	Avoid use in patients with bradycardia, heart block, cardiogenic shock, decompensated cardiac failure, or active bronchospasm, and in patients receiving IV verapamil or diltiazem. Caution in patients with asthma, COPD, uncompensated cardiac failure; extravasation can lead to skin necrosis and sloughing; anemic patients will have a prolonged half-life, because drug is metabolized by red blood cell esterases.
Calcium Channel Blockers			
Nicardipine	Continuous infusion: start at rate of 5 milligrams/h. If target BP not achieved in 15 min, increase dose by 2.5 milligrams/h every 15 min until target pressure or the maximum dose of 15 milligrams/h is reached.	Second-generation dihydropyridine calcium channel blocker with vascular selectivity for the cerebral and coronary arteries. Onset of action is 5–10 min, duration is 1-4 h. **Pregnancy category C**	Avoid in patients with advanced aortic stenosis. Caution in decompensated heart failure. Avoid in patients receiving IV β-blockers. Common side effects are headache, hypotension, vomiting, and tachycardia.
Clevidipine	Continuous infusion: initiate IV infusion at 1–2 milligrams/h. Dose titration: double dose at short (90-s) intervals initially. As BP approaches goal, increase dose by less than doubling and lengthen time between dose adjustments to every 5–10 min.	Very rapid onset and offset of effect due to its ultra-short half-life, approximately 2–4 min. Clevidipine is rapidly hydrolyzed to its inactive metabolite in blood and extravascular tissues. It exerts a selective vasodilating action on arteriolar resistance vessels, but has no effect on venous capacitance vessels. Its metabolism is independent of the kidney or liver. **Pregnancy category C**	Cautions: Clevidipine contains approximately 0.2 gram of lipid per mL (2.0 kcal). Lipid intake restrictions may be necessary for patients with significant disorders of lipid metabolism. Clevidipine may produce systemic hypotension and reflex tachycardia. Contraindicated in patients with severe aortic stenosis and egg or soy hypersensitivity
Vasodilators			
Nitroglycerin	Sublingual: 0.4 milligrams. Paste: 1–2 inches. Continuous infusion: start 5 micrograms/min, increase by 5 micrograms/min every 3–5 min to 20 micrograms/min; if no response at 20 micrograms/min, increase by 10 micrograms/min every 3–5 min, up to 200 micrograms/min (note: many clinicians initiate with a higher infusion rate).	Potent venodilator and only at high doses affects arterial tone. Onset begins at 2 min, duration is 10–20 min (paste duration 3–4 h, unless removed). Reduces BP by reducing preload and cardiac output. Decreases coronary vasospasm and cardiac workload. **Pregnancy category C**	Avoid in cases of compromised cerebral and renal perfusion; avoid concurrent use (within past 24–48 h) with phosphodiesterase 5 inhibitors (sildenafil, tadalafil, or vardenafil). Caution: may cause hypotension with reflex tachycardia, which is exacerbated by volume depletion.
Nitroprusside	Continuous infusion: 0.5 microgram/kg/min IV initial infusion, increase in increments of 0.5 microgram/kg/min; titrate to desired effect. Rates >2 micrograms/kg/min may lead to cyanide toxicity. Use lowest possible dose. For infusions of 4–10 micrograms/kg/min, institute a thiosulfate infusion.	Arterial and venous vasodilator due to its interaction with oxyhemoglobin to produce nitric oxide. It decreases preload and afterload. Onset of action is in seconds, duration is 1–2 min. Cerebral blood flow is decreased, whereas intracranial pressure is increased. **Pregnancy category C**	Avoid in patients with kidney or hepatic failure, arteriovenous shunts, hereditary optic nerve atrophy (increases nerve ischemia), or elevated ICP. Caution: intra-arterial monitoring is recommended; must be protected from light. Nitroprusside is recommended only when other agents fail. Coronary steal syndrome may occur.
Other Agents			
Phentolamine	Bolus load: 1–5 milligrams IV. Continuous infusion: 0.2–0.5 milligram/min.	α_1- and α_2-adrenergic blocking agent, effective for pheochromocytoma and hypercatecholaminergic-induced hypertension. **Pregnancy category C**	Myocardial infarction, cerebrovascular spasm, and cerebrovascular occlusion have occurred after administration.
Fenoldopam	Continuous infusion: start 0.1 microgram/kg/min, titrate to desired effect every 15 min, range 0.1–1.6 micrograms/kg/min.	Dopamine 1 receptor agonist. Onset of action in 5 min, peak effect at 15 min, duration 30–60 min. Metabolized by liver, without P-450 system. Improves creatinine clearance, urine flow, and sodium excretion. **Pregnancy category B**	Caution: causes reflex tachycardia at higher dosages. Concurrent use of acetaminophen may increase fenoldopam levels. May cause flushing, dizziness, vomiting. Caution in patients with increased ocular pressures and ICP; caution in patients who have sulfite sensitivity (it is contained in a solution of sodium metabisulfite).
Enalaprilat	Bolus: 1.25 milligrams IV over 5 min every 4–6 h, titrate at increments of 1.25 milligrams every 12–24 h, with a maximum of 5 milligrams every 6 h.	Angiotensin-converting enzyme inhibitor. Test dose of 0.625 milligrams recommended when concern for first-dose hypotension exists.[64] **Pregnancy category D**	Avoid in pregnancy. Caution: first-dose hypotension is common, especially in high renin states; may cause dizziness and headache.

Abbreviations: BP = blood pressure; COPD = chronic obstructive pulmonary disease; ICP = intracranial pressure.

TABLE 57-6 Oral Agents for Hypertensive Urgencies

Agent	Mechanism of Action	Dosage	Onset of Action	Duration	Contraindications	Adverse Effects
Labetalol	α_1-, β-Adrenergic blocker	200–400 milligrams PO, repeat every 2–3 h	30–120 min	6–12 h	Asthma, chronic obstructive pulmonary disease, bradycardia, heart block, heart failure	Bronchoconstriction, bradycardia Pregnancy category C
Captopril	Angiotensin-converting enzyme inhibitor	12.5–25 milligrams PO	15–30 min	4–6 h	Renal artery stenosis, pregnancy	Acute renal failure, angioedema, side effect of chronic cough Pregnancy category D
Losartan	Angiotensin II antagonist	50 milligrams PO	60 min	12–24 h	Second and third trimesters of pregnancy	Allergic reaction (rare) Pregnancy category C in first trimester Category D in second and third trimesters
Nifedipine (extended release) **Indicated for pre-eclampsia only**	Calcium channel blocker	10 milligrams PO, may repeat every 30–60 min	5–15 min	3–6 h	Angina, acute hypertension	Myocardial infarction, cerebrovascular accident, syncope, heart block, CHF Pregnancy category C
Clonidine **Primary indication for rebound hypertension**	Central α_2-agonist	0.1–0.2 milligram PO	30–60 min	6–8 h	CHF, second- or third-degree heart block Would not recommend as a new or singular antihypertensive agent	Drowsiness, sedation, tachycardia, dry mouth Pregnancy category C

Abbreviation: CHF = congestive heart failure.

a calcium channel blocker. In blacks, initiate a thiazide diuretic or a calcium channel blocker, alone or in combination.[95] In patients with chronic kidney disease, with or without diabetes, initiate an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker.[7,93,95] **Table 57-8** lists indications for recommended oral antihypertensive classes based on trial data, as put forward in the Seventh and Eighth Reports of Joint National Committee.[7,95]

Consider and teach patients about potential adverse effects when prescribing an antihypertensive medication to a patient at discharge. A list of the most common side effects stratified by drug class appears in **Table 57-9**.

HYPERTENSIVE EMERGENCIES IN CHILDREN

The epidemiology, presentation, and management of hypertensive emergencies in children is less well documented than in adults. A formal definition of hypertension crisis does not exist for children.[96] Hypertension in children is defined as systolic and/or diastolic blood pressure measurement that exceeds the 95th percentile for that child's age, sex, and weight on three or more occasions, and this determination can be made using the pediatric nomograms found at http://www.nhlbi.nih.gov/health-pro/guidelines/current/hypertension-pediatric-jnc-4/blood-pressure-tables; a single elevated blood pressure in the ED is insufficient to diagnose hypertension. Severe blood pressure elevation can be considered any blood pressure that exceeds the 95th to 99th percentile for that child's age, sex, and weight by an additional 20 mm Hg or more.[97] As in adults, hypertensive emergencies in children refer to severely elevated blood pressures accompanied by target organ damage. Neonates may present with apnea, cyanosis, irritability, and poor feeding, whereas older children may have symptoms that more closely approximate adult presentations, such as headache, confusion or encephalopathy, focal neurologic deficits, vision changes, shortness of breath, peripheral edema, and decreased renal output.[96]

In children who are noted to have severely elevated blood pressures but no evidence of target organ damage, consult the child's pediatrician for outpatient follow-up or initiation of an antihypertensive agent prior to discharge. In children who present with a hypertensive emergency, immediate blood pressure control is needed, along with consultation with the pediatric intensivist or nephrologist, with admission to the pediatric intensive care unit. Blood pressure control should be initiated in the ED, with the primary aim of therapy to reduce the blood pressure to <95th percentile and to <90th percentile in the presence of comorbid conditions like diabetes or cardiac or renal disease. The mean arterial blood pressure should be lowered no more than ≤25% of the initial value in the first hour, with normalization of blood pressure gradually over the next 24 to 48 hours. Preferred first-line medications for hypertensive emergencies in children include labetalol, 0.2 to 1.0 milligram/kg per dose up to 40 milligrams/dose, or an infusion of 0.25 to 3.0 mg/kg/h; or nicardipine, 0.5 to 3 microgram/kg/min infusion. Second-line agents include hydralazine, 0.2 to 0.6 milligram/kg administered as a bolus to a maximum of 20 milligrams; esmolol administered as a 100 to 500 microgram/kg loading dose followed by an infusion of 50 to 150 micrograms/kg/min to a maximum of 1000 micrograms/kg/min; and clevidipine 0.5 to 3.5 micrograms/kg/min infusion; if prior drugs fail, use IV nitroprusside, 0.5 to 10.0 microgram/kg/min.[96,98,99] Phentolamine, 0.1 milligram/kg to a maximum of 5 milligrams, is the drug of choice for conditions associated with high circulating catecholamines, such as cocaine or pseudoephedrine overdose.

TABLE 57-7 Recommended Treatment Protocol for ED Patients with Increased Blood Pressure (BP)

Systolic BP (mm Hg)		Diastolic BP (mm Hg)	Follow-Up/Treatment
120–160	*or*	80–100	Advise follow-up within 2 months
>160	*or*	>100	Advise follow-up within 1 month
>180	*or*	>110	Consider initiating therapy at discharge; follow up within 1 week
>200	*or*	>120	Begin antihypertensive therapy at discharge; follow up within 1 week

CHAPTER 58

Pulmonary Hypertension

Michael E. Winters

INTRODUCTION AND EPIDEMIOLOGY

Normally, the pulmonary vascular system is a high-flow, low-resistance circuit, with a mean pulmonary arterial pressure that constitutes approximately 15% to 20% of the systemic circulation.[1] Normal pulmonary arterial systolic pressures range from 15 to 30 mm Hg, whereas diastolic pulmonary arterial pressures range from 4 to 12 mm Hg.[1] Pulmonary hypertension is defined as a mean pulmonary arterial pressure >25 mm Hg at rest or >30 mm Hg during exertion.[1,2]

Pulmonary hypertension is classified based on measurements of pulmonary capillary wedge pressure (PCWP) and pulmonary vascular resistance. Patients with pulmonary arterial hypertension have a mean pulmonary arterial pressure >25 mm Hg, a pulmonary vascular resistance >240 dynes/s/cm^5, and a PCWP <15 mm Hg.[2] In contrast, patients with pulmonary hypertension caused by left heart disease, the most common cause of pulmonary hypertension, have a PCWP >15 mm Hg.[2] Although echocardiography can estimate pulmonary arterial pressure in a patient with suspected pulmonary hypertension, definitive diagnosis requires right heart catheterization.

The World Health Organization classifies pulmonary hypertension into five categories based on cause and response to treatment (**Table 58-1**).[1,3] Some patients have features of multiple categories, but the majority have one predominant type of pulmonary hypertension.[4] Accurate classification of pulmonary hypertension is key to directing treatments, which vary among the categories. Pulmonary venous hypertension is the most common cause of pulmonary hypertension, affecting almost 4 million patients in the United States.[4] In contrast, pulmonary arterial hypertension is the least common cause of pulmonary hypertension, with an estimated prevalence of 15 patients per million.[4,5] Pulmonary hypertension develops in up to 4% of patients with chronic thromboembolic disease.[4,6,7] Regardless of

TABLE 58-1 World Health Organization Classification of Pulmonary Hypertension

- Group 1: Pulmonary Arterial Hypertension
  - Idiopathic
  - Genetic/heritable abnormalities
  - Drug or toxin induced
  - Associated with known risk factors for pulmonary arterial hypertension (human immunodeficiency virus, liver disease, collagen vascular disorders)
- Group 2: Pulmonary Venous Hypertension (left heart disease)
  - Systolic or diastolic dysfunction
  - Mitral or aortic valve disease
- Group 3: Chronic Hypoxemic Lung Disease
  - Obstructive lung disorders (chronic obstructive pulmonary disease)
  - Interstitial lung disease
    - Idiopathic pulmonary fibrosis
    - Collagen vascular disorders
  - Sleep-disordered breathing (obstructive sleep apnea)
  - Chronic exposure to high altitude
- Group 4: Embolic Disease
- Group 5: Miscellaneous
  - Lymphatic obstruction
  - Hematologic disorders: myeloproliferative disorders
  - Systemic disorders: sarcoidosis, neurofibromatosis
  - Metabolic disorders: glycogen storage disease, thyroid disorders

the cause, patients with pulmonary hypertension have high morbidity and mortality rates,[4,8] with a 5-year mortality rate for patients with idiopathic pulmonary arterial hypertension exceeding 30%.[5]

PATHOPHYSIOLOGY

The exact pathophysiology of all forms of pulmonary hypertension remains unknown. In **pulmonary arterial hypertension**, the initial abnormality is endothelial dysfunction, which results in an imbalance between endogenous vasodilators (e.g., prostacyclin) and vasoconstrictors (e.g., endothelin-1). The net effect is vasoconstriction and the formation of in situ thrombi. Additional pathologic processes include alterations in microvascular permeability, abnormal hypoxic vasoconstriction, microvascular thrombosis, and the formation of plexiform lesions, leading to vascular remodeling. Ultimately, these abnormalities result in sustained elevations of pulmonary vascular resistance and impairment of pulmonary blood flow.

With persistent elevations in pulmonary vascular resistance, the right ventricle (RV) dilates to maintain an adequate stroke volume. RV dilation increases the ventricular wall tension, increases oxygen consumption, and eventually decreases contractility. With progressive RV dilation, the intraventricular septum is displaced toward the left ventricle. This displacement inhibits left ventricular filling and ultimately impairs cardiac output and systemic perfusion.

Perfusion of the **right coronary artery (RCA)** depends on the gradient between the aorta and RV. Normally, the RCA is perfused during both systole and diastole. In patients with advanced pulmonary hypertension, RCA perfusion occurs almost exclusively during diastole.[9,10] Decreased perfusion results in right ventricular ischemia and further impairment of left ventricular output. Eventually, this cycle results in right ventricular failure and cardiovascular collapse.

CLINICAL FEATURES

The most common symptom of pulmonary hypertension is dyspnea, either at rest or with exertion, which is present in over 50% of patients.[1,11] Other symptoms include fatigue, chest pain, near syncope, syncope, and exertional lightheadedness.[3,11,12] Since these initial symptoms are nonspecific, it is not surprising that delays in diagnosis are common, with an average interval between symptom onset and diagnosis of pulmonary hypertension of 2 years.[13] As pulmonary arterial pressure increases, patients can develop early satiety, anorexia, orthopnea, paroxysmal nocturnal dyspnea, and peripheral edema.

The physical examination is often normal in the early stages of pulmonary hypertension.[1] As pulmonary hypertension worsens, findings of right ventricular failure emerge (e.g., a holosystolic tricuspid regurgitation murmur, jugular venous distention, hepatomegaly, ascites, and lower extremity edema).[1,4] Additional findings include an increased intensity of the pulmonary component of the second heart sound (P_2), a parasternal heave, and a subxiphoid thrust in patients with right ventricular hypertrophy.[1,4]

DIAGNOSTIC TESTING

ELECTROCARDIOGRAM

The most common ECG abnormality seen in pulmonary hypertension patients is right axis deviation.[12] Additional findings associated with pulmonary hypertension include an R/S ratio >1 in lead V_1, an R/S ratio <1 in leads V_5 and V_6, a qR complex in lead V_1, an $S_1Q_3T_3$, right atrial enlargement in the inferior leads, and an incomplete or complete right bundle branch block[14] (**Figure 58-1**). These findings are neither sensitive nor specific for the identification of pulmonary hypertension.

The ECG may show signs of right ventricular ischemia or dysrhythmia. The most common dysrhythmias in patients with pulmonary hypertension are atrial fibrillation, atrial flutter, and atrioventricular nodal reentrant tachycardia.[15,16] Of these, atrial fibrillation is associated with the highest mortality rate.[15]

LABORATORY TESTING

Routine laboratory testing (e.g., CBC, comprehensive metabolic panel) is often nonspecific in the initial evaluation of the pulmonary hypertension patient with dyspnea. **B-type natriuretic peptide** and **N-terminal B-type natriuretic peptide** are often elevated and correlate with outcomes in patients with pulmonary hypertension but have limited impact in ED care.[17-19] Elevations in troponin from myocardial ischemia or a strain-induced leak can be seen and are associated with higher morbidity and mortality.[20,21]

IMAGING

Common chest radiographic abnormalities associated with pulmonary hypertension include enlargement of the right atrium, RV, and hilar pulmonary arteries.[12,22] Depending on the cause of the pulmonary hypertension, additional radiographic findings might include pulmonary edema, hyperinflation, or interstitial lung disease. In most patients presenting with dyspnea, a chest radiograph is obtained to identify other causes of dyspnea, such as pneumonia or pneumothorax.

Transthoracic echocardiography is the best initial diagnostic test to assess pulmonary hypertension in the ED. It allows estimation of the

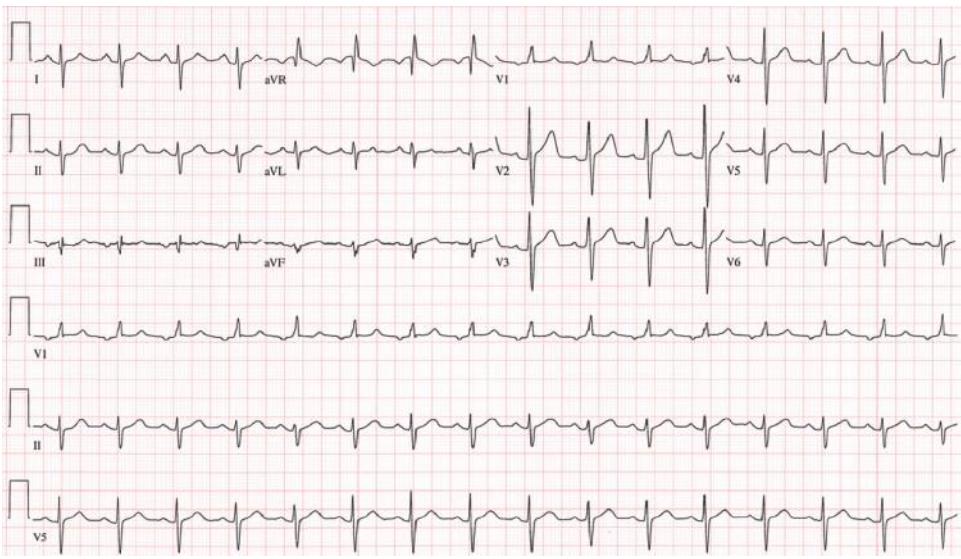

FIGURE 58-1. ECG with findings predictive of pulmonary hypertension: S wave in V_1 <2 mm, R/S ratio in V_1 >1, R/S ratio in V_6 <1, and QRS axis >110 degrees.

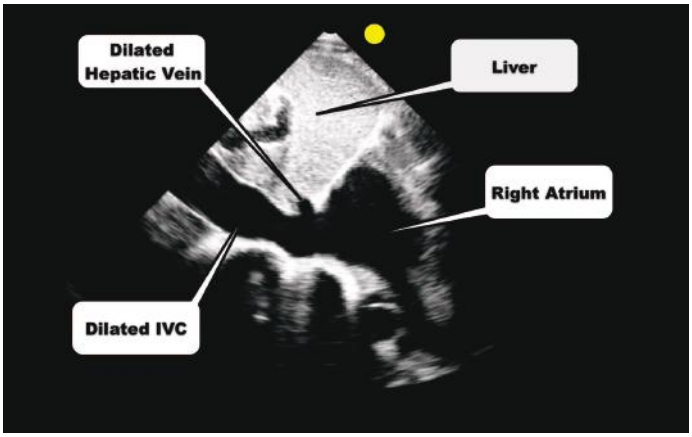

FIGURE 58-2. US of elevated right atrial pressures. Inferior vena cava (IVC) and hepatic vein dilation. [Image used with permission of Haney Mallemat, MD, in the Department of Emergency Medicine at the University of Maryland School of Medicine.]

pulmonary artery systolic pressure[4] and detection of decreased RV function, right atrial hypertrophy, and right ventricular hypertrophy, each of which is indicative of more severe disease.[1] Additional echocardiographic findings in patients with severe pulmonary hypertension include leftward deviation of the intraventricular septum and a right ventricle-to-left ventricle end-diastolic diameter >1 in the four-chamber view.[1,23] **Figures 58-2, 58-3, and 58-4** demonstrate typical echocardiographic findings in patients with pulmonary hypertension.

Echocardiography can also detect precipitating factors for right ventricular failure, including pericardial effusion, regional wall motion abnormalities of the RV or left ventricle, and acute valvular abnormalities.[24]

TREATMENT

No consensus guidelines exist for the management of critically ill patients with pulmonary hypertension in the ED. The mainstays of ED therapy include supplemental oxygen, optimizing intravascular volume, augmenting right ventricular function, maintaining coronary artery perfusion, and decreasing right ventricular afterload (**Table 58-2**).[25]

OXYGEN AND MECHANICAL VENTILATION

While the optimal oxygen saturation is unknown, consensus opinion is to titrate supplemental oxygen to maintain a level >90%.[25] Although intubation and mechanical ventilation are common ED therapies for the patient with acute respiratory failure, be wary of the complications. **In patients with severe pulmonary hypertension, intubation and ventilation can cause rapid cardiovascular collapse due to increased intrathoracic pressure from positive-pressure ventilation and effects of sedative medications on right ventricular function and systemic vascular resistance.**

When mechanical ventilation is needed, set the ventilator to maintain low airway pressure,[25] using lung-protective settings (i.e., a tidal volume of 6 mL/kg of ideal body weight and the lowest positive end-expiratory pressure to maintain the oxygen saturation above 90%). Monitor serial plateau pressure measurements and target pressures to <30 cm H_2O. Adjust the respiratory rate to avoid hypercapnia, which can increase pulmonary vascular resistance, pulmonary artery pressure, and RV strain.[26]

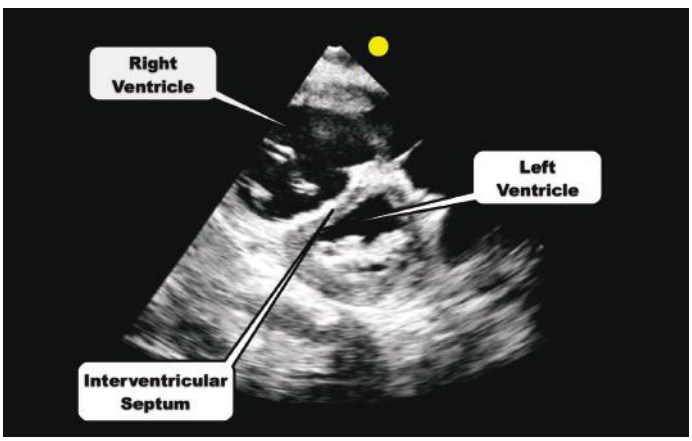

FIGURE 58-3. Cardiac US, parasternal short-axis view of right and left ventricles. Notice the flattening of the interventricular septum occurring in systole, suggesting elevated right ventricular systolic pressures. This is also known as a D-shaped septum. IVC = inferior vena cava. [Image used with permission of Haney Mallemat, MD, in the Department of Emergency Medicine at the University of Maryland School of Medicine.]

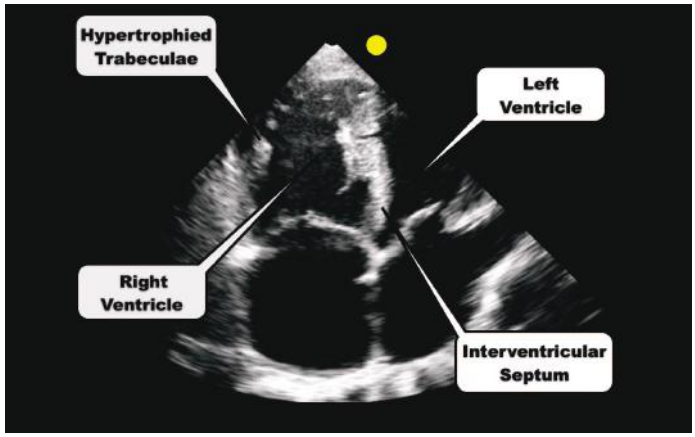

FIGURE 58-4. Apical four-chamber view of right and left ventricles. The right ventricle is dilated with hypertrophy of the right ventricular trabeculae, indicating chronic right ventricular overload. The interventricular septum is also shifted toward the left ventricle in systole, suggesting right ventricular pressure overload. IVC = inferior vena cava. [Image used with permission of Haney Mallemat, MD, in the Department of Emergency Medicine at the University of Maryland School of Medicine.]

INTRAVASCULAR VOLUME

Volume overload can cause RV dilation, displacing the intraventricular septum, impairing left ventricular output, and ultimately compromising tissue perfusion.[3] For patients who are hypovolemic, give serial boluses of an isotonic crystalloid solution in 250- to 500-mL aliquots with close monitoring. As a result of baseline elevations in right-sided pressures, common methods used to monitor volume responsiveness, such as absolute values of central venous pressure and respiratory variation of the inferior vena cava with US, are less reliable in the patient with pulmonary hypertension.

RIGHT VENTRICULAR FUNCTION

For RV failure, start an inotropic medication to augment function and improve cardiac output. **Dobutamine is preferred**,[25,27,28] starting at

TABLE 58-2 Drugs for Pulmonary Hypertension

Condition	Drug	Comments
RV failure	Dobutamine 2–10 micrograms/kg/min *OR* Milrinone 0.375 micrograms/kg/min	Avoid >10 micrograms/kg/min Higher doses can cause hypotension
RCA perfusion	Norepinephrine 0.05–0.75 micrograms/kg/min	Avoid high doses of norepinephrine; avoid dopamine and phenylephrine
RV afterload	Prostanoids	Rarely initiated in ED

Abbreviations: RCA = right coronary artery; RV = right ventricle.

2 micrograms/kg/min and titrated to 10 micrograms/kg/min. Avoid doses >10 micrograms/kg/min, because large doses can increase pulmonary vascular resistance and cause tachydysrhythmias and hypotension.[29,30] For patients unable to tolerate dobutamine, **milrinone** is an alternative. Milrinone is a phosphodiesterase-3 inhibitor and can indirectly augment right ventricular function through a reduction in pulmonary vascular resistance.[25] Start milrinone at 0.375 micrograms/kg/min and titrate to a maximum of 0.75 micrograms/kg/min. Higher doses of milrinone can cause hypotension.

RIGHT CORONARY ARTERY PERFUSION

Adequate perfusion of the RCA is necessary to maintain right ventricular function and cardiac output. To maintain RCA blood flow, arterial pressure at the aortic root must be higher than the pulmonary artery pressure. For the hypotensive pulmonary hypertension patient, use a vasopressor to increase aortic root pressure and maintain RCA perfusion. Although there are limited data regarding a singular superior agent, norepinephrine is recommended.[25] **Norepinephrine** improves cardiac output and is initiated at a dose of 0.05 micrograms/kg/min. Avoid high doses of norepinephrine because it can increase pulmonary vascular resistance and impair right ventricular output. Avoid dopamine and phenylephrine because these drugs can cause tachydysrhythmias and can elevate pulmonary artery pressure and pulmonary vascular resistance.

RIGHT VENTRICULAR AFTERLOAD

Reducing right ventricular afterload with pulmonary vasodilators is a critical component in the management of stable patients with pulmonary hypertension. The most commonly used pulmonary vasodilators are prostanoids, endothelin receptor antagonists, and phosphodiesterase-5 (PDE-5) inhibitors. These medications are used primarily in the treatment of patients with pulmonary arterial hypertension; they are rarely, if ever, administered in the ED, but understanding the therapeutic agents is important. **Prostanoids** (epoprostenol, treprostinil, and iloprost) are potent vasodilators and are the initial treatment of choice in patients with pulmonary arterial hypertension and right ventricular failure. These medications have antiplatelet and antiproliferative properties.[1] Epoprostenol is the only therapy proven to improve survival.[25] It has a half-life of just 2 to 5 minutes and must be given by continuous IV infusion.[31,32] In contrast, treprostinil has a half-life of 4 to 5 hours and is approved for both IV and SC administration.

For the acutely ill pulmonary hypertension patient receiving ongoing IV prostanoid, the first step is to confirm catheter and pump function. If occlusion or malfunction is detected, consult with the primary provider. Both epoprostenol and treprostinil can be administered by peripheral IV. Iloprost is given as an aerosol and is usually reserved for patients unable to tolerate a parenteral prostanoid.[25] Side effects of prostanoids include headache, nausea, vomiting, flushing, diarrhea, and jaw pain.[1]

Endothelin receptor antagonists are administered orally and increase exercise capacity, improve hemodynamics, and can delay the time to clinical worsening in pulmonary hypertension patients.[1,33-37] Currently, bosentan and ambrisentan are the only available endothelin receptor antagonists, but neither drug has been evaluated in the acutely decompensating pulmonary hypertension patient with right ventricular failure.[25] Side effects of these medications include an elevation in liver transaminase levels and a decrease in hemoglobin concentration.[1]

The **PDE-5 inhibitors** sildenafil and tadalafil are approved for use in patients with pulmonary hypertension. They are administered orally, seeking to improve hemodynamics and exercise capacity in patients with pulmonary arterial hypertension.[1,38-43] Like the endothelin receptor antagonists, they are not currently used in acutely ill pulmonary hypertension patients. Side effects of the PDE-5 inhibitors include headache, flushing, dyspepsia, and hypotension when used concomitantly with nitrates.[1]

DISPOSITION AND FOLLOW-UP

When patients with pulmonary hypertension present to an ED, they are often critically ill, with signs and symptoms of acute right heart failure. As a result, nearly all require admission, often to an intensive care or coronary care unit with expertise in pulmonary hypertension. On rare occasions, a mildly symptomatic patient may be discharged home after consultation, care plan development, and close follow-up with the primary provider.

PRACTICE GUIDELINES

No consensus guidelines exist for the evaluation and management of critically ill ED patients with pulmonary hypertension. Current recommendations are based on expert opinion.

CHAPTER 59

Aortic Dissection and Related Aortic Syndromes

Gary A. Johnson
Louise A. Prince

INTRODUCTION AND EPIDEMIOLOGY

Acute aortic syndromes encompass a number of life-threatening aortic emergencies. These include aortic dissection, penetrating atherosclerotic ulcer, intramural hematoma, and aortic aneurysmal leakage or ruptured abdominal aortic aneurysm (see chapter 60, Aneurysmal Disease).

Acute aortic syndromes are uncommon but frequently fatal. The incidence ranges from 2.9 to 4.7 cases per 100,000 people per year.[1-4] The 1-year, 5-year, and 10-year actuarial survival rates are 92%, 77%, and 57%, respectively, for operative patients.[4] Twenty-two percent of cases are undiagnosed prior to death.[5] The most common cardiovascular complication of Marfan's syndrome is aortic root disease and type A dissection (ascending aorta). The identification of gene mutations associated with Marfan's syndrome, such as *TGFBR2* and *FBN1*, combined with regular follow-up can reduce fatal outcomes.[6]

PATHOPHYSIOLOGY

Acute aortic syndromes occur in the setting of chronic hypertension and other factors that lead to degeneration of the media of the aortic wall. Bicuspid aortic valve, Marfan's syndrome, Ehlers-Danlos syndrome, and familial history of aortic dissection all predispose to aortic syndromes. Chronic cocaine or amphetamine use accelerates atherosclerosis, increasing the risk for dissection.[7] Prior cardiac surgery is another risk factor for aortic dissection. All mechanisms involve weakening of the medial layer and intimal wall stress. Response to stress may include aortic dilation, aneurysm formation, development of a penetrating ulcer, intramural hemorrhage, aortic dissection, and aortic rupture.

Aortic dissection occurs after a violation of the intima allows blood to enter the media and dissect between the intimal and adventitial layers. The dissecting column of blood forms a false lumen and may extend proximally, distally, or in both directions. Blood may dissect and reenter the intima, and this may clinically suggest a spontaneous cure. Alternatively, the blood may dissect through the adventitia, which nearly always proves rapidly fatal.

Aortic dissection has a bimodal age distribution.[4] The first peak involves younger patients with specific predisposing conditions such as connective tissue disorders. The second peak includes those aged >50 years with

chronic hypertension. Other atherosclerotic risk factors appear to be only minor contributors to pathogenesis of acute aortic syndromes.

Aortic dissections are classified using two separate systems, the Stanford and DeBakey systems. The **Stanford classification** considers any involvement of the ascending aorta a type A dissection. Stanford type B dissections are restricted to only the descending aorta. **DeBakey** type 1 dissections simultaneously involve the ascending aorta, the arch, and the descending aorta. DeBakey type 2 dissections involve only the ascending aorta, and type 3 involve only the descending aorta.

An **aortic intramural hematoma** results from infarction of the aortic media, usually from injury to the vasa vasorum.[8] An intramural hematoma may resolve spontaneously or may lead to dissection.[9] **Penetrating atherosclerotic ulcer** can lead to intramural hematoma, aortic dissection, or perforation of the aorta.[8,10]

CLINICAL FEATURES

HISTORY

The site of initial intimal disruption predicts the initial symptoms.[11] Symptoms may change as the dissection extends along the aorta or involves other arteries or organs. Classically, dissection presents with abrupt and severe pain in the chest that radiates to an area between the scapulae and may be accompanied by a feeling of impending doom. In a case series of 464 dissections,[5] 60% of patients had anterior chest pain (more common in Stanford type A); abdominal pain is more common in Stanford type B. Most patients describe the pain as severe or the worst they have ever experienced. Sixty-four percent describe it as sharp pain and 50% as tearing or ripping pain. Syncope occurs almost 10% of the time (more common in Stanford type A). Twenty-two percent of dissections occur in patients with prior cardiac surgery.[5]

Dissection in or near a carotid artery may present as a classic **stroke**, and 20% of patients with type A dissection display neurologic findings, which predicts a poorer prognosis.[12,13] Interruption of blood supply to the spinal cord may lead to paraplegia. Further distal dissection may present as back, flank, or abdominal pain. A proximal dissection to the aortic root may lead to **cardiac tamponade** and is generally fatal.

PHYSICAL EXAMINATION

For most patients with aortic dissection, examination findings are relatively normal. An aortic insufficiency murmur may occur (32%), and a pulse deficit in radial arteries or femoral arteries can be found (15%).[9] Hypertension is common (49%), but hypotension occurs in 18% to 25% and worsens prognosis.[5,9,14] Aneurysmal dilation of the aorta may compress regional structures such as the esophagus, the recurrent laryngeal nerve, or the superior cervical sympathetic ganglion, causing dysphagia, hoarseness, or Horner syndrome.

Using retrospective data from the International Registry of Acute Aortic Dissection,[15,16] three clinical categories (underlying condition; pain quality and location; examination findings) were parsed into 12 features[15,16] associated with acute aortic dissection (**Table 59-1**).

TABLE 59-1 Acute Aortic Dissection: Features From the International Registry of Acute Aortic Dissection

Category 1: Underlying Condition	Category 2: Pain in Chest, Back, or Abdomen	Category 3: Abnormal Examination
Marfan's syndrome	Abrupt onset	Systolic blood pressure differential in extremities or pulse amplitude difference
Family history of aortic disease	Severe in intensity	Focal neurologic deficit and chest, back, or abdominal pain
Aortic valvular disease	Ripping or tearing	New murmur of aortic insufficiency and chest, back, or abdominal pain
Recent aortic manipulation		Shock or hypotension
Thoracic aortic aneurysm		

TABLE 59-2 Differential Diagnosis of Aortic Dissection

Myocardial infarction or acute coronary syndromes
Pericardial disease
Stroke
Musculoskeletal disease of the extremity
Spinal cord injuries and disorders
Intra-abdominal disorders
Pulmonary disorders, including pulmonary embolus, pneumonia, pleurisy, pneumothorax

DIAGNOSIS

The large differential diagnosis for chest pain plus the many end-organ ischemic manifestations associated with aortic dissections make the diagnosis challenging. The most important differential diagnoses are listed in **Table 59-2**.

Ischemic manifestations may change with time (as the dissection progresses), and this may distract the physician from making the correct diagnosis. Rupture of the dissection into the true aortic lumen may cause a cessation of symptoms, and the correct diagnosis may then be inappropriately dismissed. History, physical examination, and chest radiography can suggest the diagnosis, but only if one is alert to aortic dissection as one of the diagnostic possibilities in a patient with acute chest pain, syncope, or acute focal neurologic signs. Factors associated with misdiagnosis include walk-in mode of admission, normal mediastinal width/aortic contour on chest radiograph, absent extremity pulse amplitude differences, and nonspecific symptoms.[17-19]

ECG

It may be difficult to differentiate aortic dissection from acute coronary syndromes on ECG, because both conditions are associated with ECG changes; dissection may limit or obstruct coronary artery blood flow. Abnormal ECG findings include new Q waves or ST-segment elevation in 3% to 4%, ST depression in 15% to 22%, and nonspecific ST and T-wave changes in 41% to 62%.[5,9,20] The ECG is normal in only 19% to 31% of patients.[5,20]

BIOMARKERS

Several potential biomarkers have been investigated for their utility to identify or exclude aortic dissection.[21] **D-Dimer** is the marker most thoroughly investigated. A meta-analysis of seven studies involving 298 subjects with acute aortic dissection and 436 without found a sensitivity of 97% (95% confidence interval, 94% to 99%) and negative predictive value of 96% (95% confidence interval, 93% to 98%) using a D-dimer cut point of 500 ng/mL (1620 nmol/L).[22] The specificity was low at 56% (95% confidence interval, 51% to 60%). Guidelines do not endorse the use of D-dimer as the sole means of excluding aortic dissection,[15] and several authors have cautioned against this practice.[23-26] One report found that young adult patients with short dissection length and thrombosed false lumen were likely to have a false-negative D-dimer.[24] The false-negative rate using D-dimer is as high at 18%.[25]

IMAGING

A plain chest radiograph may provide important clues for the diagnosis. However, from 12% to 37% of patients have no abnormality, and this study should not be used to exclude dissection.[5,27] The most common radiographic abnormality is a widened mediastinum or abnormal aortic contour. Other possible findings include pleural effusion, displacement of aortic intimal calcification, and deviation of the trachea, mainstream bronchi, or esophagus (**Figure 59-1**).

CT (especially multidetector-row CT) is the imaging modality of choice for diagnosis of dissection.[11,15,28] CT can reliably identify a false lumen (**Figure 59-2**) and can provide additional details such as the anatomy of the dissection, the location of the dissection flap, extension of the flap into great vessels (**Figure 59-3**), signs of aortic rupture, and

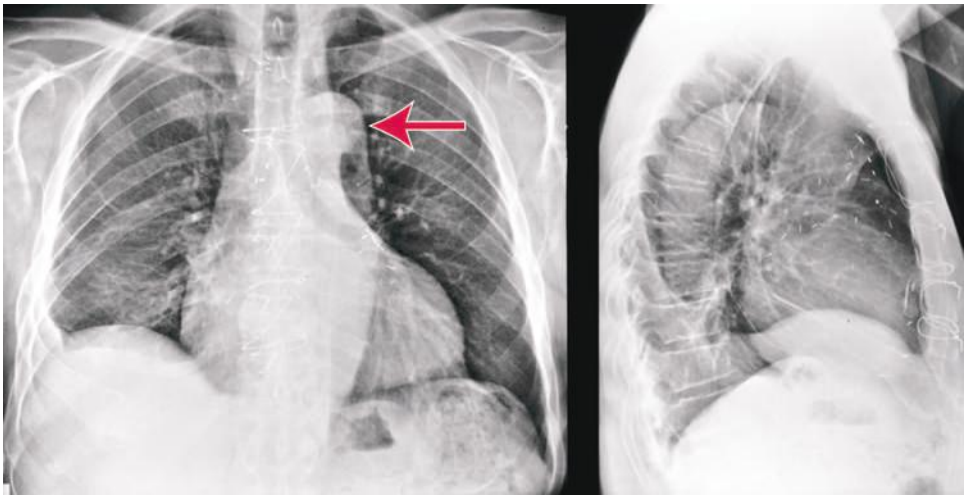

FIGURE 59-1. Abnormal aortic contour on chest radiography. Frontal and lateral radiographs of the chest in a patient with type B aortic dissection reveal an abnormal aortic contour (*arrow*). A right pleural effusion is present, and multiple postoperative clips and wires are also seen.

signs of end-organ damage. CT protocols should be both with and without IV contrast. Invasive catheter angiography is rarely necessary.

CT may also diagnose intramural hematoma and penetrating atherosclerotic ulcer.[28] Penetrating atherosclerotic ulcer can be difficult to distinguish from large atheromatous plaques (**Figure 59-4**). CT diagnosis of penetrating atherosclerotic ulcer depends on extension of the ulcer past the intima. Ulcers often have overhanging edges and focal outpouchings of the aorta itself. Intramural hematoma is often identified by a high-signal mass in the aorta on CT (**Figure 59-5**). This often appears as a crescent and is best seen on noncontrasted images.

In experienced hands, **transesophageal echocardiography** may be as sensitive and specific as CT. The procedure generally has to be performed under moderate sedation or even general anesthesia. Known esophageal disease is a relative contraindication. Sound transmission is disrupted by air in the trachea or left bronchia, which may make evaluation of the ascending aorta difficult. The accuracy and precision of transesophageal echocardiography are highly operator dependent. **MRI** has been used to evaluate stable patients with suspected aortic disease.[28]

Coronary CT angiography, or the "**triple rule-out**," can diagnose and differentiate coronary artery disease, pulmonary embolism, and acute aortic dissection.[29,30] However, it requires a specialized contrast infusion protocol to image the three vascular beds of interest and an increased radiation dosage.[31] Furthermore, the "triple rule-out" study has not been shown to improve diagnostic yield, reduce clinical events, or diminish downstream resource use.[32]

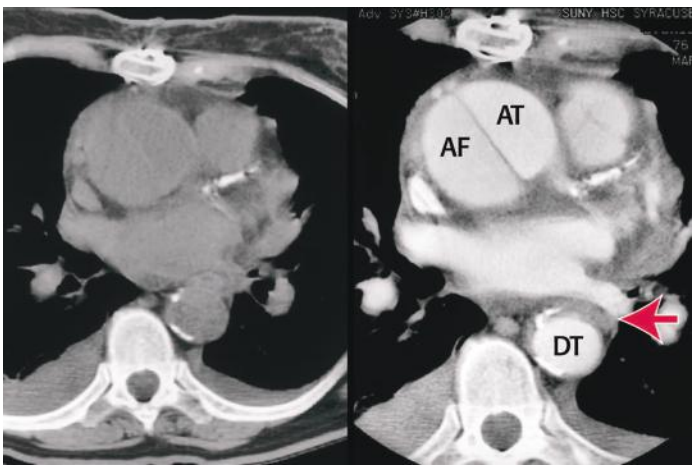

FIGURE 59-2. CT image of a type A aortic dissection. True and false lumens are present in the ascending aorta and descending aorta (descending false lumen at arrow) on noncontrast (*left*) and contrast (*right*) images. AF = ascending false lumen; AT = ascending true lumen; DT = descending true lumen.

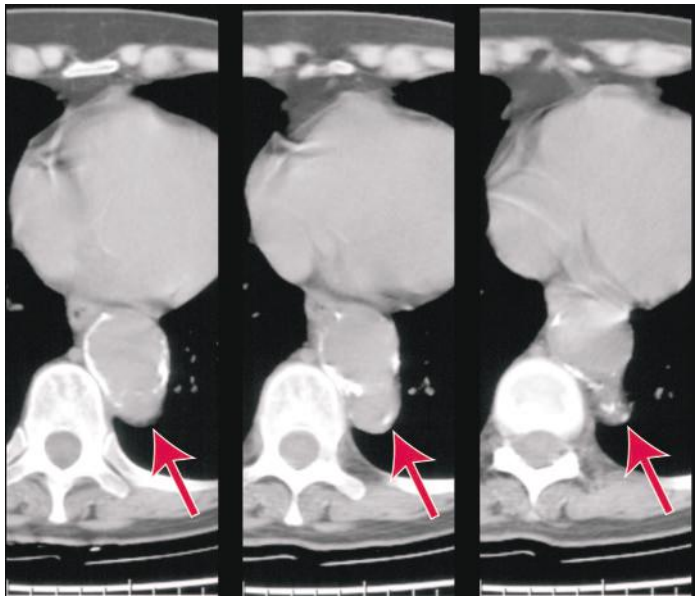

FIGURE 59-4. Noncontrast CT image of a penetrating aortic ulcer in the descending aorta (*arrows*), demonstrating an outpouched, abnormal contour of the aorta in three sections. [Image used with permission of Dr. Ernest Scalzetti, MD.]

TREATMENT

ANTIHYPERTENSIVES: NEGATIVE INOTROPIC AGENTS

While aortic dissections may cause hypotension that requires fluid or blood product resuscitation, suspected aortic dissection commonly requires antihypertensive treatment. Initial treatment is with a negative inotropic agent in order to lower blood pressure without increasing the shear force on the intimal flap of the aorta. β-Blockade is ideal, and short-acting β-blockers such as propranolol, labetalol, or esmolol are preferred over long-acting β-blockers. The ideal target blood pressure is undefined by controlled trials and must be tailored to each patient (see chapters 57, "Systemic Hypertension" and 58, "Pulmonary Hypertension"). However, **a systolic pressure of 120 to 130 mm Hg is a reasonable starting point; guidelines suggest a goal of 100 to 120 mm Hg**.[15]

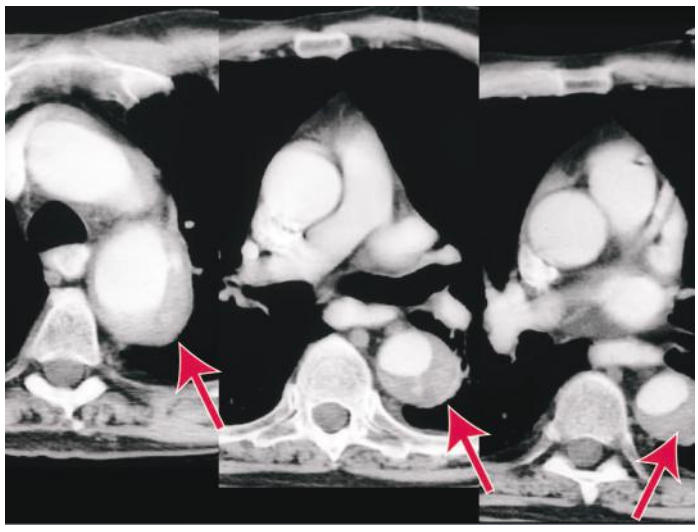

FIGURE 59-5. Contrast CT image of an intramural hematoma (*arrows* point to the crescent-shaped lesion along the posterior lateral aortic wall) in the descending aorta. [Image used with permission of Dr. Ernest Scalzetti, MD.]

Esmolol may be given as an initial bolus of 0.1 to 0.5 milligram/kg IV over 1 minute followed by an infusion of 0.025 to 0.2 milligram/kg/min. **Labetalol** (a β-blocker with limited α-blocking characteristics in a 7:1 ratio) also may be used at an initial dose of 10 to 20 milligrams IV with repeat doses of 20 to 40 milligrams every 10 minutes to desired effect or a maximum dose of 300 milligrams. Calcium channel blockers may be used in the event of a contraindication to β-blockade, but experience with their use in the setting of aortic dissection is limited. β-Blocker use has been associated with improved survival in the International Registry of Acute Aortic Dissection (IRAD) database.[33,34]

VASODILATORS

Vasodilators such as **nitroprusside** may be added for further antihypertensive treatment after successful administration of a negative inotrope. Adequate β-receptor or calcium channel blockade should be achieved prior to starting a vasodilator (see chapters 57 and 58). **Nicardipine,** a parenteral dihydropyridine calcium channel blocker, has been used with success as a replacement for nitroprusside.[35]

DEFINITIVE REPAIR

Rapid referral to a surgeon is mandatory. Dissection with involvement of the ascending aorta requires prompt surgical repair.

Endovascular repair treats some aortic type A and complicated type B[36] dissections (patients with malperfusion, persistent severe pain, persistent false lumen, resistant hypertension, or expanding aortic diameter), penetrating ulcers,[37] and intramural hematomas.[38] Stenting has been combined with fenestration for patients with malperfusion.[39] Endovascular therapy has uncertain long-term effects but has shown short-term benefit.[36] Endovascular treatment is minimally invasive and avoids sternotomy and circulatory arrest. In treating dissection, goals of therapy include expansion and stabilization of the true lumen and passive resorption of thrombosis of the false lumen. In addition, visceral artery blood flow can be restored passively or by fenestration of the initial flap. Refractory pain in patients treated medically with type B dissection may be an indication for invasive intervention.[40]

DISPOSITION AND FOLLOW-UP

Patients with acute aortic syndromes are likely to require admission to an intensive care unit for hemodynamic therapy and careful monitoring. Acute intermural hematomas and penetrating ulcers have an unclear clinical course and natural history. Therefore, the management of patients with these disorders remains controversial.[41] Clearly no patient with an acute aortic syndrome should be discharged without consultation with a cardiovascular or vascular surgeon.

SPECIAL CONSIDERATIONS

AORTIC DISSECTION COMPLICATING PREGNANCY

Aortic dissection in pregnancy is rare and usually occurs in the third trimester and postpartum period.[41] Risk factors are bicuspid aortic valve, connective tissue disorders, hypertension, and a family history. Pregnancy increases the risk of dissection in patients with Marfan's syndrome, complicating 4.4% of pregnancies in women with the syndrome.[42] Depending on the gestational age[43] of the fetus, cesarean section with concomitant aortic repair is recommended for type A dissection. Simultaneous consultation with obstetrics and cardiovascular surgery is needed if the diagnosis is considered.

PRACTICE GUIDELINES

Guidelines have been published on the management of thoracic aortic disease, including type A dissection, by the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College

of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine.[15] Because of the relative infrequency of this condition, most of the recommendations are consensus based.

CHAPTER 60

Aneurysmal Disease

Louise A. Prince
Gary A. Johnson

INTRODUCTION

An aneurysm is dilation of the arterial wall to >1.5 times its normal diameter. Aneurysms have been classically distinguished as true aneurysms, pseudoaneurysms, and mycotic aneurysms. The wall of a **true aneurysm** involves of all layers of the vessel. Risk factors for these include connective tissue disorders, familial history of aneurysm, and atherosclerotic risk factors (i.e., age, smoking, hypertension, and hyperlipidemia). A progressive decrease in elastin, collagen, and fibrolamellar units results in thinning of the media of the vascular wall and a decrease in its tensile strength. In aortic true aneurysm, the dilatation and increased wall force are intertwined, creating more dilatation (Laplace law: wall tension = pressure × radius). The rate of aneurysmal dilatation is variable and predictable, with larger aneurysms expanding more quickly and changing a mean 0.25 to 0.5 cm per year. However, abrupt expansion occurs and is not predictable, with larger aneurysm more likely to rupture. Rupture is catastrophic, occurring once the stress on the vessel wall exceeds its tensile strength.

The wall of a **pseudoaneurysm** consists partly of the vessel wall and partly of fibrous or other surrounding tissue. A pseudoaneurysm can develop at the site of previous vessel catheterization and at anastomoses from prior vascular reconstruction, trauma, or infection.[1] Small pseudoaneurysms may eventually spontaneously thrombose.

A **mycotic aneurysm** develops as a result of infection in the vessel wall, often in an immunocompromised patient. The source can be direct extension from a neighboring infection or embolization from valvular endocarditis.

Peripheral and visceral aneurysms are less frequent but an important subset of arterial aneurysmal disease. Popliteal artery aneurysms are the most common peripheral aneurysm; they often co-exist with contralateral popliteal aneurysms or abdominal aortic aneurysms.[2] Aneurysms of the femoral artery are uncommon and often accompany aneurysmal disease at other sites. Visceral artery aneurysms may occur anywhere but are most common in the renal, splenic, and hepatic arteries. Most visceral aneurysms remain silent and undetected until a complication such as rupture occurs. All but splenic artery aneurysms are more common in elderly men. Complications of aneurysms include rupture, which has an 80% mortality rate,[3] and thrombosis, creating ischemia in the perfused organ.[4,5]

GENERAL CLINICAL FEATURES OF ANEURYSMS

Clinical signs and symptoms can be nonspecific; often, the symptoms are driven by location, the pressure exerted upon neighboring structures, or the signs of peripheral embolization from an intramural thrombus. Visceral aneurysms are often detected after an abdominal CT scan for abdominal or flank complaints; similarly, lower extremity aneurysms are often detected during an extremity Doppler US examination in a search for deep venous thrombosis. Once rupture occurs in any truncal aneurysm, hemorrhagic shock develops and mortality is high without prompt surgical intervention.

SYMPTOMATIC ABDOMINAL AORTIC ANEURYSMS

An abdominal aortic aneurysm is defined as an aorta ≥3.0 cm in diameter; repair is considered for an aneurysm ≥5.0 cm in diameter. Patients with an abdominal aortic aneurysm often (18%) have a first-degree relative with an aortic aneurysm, compared with <3% of those without aneurysm. Most patients are >60 years old, and males have an increased risk of the disease. Patients with aneurysms involving other major arteries and those with peripheral arterial disease are also at increased risk for aortic aneurysmal disease. The risk increases with the number of years of smoking and decreases with the number of years since quitting smoking.[6] As smoking becomes less prevalent in the United States, abdominal aortic aneurysm deaths have decreased.[7]

CLINICAL FEATURES

Symptomatic abdominal aortic aneurysms may present with a variety of signs or symptoms that can mimic other primary diagnoses: syncope; flank, back, or abdominal pain; GI bleeding from an aortoduodenal fistula; extremity ischemia from embolization of a thrombus in the aneurysm; shock; or sudden death. Sudden death most commonly occurs from intraperitoneal rupture of the aneurysm, which leads to massive, rapid blood loss. Syncope without warning symptoms followed by severe abdominal or back pain suggests rupture of an abdominal aortic or visceral aneurysm with some temporary containment. Syncope is caused by rapid blood loss and a lack of cerebral perfusion. Patients may regain consciousness, but irreversible hemorrhagic shock follows without prompt diagnosis and intervention.

Back or abdominal pain is the most common presenting symptom with aortic aneurysm or rupture. The pain is classically severe and abrupt in onset, with about half of patients describing a ripping or tearing pain. Syncope occurs in about 10%. Many patients present with nonclassic sites of pain: flank, groin, isolated quadrants of the abdomen, and hip. Other common symptoms exist, such as nausea, vomiting, bladder pain, hip pain, or tenesmus.

DIAGNOSIS

Physical examination has only a moderate ability to detect a large abdominal aortic aneurysm. The sensitivity of abdominal palpation increases with aortic aneurysm diameter, ranging from 29% for a diameter of 3.0 to 3.9 cm to 50% for a diameter of 4.0 to 4.9 cm and 76% for a diameter of ≥5.0 cm.[8] Tenderness to palpation of an aneurysm is commonly interpreted as a sign of aneurysmal expansion or rupture. However, a lack of tenderness does not indicate an intact aorta. Examination is difficult in the obese and the very thin.

The differential diagnoses include the causes of syncope, abdominal pain, chest pain, back pain, and shock. When seeing patient with abrupt back pain with syncope or shock, consider aortic aneurysm rupture. However, other cardiac, abdominal, and retroperitoneal diseases may be the cause, including renal disorders, hepatobiliary disorders, and pancreatic disease. If symptoms are insidious, it is possible that some patients may appear well enough and receive benign diagnoses, such as musculoskeletal back pain, and are discharged from the ED.

Diagnosis is confounded by coexisting pathology. Coronary artery disease and chronic lung disease are often present, and signs and symptoms of these disorders may distract the physician from the diagnosis of aneurysmal disease. This is especially true in patients without severe pain or with findings that seem congruent with another cause (e.g., ECG changes or dyspnea).

External signs of acute rupture are rare and include periumbilical ecchymosis (**Cullen sign**) or flank ecchymosis (**Grey Turner sign**). Retroperitoneal blood may dissect into the perineum or groin, causing scrotal or vulvar hematomas, or inguinal masses. Retroperitoneal blood

may irritate the psoas muscle, triggering an "iliopsoas sign" (pain upon extension of the hip, typically with the patient lying on the opposite side). Blood may compress the femoral nerve and present as a neuropathy. The presence or rupture of an abdominal aortic aneurysm typically does not alter femoral arterial pulsations.[9]

Think of **aortoenteric fistulas** in patients with unexplained or high-volume upper or lower GI bleeding, especially in patients without liver disease. A history of aortic graft placement increases the risk of fistula. Fistulas most frequently involve the duodenum, with hematemesis, melenemesis, melena, or hematochezia. While massive, life-threatening bleeding is common, mild sentinel bleeding may be the first sign. Aortic aneurysms also may erode into the venous vasculature and form **aortovenous fistulas**, which cause high-output cardiac failure, decreased arterial blood flow distal to the fistula, and increased central venous volume.

Contained chronic abdominal aortic aneurysmal ruptures are not common. A retroperitoneal rupture may cause enough fibrosis to limit blood loss, and the patient may look well. The inflammatory response commonly causes pain, with pain continuing for an extended interval, clouding the diagnosis.

Imaging Imaging performed away from the bedside can delay emergency consultation and operative repair, so consult a surgeon early and before any transport for imaging when a symptomatic aneurysm is suspected.

Radiologic evaluation may include plain radiography (**Figure 60-1**), US (**Figure 60-2**), CT scanning (**Figure 60-3**), or MRI. Plain abdominal films may show a calcified and bulging aortic contour, implying the presence of an aneurysm (Figure 60-1). Approximately 65% of patients with symptomatic aortic aneurysmal disease have a calcified aorta, often better seen on a lateral view. An anteroposterior projection may show an arch of calcification, most commonly on the patient's left. Rarely, a chronic aneurysm may erode into a vertebral body and be seen on plain film. Plain film radiographs do not exclude the presence of

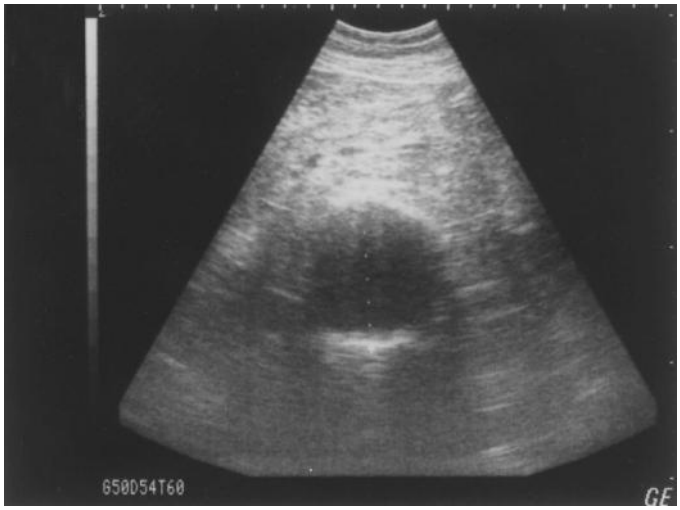

FIGURE 60-2. Bedside US image of an abdominal aortic aneurysm. This aneurysm measures 6.5 cm.

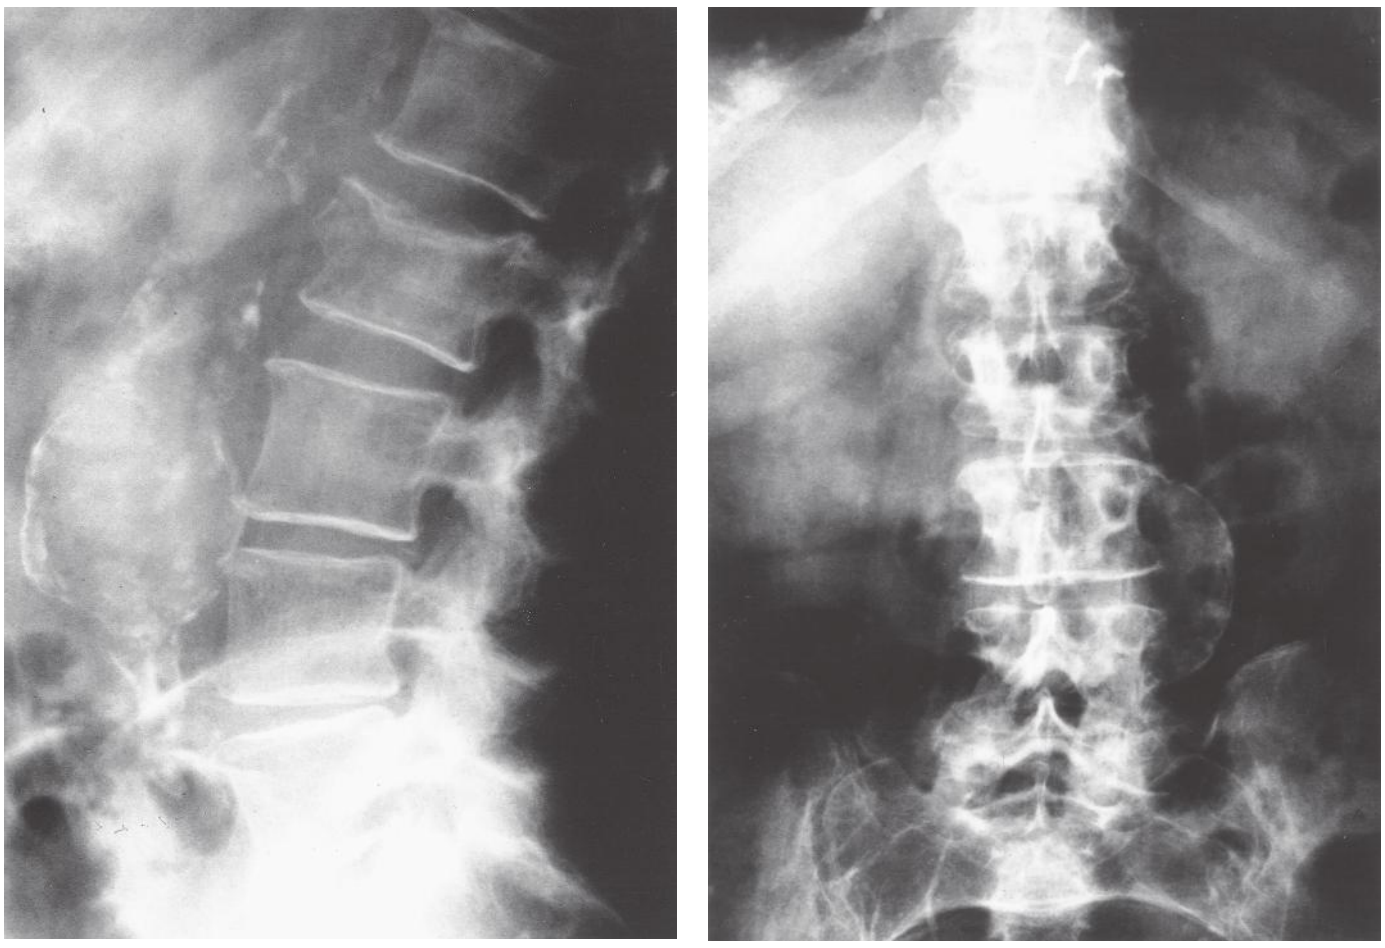

A B

FIGURE 60-1. Plain radiographic images of an abdominal aortic aneurysm. **A.** Lateral view of a calcified infrarenal aortic aneurysm. **B.** Posteroanterior view of a calcified infrarenal aortic aneurysm.

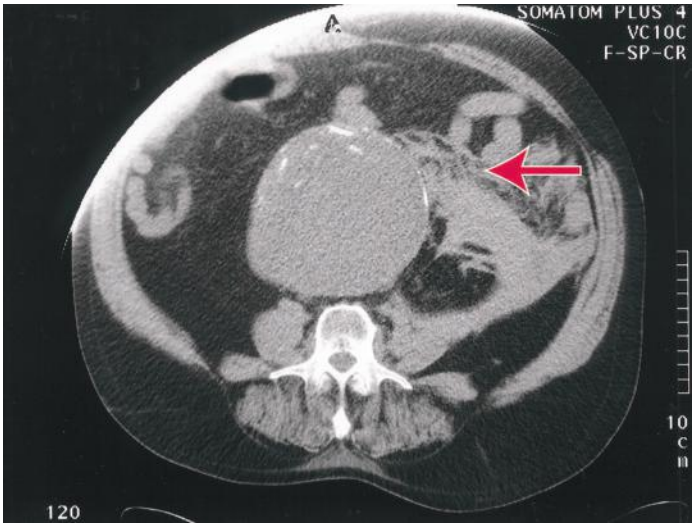

FIGURE 60-3. CT scan of a patient with a 12-cm abdominal aortic aneurysm. Calcification of the aortic wall is seen in the anterior aspect of the aneurysm. Evidence of hemorrhage and surrounding inflammation (*arrow*) is seen in the left side of the abdomen.

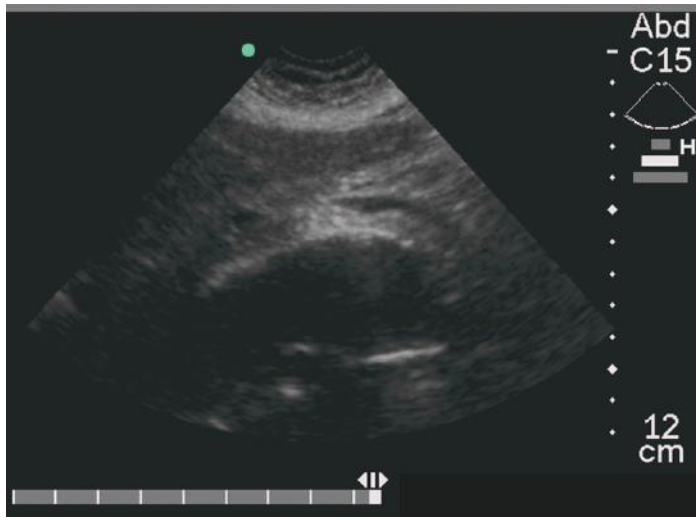

FIGURE 60-5. US image of an abdominal aortic aneurysm in the longitudinal plane.

abdominal aortic aneurysm or detect rupture and can be omitted in most patients.

Bedside US (Figure 60-2) is ideal for initial screening and for patients with any hemodynamic compromise. Emergency US is noninvasive, easily deployed, and does not entail removal of the patient from the resuscitation area.[10] **A technically adequate US study has >90% sensitivity for demonstrating the presence of an aneurysm and measuring its diameter.**[10] Obesity, bowel gas, and abdominal tenderness may make the study difficult to perform. Measure aneurysms from the outside margin of one wall to the outside margin of the opposite wall in both the transverse (**Figure 60-4**) and longitudinal (**Figure 60-5**) planes. Identifying the superior mesenteric artery (**Figure 60-6**) allows distinguishing the aorta from the vena cava. **An aortic diameter <3.0 cm excludes acute aneurysmal disease.**

CT scanning with IV contrast (Figure 60-3) best detects the anatomic details of the aneurysm and associated hemorrhage. Scan all stable patients with suspected abdominal aneurysmal disease or rupture. For those who cannot have IV contrast, unenhanced CT can reveal aneurysm size and retroperitoneal hemorrhage.

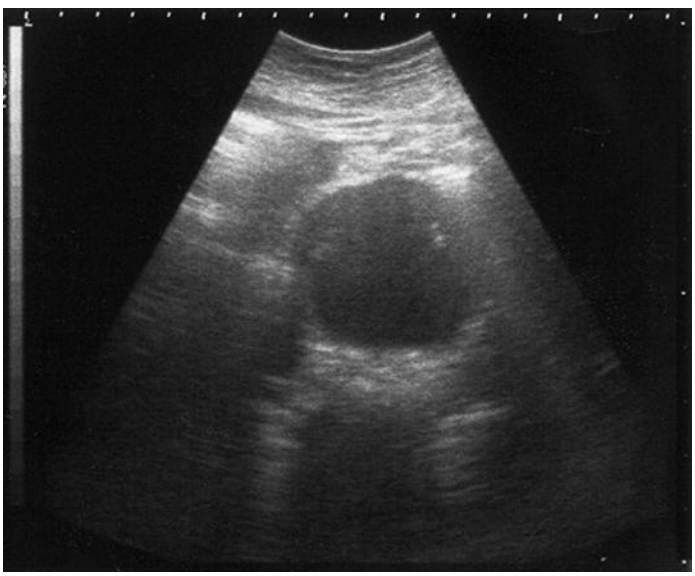

FIGURE 60-4. US image of an abdominal aortic aneurysm in the transverse plane.

TREATMENT

ED interventions are listed in **Table 60-1**.

All asymptomatic aortic aneurysms should be referred for follow-up. **Abdominal aortic aneurysms ≥5 cm in diameter are at an increased risk of rupture (size is measured from outer wall to outer wall) and require prompt (days) follow-up.** Aneurysms of 3 to 5 cm are less likely to rupture and can be followed by their primary care physicians or surgeons. The management of patients with small, asymptomatic aneurysms (including the timing of surgery) varies. **Symptomatic aneurysms of any size are considered emergent.**

All symptomatic aortic aneurysms require emergency surgical consultation or transfer to an institution capable of performing emergency repair. If at a site without appropriate surgical ability, initiate patient resuscitation and arrange for immediate transfer to a medical center that can provide emergency repair. Outcomes are better if prompt transfer occurs rather than local diagnostics (aside from bedside US).[11,12] Immediate transfer with providers able to recognize and treat shock (having fluid, blood, and blood products available) is the best option for patients in unstable condition.

In the ED, detection and arranging rapid care for hemorrhage control are key. Consult a surgeon early while evaluating any patient with the triad of abdominal and/or back pain, a pulsatile abdominal mass, and

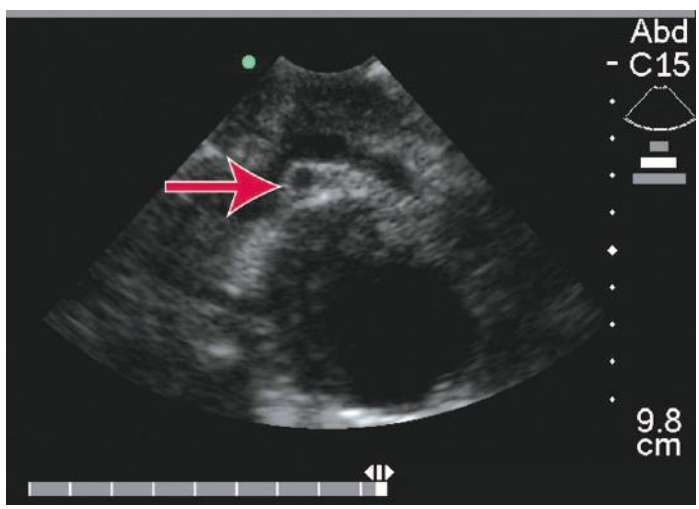

FIGURE 60-6. US image of an abdominal aortic aneurysm in the transverse plane showing the superior mesenteric artery (*arrow*) coursing parallel to the aorta.

TABLE 60-1 ED Interventions for Symptomatic Abdominal Aortic Aneurysms

Intervention	Comments
Consultation	As soon as diagnosis is suspected, consult with vascular or general surgeon or transfer to an institution capable of emergency repair.
Blood and fluids	Targets unclear; restoring normal blood pressure may worsen outcomes; often, permissive hypotension seeking a blood pressure of 90 mm Hg is best. Level of consciousness is another target for volume replacement.[14]
Pain control	Be careful to avoid hypotension or depressed respiratory drive.

hypotension[13]; however, this triad occurs in only one third of patients with ruptured abdominal aortic aneurysm.[8] Never delay consultation for imaging if hypotension or acute end-organ perfusion deficit is evident; often, bedside US can aid in quick tentative diagnosis.[13]

Any ruptured aortic aneurysm requires prompt operative repair. Use imaging only in those **fully** compensated or unlikely to have a ruptured abdominal aortic aneurysm. Standard resuscitative actions include insertion of two large-bore IV catheters, initiation of cardiac monitoring, and supplemental oxygen. Vigorous fluid resuscitation may be harmful; there are limited data, but animal research and anecdote support limiting resuscitation to a target of 90 mm Hg blood pressure and intact mentation until surgical control occurs.[15] Perioperative administration of β-blockers in nonruptured aneurysms reduces dysrhythmias and myocardial ischemia but does not appear to affect the rate of myocardial infarction, mortality, or length of hospitalization.[13] When used, esmolol (a short-acting β-blocker) is a common choice.

Endovascular techniques for the repair of ruptured abdominal aortic aneurysm are a feasible alternative to an open repair.[16] This intervention requires a skilled provider and appropriate facilities and team members.

Refer any patient with asymptomatic aortic abdominal aneurysms to a vascular surgeon and a primary care provider, the latter for blood pressure control.[17] Repairing aortic abdominal aneurysms smaller than 5.5 cm does not improve survival in men,[17] but may be indicated in women.[14]

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysms may compress or erode into adjacent structures. Presenting symptoms include esophageal, tracheal, bronchial, or even neurologic complaints. A thoracic aneurysm that erodes into an adjacent structure is generally immediately fatal unless in the presence of rapid hemodynamic resuscitation. Refer any asymptomatic thoracic aortic aneurysm patient to a surgeon and primary care provider for management, including blood pressure control. Repair may involve open or endovascular methods, with controversy over the best long-term outcomes between these approaches.[18]

EXTREMITY AND VISCERAL ANEURYSMS

Aneurysms of arteries other than the aorta cause symptoms by expansion or rupture. **Table 60-2** lists the risk factors, clinical presentation, and management of nonaortic large-artery aneurysms. Aneurysms of peripheral arteries, such as the popliteal, subclavian, or femoral, may present with limb-threatening complications, including rupture, thrombosis, and peripheral embolization. Visceral artery aneurysms remain silent until a complication occurs. Complications include renovascular hypertension, renal artery thrombosis, organ infarction from distal embolization, arteriovenous fistula formation, and rupture.[19,20] Consider visceral artery aneurysms in the differential diagnosis of a patient with sudden acute abdominal pain and evidence for intraperitoneal hemorrhage.[4,5,13,21]

A **popliteal aneurysm** is a localized dilation of the popliteal artery of >2 cm or >150% of the normal arterial caliber. Symptoms include discomfort behind the knee, leg swelling with or without deep venous thrombosis, or claudication. Rupture is rare. Sudden acute limb ischemia caused by thrombosis or embolization from the aneurysm is the most serious common complication.[2] On physical examination, a firm mass or a palpable pulsatile mass is evident in the popliteal fossa. Confirm the diagnosis with arterial US, and assess both extremities since popliteal aneurysms can be bilateral.

Femoral or iliac artery aneurysms present as a pulsatile mass in the groin or upper thigh, scrotal hematoma, or acute limb ischemia. Iliac artery aneurysms are notoriously difficult to suspect clinically because the iliac artery cannot be examined directly, and symptoms suggest urologic, bowel, or groin disorders.

Hepatic artery aneurysms result from atherosclerosis or trauma and present as acute hemorrhagic shock with intraperitoneal or retroperitoneal rupture. **Quincke's triad** (jaundice, biliary colic, and upper GI bleeding) is seen when hemobilia from a leaking hepatic artery aneurysm occurs.

Splenic artery aneurysms present with left upper quadrant pain, undifferentiated shock, or intra-abdominal hemorrhage. A rupture of

TABLE 60-2 Nonaortic Large-Artery Aneurysms

Artery	Risk Factors	Clinical Presentation	Management
Popliteal (>2 cm or >150% of normal caliber)	Advanced age, male gender, trauma, congenital disorders	Most common peripheral aneurysm; discomfort behind knee with swelling with or without deep venous thrombosis	Thrombolysis, ligation, arterial bypass, endovascular repair
Subclavian	Arteriosclerosis, thoracic outlet obstruction	Pulsatile mass above or below clavicle, dysphagia, stridor, chest pain, hoarseness, upper extremity fatigue or numbness and tingling, limb ischemic symptoms	Surgical repair
Femoral	Advanced age, male gender, trauma, congenital disorders	Pulsatile mass with or without pain, limb ischemic symptoms, peripheral embolic symptoms	Thrombolysis, ligation, arterial bypass, endovascular repair
Femoral pseudoaneurysm	Prior femoral artery catheterization, trauma, infection	Pulsatile mass with or without pain	Surgical repair
Iliac		Pain in groin, scrotum, or lower abdomen; sciatica; vulvar or groin hematoma with rupture	Surgical repair
Renal	Age 40–60 y, no gender preference, HTN, fibrodysplasia, arteriosclerosis	Flank pain, hematuria, collecting system obstruction, shock if ruptured	Surgical repair, nephrectomy
Splenic	Advanced age, female gender, HTN, congenital, arteriosclerosis, liver disease, multiparous, rupture increased in pregnancy	Rapid symptom onset; epigastric or left upper quadrant pain first, then diffuse abdominal pain with rupture, shock	Surgical repair, splenectomy, embolization if unruptured
Hepatic	Infection, arteriosclerosis, trauma, vasculitis	Obstructive jaundice, hemobilia from rupture into common bile duct, right upper quadrant pain, peritonitis, upper GI bleed	Surgical ligation, embolization

Abbreviation: HTN = hypertension.

the splenic artery has a poor prognosis because of its intraperitoneal location and nondescript presentation; be wary of these in the third trimester of pregnancy.[21]

Symptomatic **subclavian and innominate artery aneurysms** can lead to limb ischemia. When evaluating a patient with upper extremity pain, weakness, pallor, or nondermatome sensory changes, think of this as a possible cause.

Anastomotic aneurysms may occur in the aortic, iliac, or femoral arteries. These aneurysms cause catastrophic bleeding if they rupture; however, they may present with smaller sentinel hemorrhages noted as pain or transient hypotension. Anastomotic aneurysms may erode into the adjacent intestine and form an aortoenteric fistula. Severe lower GI bleeding in a patient with a history of abdominal aortic aneurysm repair is a classic presentation of this event.

Doppler US is the initial noninvasive diagnostic study for peripheral aneurysmal disease of the femoral, popliteal, and subclavian artery. If ischemia and thrombosis exist, emergent arteriography is usually performed for both diagnosis and potential treatment.

Symptomatic peripheral artery aneurysms require rapid diagnosis and consultation, especially in light of the potential for rupture, thrombosis, and limb ischemia (Table 60-2). For patients with clinical extremity ischemia, consult immediately with a vascular surgeon to expedite repair and limb salvage. Asymptomatic peripheral aneurysms are managed by a vascular consultant as an outpatient.

PRACTICE GUIDELINES

The 2011 American Heart Association guidelines are available at http://circ.ahajournals.org/content/124/18/2020.

CHAPTER 61

Arterial Occlusion

Anil Chopra
David Carr

INTRODUCTION AND EPIDEMIOLOGY

Acute limb ischemia requires rapid recognition and therapy for limb salvage. *Critical limb ischemia* occurs in chronic progressive peripheral arterial disease when pain at rest, ulceration, or gangrene exists. Despite improvements in the management of peripheral arterial disease, current 1-year mortality after the onset of critical limb ischemia is 25%, and 25% of survivors require amputation.[1,2]

The prevalence of peripheral arterial disease (defined as an ankle-brachial index of <0.9) in the United States is 4.3% for those >40 years old and 15.5% for those >70 years old.[3] This prevalence increases to 29% in high-risk populations in those >70 years old and those >50 years old with diabetes or a smoking history.[4] In the elderly, both sexes are affected equally, although symptoms are present two to four times more commonly in men. Smoking and diabetes are the most important risk factors for arterial insufficiency.[5] Additional risk factors include hyperlipidemia, hypertension, hyperhomocysteinemia, and an elevated C-reactive protein level.

Between 40% and 60% of patients with occlusive arterial disease have either coronary or cerebrovascular disease.[6] The severity of peripheral vascular disease is closely linked to the risk of myocardial infarction, ischemic stroke, and death from vascular disease.[7] The most frequently diseased arteries leading to limb ischemia are, in order of occurrence, the femoropopliteal, tibial, aortoiliac, and brachiocephalic vessels.

PATHOPHYSIOLOGY

Acute limb ischemia results from a lack of blood supply to meet tissue oxygen and nutrient requirements. As time proceeds, cell death or irreversible tissue damage occurs. Peripheral nerves and skeletal muscle are more sensitive to ischemia, and irreversible changes occur in these tissues within 6 hours.

After restoration of the blood flow, **reperfusion injury** can occur, noted by the presence of muscle pain and swelling, renal failure, and peripheral muscle infarction. Often, hyperkalemia, myoglobinemia, metabolic acidosis, and an elevation in creatine kinase level exist. The extent of reperfusion injury depends on the duration and location of the arterial blockage, the amount of collateral flow, and the previous health of the involved limb. Approximately one third of all deaths from occlusive arterial disease are secondary to metabolic complications after revascularization.[8]

Disorders that can lead to arterial occlusion are compared in **Table 61-1**.

THROMBOSIS

Thrombotic occlusion is the most common cause of *acute* limb ischemia. Both native vessels and bypass grafts can thrombose. In the lower limbs, thrombotic occlusion accounts for >80% of cases.[14] In the upper limbs, about half of all cases of acute limb ischemia are due to thrombosis, one third are due to embolism, and one fourth are secondary to arteritis.[15] The distinction between a thrombosis and an embolism in any given patient is not always clear.

Nonembolic limb ischemia is secondary to atherosclerosis in most patients. Complete or high-grade obstruction occurs from plaque rupture or endothelial erosion followed by thrombus formation. Acute limb ischemia from plaque rupture obstructs flow completely, triggering symptoms. However, most nonembolic ischemia is characterized by chronic occlusion that may be clinically silent or muted depending on the collateral network.

Other than plaque rupture, progression of ischemic injury occurs through several mechanisms: (1) propagation of clot to occlude collateral vessels, (2) ischemia-related distal edema leading to high compartment pressures (compartment syndrome), (3) fragmentation of clot into the microcirculation, and (4) edema of the microvasculature cells. Large-vessel reperfusion may not resolve obstruction of the microvasculature.

Uncommonly, arterial thrombosis can develop in an apparently normal vessel without an atherosclerotic plaque; if seen, seek an underlying hypercoagulable condition. Subclinical vessel injury (from injections, catheters, or other mechanical events) or early atherosclerosis may still underlie these events.

EMBOLISM

Occlusion from embolism is less common than occlusion from thrombosis, in part due to the decline in the incidence of rheumatic heart disease and the treatment of **atrial fibrillation** with anticoagulants. Emboli originate from the heart in most cases. Atrial fibrillation is associated with at least two thirds of all peripheral emboli, and the clot most commonly originates in the left atrial appendage. The second most frequent source is a **mural thrombus** in the ventricle after recent myocardial infarction, accounting for about 20% of all limb emboli. Both atrial fibrillation and acute myocardial infarction predispose to poor cardiac wall motion and stagnant blood flow that promote clot formation. The mean time to development of a clot after myocardial infarction is 14 days (range, 3 to 28 days).[16] The incidence of emboli originating from a mechanical valve has been lowered by advances in anticoagulation. Rare cardiac sources of emboli include tumor emboli from atrial myxomas, vegetations from valve leaflets, and parts of prosthetic cardiac devices.

Noncardiac sources of arterial emboli include thrombi from aneurysms and atheromatous plaques. Mural thrombi in aneurysms of aortoiliac, femoral, popliteal, and subclavian arteries are the most notable sources. Atheroemboli result from plaque fragmentation and cause obstruction of the microcirculation, producing symptoms in the hands, feet (blue toe syndrome), or cerebral circulation (transient ischemic attack). Atheroemboli consist of cholesterol-laden debris and

TABLE 61-1 Disorders Associated with Acute Arterial Occlusion

Disorder	Cause	Symptoms/Signs	Management
Thrombus	Atherosclerosis or thrombosis of bypass grafts	Intermittent claudication	Medical first, then consider interventional
Embolism	Cardiac source: atrial fibrillation, rheumatic heart disease, mechanical valves, post–myocardial infarction thrombus, atrial myxomas and leaflet vegetations	Sudden onset of territorial arterial symptoms	Preventative anticoagulation, embolectomy
Catheterization complication (brachial or femoral)	Can occur during standard angioplasty, angiography, or arterial blood gas	Expanding hematoma, pain, temperature and pulse changes	Conservative vs. operative repair
Trash foot or blue toe syndrome	Cholesterol/platelet aggregate emboli	Painful cyanotic discoloration of isolated portion of foot; remainder of the foot is warm	Conservative therapy
Vasculitis: rheumatoid arthritis, lupus, polyarteritis nodosa	Autoimmune inflammation of small arteries	Systemic symptoms and multiorgan ischemia	Steroids, immunosuppressive agents
Raynaud's disease	Vasospasm in small arteries or arterioles provoked by cold or stressors	Local pain, pallor, cyanosis, numbness, paresthesias in hands usually resolving in 30–60 min	Rewarming, medications: calcium channel blockers, α-blockers, vasodilators
Takayasu's arteritis	Autoimmune vasculitis of aortic arch and branches	Young Asian women: peripheral ischemia and necrosis leading to pulseless phase; may have fever, rash, muscle aches, arthritis	Steroids, immunosuppressive agents
Thromboangiitis obliterans (Buerger's disease)	Nonatherosclerotic segmental inflammation of small/medium vessels; typically, only seen in smokers	Painful nodules, ulceration, and gangrenous digits in young adults (age 20–40 y)	Smoking cessation
HIV arteritis[9]	Chronic inflammation of arteries associated with low CD4 counts	Intermittent claudication	Optimization of HIV management, angioplasty, or vein graft
Hypothenar hammer syndrome	Repeated trauma to the hypothenar area with hammering in laborers, as well as those using vibrational tools, causing narrowing of ulnar artery or aneurysmal degeneration	Painful discoloration of one or more ulnar fingers with sparing of thumb	Aspirin, nifedipine, intra-arterial fibrinolysis, interposition vein graft
Popliteal artery entrapment (young males) and popliteal aneurysms (older males)[10]	Anatomic crowding of popliteal fossa with anomalous relationships between popliteal artery and surrounding muscle and fascia or luminal narrowing and thrombosis of aneurysm	Pain in anterior aspect of lower one third of leg with exercise, reproducible with active ankle plantar flexion or passive dorsiflexion	Surgical repair of popliteal fossa or aneurysm and grafting
External iliac artery endofibrosis[11]	External iliac artery fibrosis secondary to prolonged hip flexion	Thigh pain and numbness in cyclists and triathletes: measure pre- and postcycling ankle-brachial indexes	Surgical management or catheter dilatation
Local arterial trauma[12,13]	Penetrating or blunt damage to vessel	Suspect in patients with knee dislocation or penetrating extremity trauma	Surgical repair
Shock-related arterial ischemia	Low cardiac output states: congestive heart failure, sepsis, cardiogenic or hypovolemic shock	Generalized hypoperfusion	Resuscitation with fluids, blood products, vasopressors, inotropes; treat infection
Thoracic aortic dissection	False lumen of dissection occludes arteries	Chest or back pain	Surgical repair

Abbreviation: HIV = human immunodeficiency virus (infection).

platelet aggregates that can disseminate to multiple sites in the body. Paradoxical embolization can occur when a venous clot passes from the right to the left side of the heart through an intracardiac shunt, most commonly a patent foramen ovale.

The natural history of an embolus is either to fragment and embolize distally or to propagate locally into a larger clot. Two thirds of all nonce-rebral emboli enter vessels of the lower limbs and lodge where vessels branch or taper. The most common location for an embolus in the leg is the bifurcation of the common femoral artery, followed by the popliteal artery. In the upper limb, the brachial artery is the vessel most commonly affected by an embolism.

OTHER CAUSES

Intentional or accidental **intra-arterial drug injections** by medical personnel or those taking illicit drugs can result in local vasospasm, infectious arteritis, thrombosis, pseudoaneurysm, and mycotic aneurysm. Inert particles or drug crystals can embolize to obstruct end arteries, which can lead to gangrene of the digits. The prolonged use of vasopressor medications may result in arterial ischemia and occlusion, and their use requires close observation of extremity perfusion, particularly in patients with known pre-existing vascular disease.

Limb ischemia may also occur with nonembolic central causes. A **thoracic aortic dissection** can propagate into the subclavian and iliofemoral systems and present with neurologic and/or extremity findings. The false lumen created by the dissection occludes flow in the involved artery.

CLINICAL FEATURES

Patients with acute limb ischemia exhibit one or more of the **"six Ps": pain, pallor, paralysis, pulselessness, paresthesias, and polar**

TABLE 61-2 Rutherford Criteria for Acute Limb Ischemia

		Findings		Doppler Signals	
Category	Description/Prognosis	Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

(for cold). A lack of one or more of these findings does not exclude ischemia. Furthermore, total occlusion of a severely diseased artery in patients with peripheral vascular disease with well-developed collateral blood supply may not be a dramatic event and can be silent. Pain alone may be the earliest symptom of ischemia, localized in the limb distal to the site of obstruction.

Skin changes include pallor first, followed by blotchy and mottled areas of cyanosis, and then associated petechiae and blisters. Late findings consist of skin and fat necrosis.

With vessel occlusion, severe and steady pain in the involved extremity associated with decreased skin temperature is common. Hypoesthesia or hyperesthesia due to ischemic neuropathy is typically an early finding, as is muscle weakness. Two-point discrimination, vibratory sensation, and proprioception are often diminished prior to the loss of deep sensation. Absence of a palpable distal pulse is not a particularly helpful sign in a patient with long-standing vascular disease unless accompanied by skin changes compatible with acute arterial obstruction. An abrupt loss of a previously strong pulse is suggestive of acute embolization.

As ischemic injury progresses, anesthesia and paralysis become evident and foreshadow impending gangrene and the loss of limb viability. Preservation of light touch on skin testing is a good guide to tissue viability. A patient with an acute ischemic limb with signs of muscle paralysis, sensory loss, and prolonged ischemia has a limb that is likely nonviable. The **Rutherford criteria** (**Table 61-2**) provide a more formal prognostic stratification of the clinical stages of acute limb ischemia.

The time limit for limb viability is dependent on the effectiveness of collateral circulation. Therefore, no arbitrary time period should be used to rule out treatment options despite the common belief that "treatment must occur in 4 to 6 hours."

Microemboli present clinically with pain and cyanosis in the involved digit, petechiae, and local muscle pain and tenderness at the site of infarction. Showering of these emboli creates several different small areas of involvement. Although mottling and decreased function may occur, pulses are preserved, assuming they were present to start, which is unusual in this population. Table 61-1 notes symptoms of related disorders.

ACUTE VERSUS CHRONIC ARTERIAL DISEASE

Acute limb ischemia is defined as symptoms starting within a 2-week period. Pain over the distal forefoot waking the patient at night or requiring the patient to hang his or her feet over the bed is suggestive of severe arterial occlusion and requires prompt consultation and treatment.

Claudication is a cramp-like pain, ache, or tiredness that is brought on by exercise and relieved by rest. It is reproducible, resolves within 2 to 5 minutes of rest, and recurs at consistent walking distances. The pain of acute limb ischemia is not well localized, is not relieved by rest or gravity, and can be a worsening of chronic pain (if it is caused by a thrombotic event).

Chronic obstructive arterial disease is characterized by intermittent claudication, which may progress to intermittent ischemic pain at rest. Femoropopliteal disease and aortoiliac disease often cause reproducible calf pain with activity that is relieved with rest. Pain at rest typically localizes to the foot and is aggravated by leg elevation, improves with standing, and is poorly controlled with analgesics. Classical teaching suggests that single-level disease in one of the segments noted in **Table 61-3** may result in claudication, whereas multilevel disease results in rest pain or tissue loss. Table 61-3 lists symptom sites of commonly compromised arteries.

The pain associated with intermittent vascular claudication can be confused with leg pain from many causes (**Table 61-4**) including spinal stenosis or lumbosacral radiculopathy.

Uncommon presentations of deep venous thrombosis—**phlegmasia cerulea dolens** (painful blue inflammation) and **phlegmasia alba dolens**, or "milk leg"—can be confused with obstructive arterial disease. In phlegmasia cerulea dolens, the leg is markedly swollen and cyanotic from venous engorgement due to massive iliofemoral thrombosis. This high-grade obstruction can compromise perfusion to the foot from high compartment pressures and lead to venous gangrene.[17] Phlegmasia alba dolens is usually seen during pregnancy and is a result of iliofemoral thrombosis with concomitant leg pallor from arterial spasm. Dorsalis pedis and posterior tibial pulses may be diminished or absent, which can lead to a false diagnosis of arterial occlusion. The arterial spasm with milk leg is transient and often followed by venous engorgement, which aids diagnosis. For a more complete list of the differential diagnoses for intermittent claudication, see Table 61-4.

On physical examination, examine the skin and all peripheral pulses of both extremities. Compare the unaffected to the affected limb. Shiny, hyperpigmented skin with hair loss and ulceration, thickened nails, muscle atrophy, vascular bruits, and poor pulses are the hallmark of chronic obstructive arterial disease. In contrast to the common medial malleolar location of venous insufficiency ulcers, arterial ulcers tend to occur on the foot and toes and are typically more painful. When evaluating someone with a chronic, nonhealing ulcer, consider the possibility of both venous and arterial insufficiency. Perform a cardiovascular and abdominal examination, including auscultation for bruits, search for murmurs, and palpation of the abdominal aorta.

DIAGNOSIS

The clinical exam guides initial decisions and causes (**Table 61-5**); if severe or limb-threating new ischemia of any cause is suspected, promptly consult

TABLE 61-3 Artery-Specific Claudication Sites

Artery Involved	Claudication Site
Iliac artery	Buttocks, thigh, and sometimes calf (if bilateral, may cause impotence in men)
Common femoral artery	Thigh
Superficial femoral artery	Upper two thirds of calf
Popliteal artery	Lower one third of calf
Infrapopliteal (tibial and peroneal) artery	Foot

TABLE 61-4 Differential Diagnoses of Intermittent Claudication (IC)

Condition	Location	Prevalence	Characteristic	Effect of Exercise	Effect of Rest	Effect of Position	Other Characteristics
Calf IC	Calf muscles	3%–5% of adult population	Cramping, aching discomfort	Reproducible onset	Quickly relieved	None	May have atypical limb symptoms on exercise
Thigh and buttock IC	Buttocks, hip, thigh	Rare	Cramping, aching discomfort	Reproducible onset	Quickly relieved	None	Impotence May have normal pedal pulses with isolated iliac artery disease
Foot IC	Foot arch	Rare	Severe pain on exercise	Reproducible onset	Quickly relieved	None	Also may present as numbness
Chronic compartment syndrome	Calf muscles	Rare	Tight, bursting pain	After much exercise (jogging)	Subsides very slowly	Relief with elevation	Typically heavily muscled athletes
Venous claudication	Entire leg, worse in calf	Rare	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep venous thrombosis, signs of venous congestion, edema
Nerve root compression	Radiates down leg	Common	Sharp lancinating pain	Induced by sitting, standing, or walking	Often present at rest	Improved by change in position	History of back problems Worse with sitting Relief when supine
Symptomatic Baker's cyst	Behind knee, down calf	Rare	Swelling, tenderness	With exercise	Present at rest	None	Not intermittent
Hip arthritis	Lateral hip, thigh	Common	Aching discomfort	After variable degree of exercise	Not quickly relieved	Improved when not weight bearing	Symptoms variable History of degenerative arthritis
Spinal stenosis	Often bilateral buttocks, posterior leg	Common	Pain and weakness	May mimic IC	Variable relief but can take a long time to recover	Relief by lumbar spine flexion	Worse with standing and extending spine
Foot/ankle arthritis	Ankle, foot, arch	Common	Aching pain	After variable degree of exercise	Not quickly relieved	May be relieved by not bearing weight	Variable, may relate to activity level and be present at rest

a vascular surgeon prior to performing confirmatory imaging. Other features guide care; a history of an abruptly ischemic limb in a patient with atrial fibrillation or recent myocardial infarction strongly suggests an embolus. Acute ischemia in the limb of a patient known to have advanced obstructive arterial disease is more likely due to thrombosis or a low cardiac output state. In patients without antecedent claudication and a normal uninvolved limb, embolic occlusion is likely present. If there are ischemic changes, an arterial thrombotic cause is more likely than an embolism.

For a more detailed comparison of acute embolism and thrombosis, see Table 61-5.

Decreased perfusion is detected by blanching the involved extremity with finger pressure and noting a delay in the return of blood compared with the uninvolved extremity; 2 to 3 seconds is considered normal. The test is influenced by many other factors, so it alone cannot determine perfusion status.

TABLE 61-5 Embolic versus Thrombotic Occlusion

Factor	Embolism	Thrombosis
History of claudication	No	Yes
Physical examination	Normal contralateral limb	Marked signs of occlusive arterial disease bilaterally
Source identified	Often	None
Timing	Sudden, exact time known	More gradual
Radiologic features	Sudden abrupt cutoff in blood flow with no collateral circulation and minimal diseased vessel	Widespread disease with collaterals present and gradual narrowing of blood flow seen

Use a hand-held Doppler ultrasound device over pulse areas to detect presence or absence of blood flow and the amplitude. Approximately 10% of patients have only one pedal or ankle pulse present secondary to an anatomic variation. If Doppler flow is detected in the affected limb, check the **ankle-brachial index** and segmental leg pressures. The ankle-brachial index is the ratio of the systolic blood pressure with the cuff just above the malleolus (with the Doppler probe over the posterior tibial or dorsalis pedis artery) to the highest brachial pressure in either arm (**Figure 61-1**). Patients with chronic obstructive arterial disease have an ankle-brachial index of <0.9. Values of <0.25 suggest potentially limb-threatening vascular disease. An ankle-brachial index of >1.3 is likely secondary to a noncompressible vessel; it may be seen in patients with severe vascular calcification, especially diabetics, and is notoriously unreliable in this patient population. In such cases, toe-brachial pressures can be measured, but the technique requires specialized equipment. Segmental blood pressures measured with the Doppler device on the posterior tibial or dorsalis pedis artery and the cuff placed below the knee, above the knee, and on the high thigh can aid assessment. **A difference of 30 mm Hg or more between any two adjacent levels localizes the site of obstruction.** With successful reperfusion, the ankle-brachial index and segmental pressures begin to return to baseline or normalize if no residual obstruction remains after clot dissolution.

LABORATORY EVALUATION

Aside from seeking markers of cellular death (e.g., creatine kinase or myoglobin and serum lactate), obtain other tests to assess metabolic

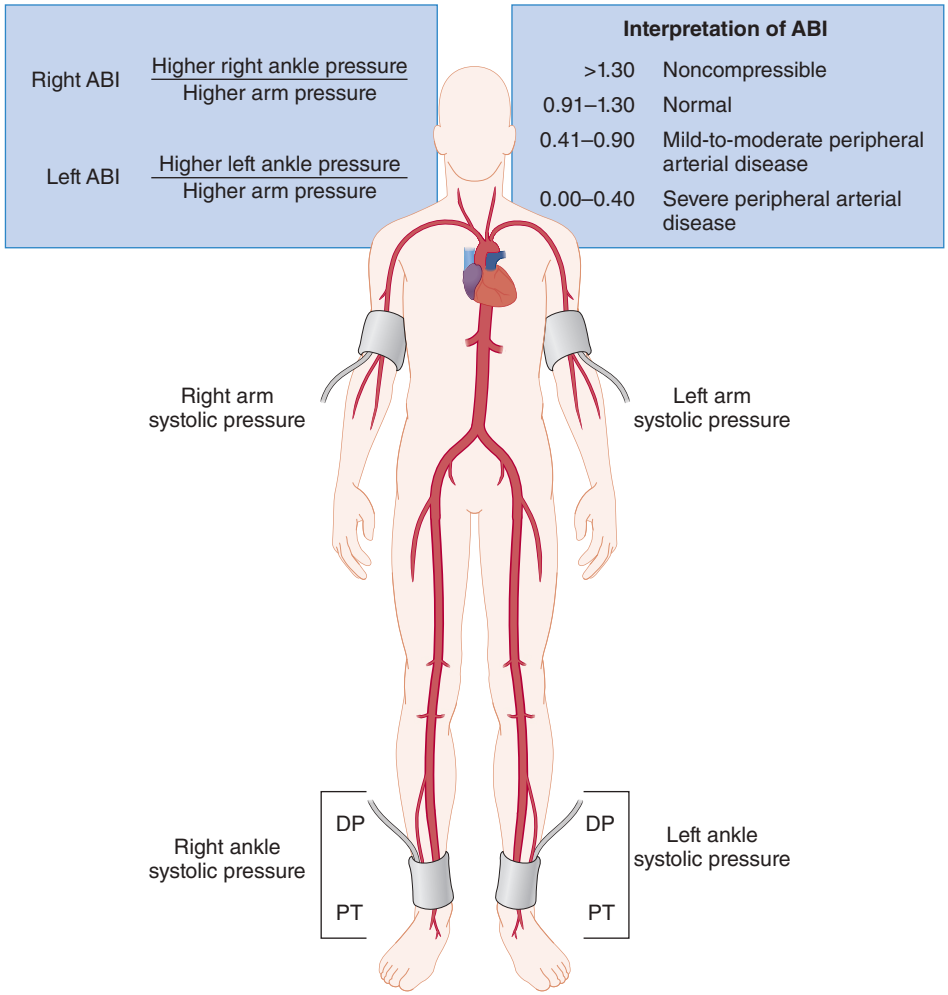

FIGURE 61-1. Measurement of the ankle-brachial index (ABI). Measure the systolic blood pressure using Doppler US in each arm and in the dorsalis pedis (DP) and posterior tibial (PT) arteries in each ankle. Select the higher of the two arm pressures (right vs. left) and the higher of the two pressures in the ankle (DP vs. PT). Determine the right and left ABI values by dividing the higher ankle pressure in each leg by the higher arm pressure. The ranges of the ABI and the interpretation are shown in the figure. In the case of a noncompressible calcified vessel, the true pressure at that location cannot be obtained, and alternative tests are required to diagnose peripheral arterial disease. Patients with claudication typically have ABI values ranging from 0.41 to 0.90, and those with critical leg ischemia have values <0.41.

status (electrolytes and glucose), renal function (BUN and creatinine plus urinalysis), anemia and infection (CBC), and bleeding tendency (prothrombin and partial thromboplastin times). Levels of cardiac markers and ECG may identify associated cardiac triggers (including infarction or rhythm change).

IMAGING

If the diagnosis of arterial occlusion is in question, duplex US is very accurate for detecting complete or incomplete obstruction. Sensitivity declines for localization of thromboembolic occlusion at or below the calf level. Transthoracic cardiac echocardiography can help detect embolic sources, and transesophageal approaches add the ability to detect aortic root pathology.

Arteriography is often obtained prior to surgical intervention[1] or to direct therapy. Embolic occlusion displays an abrupt cutoff of blood flow in a disease-free or minimally diseased vessel. Arteriography requires the administration of contrast material, so assess renal function and hydrate before the study.

CT with contrast is the most readily available added study in the ED and has a sensitivity similar to that of conventional contrast studies in large vessels. MRI has higher sensitivity and specificity but is less readily available.

TREATMENT

The objectives of therapy for acute arterial obstruction are restoration of blood flow to preserve limb and life, and prevention of recurrent thrombosis or embolism (**Table 61-6**).

IV unfractionated heparin (weight-based 80 units/kg bolus followed by an infusion of 18 units/kg/h) is common initial therapy. Anticoagulation may prevent clot extension, recurrent embolization, venous thrombosis, microthrombi distal to the obstruction, and reocclusion after reperfusion.[19] It is still unclear whether heparin administration improves outcome in the clinical circumstance of thrombosis in a plaque-laden artery.

TABLE 61-6 ED Medical Therapy for Acute Limb Ischemia

Intervention	Comments
Unfractionated heparin[18]	80 units/kg bolus followed by infusion of 18 units/kg/h
Aspirin[18]	325 milligrams PO first dose (82 milligrams daily thereafter)
Pain control	As needed for patient comfort and cooperation
Environment protection	Protect ischemic limb from temperature extremes

Enoxaparin (1 milligram/kg SC) is an alternative, although heparin remains the common choice. Aspirin (325 milligrams in naïve patients) may enhance clot reduction through antiplatelet actions.

Even before starting anticoagulation, start seeking vascular consultation, transferring if needed. Stratifying patients with acute limb ischemia by Rutherford criteria (Table 61-1) can guide initial care. Patients with stage I and stage IIa limb ischemia may undergo diagnostic imaging workup prior to more definitive treatments. Patients with stage IIb ischemia often require immediate revascularization without additional diagnostic imaging modalities prior to operative or interventional treatment. Patients with stage III ischemia have suffered irreversible damage and likely require amputation. Provide adequate analgesia and fluid resuscitation and treat heart failure (if existing) to help improve limb perfusion.

The vascular surgeon determines definitive treatment, which can include catheter-directed thrombolysis, percutaneous mechanical thrombectomy, revision of an occluded bypass graft, and revascularization with either percutaneous transluminal angioplasty or standard surgery.[2,18] Catheter-directed intra-arterial thrombolysis is now often chosen over systemic thrombolysis for peripheral artery embolic or thrombotic disease.[18,19] In a subacute thrombotic occlusion with a well-developed collateral blood supply, medical management is common.

The longer-term nonsurgical management of chronic obstructive arterial disease focuses on the combination of smoking cessation, exercise, and pharmacotherapy. Daily aspirin (81 to 162 milligrams) reduces mortality by 25%.[4,20-23] Anticoagulants, such as warfarin, factor Xa, or thrombin inhibitors, are used when clot formation is severe or recurrent.[20] Lowering cholesterol and blood pressure and improving glycemic control also are key secondary modifiers.[4]

The American College of Cardiology/American Heart Association 2005 guidelines include cilostazol, a phosphodiesterase inhibitor, as a Class I recommendation for the treatment of claudication in patients with obstructive arterial disease[2] (avoid in patients with heart failure). Pentoxifylline is a second-line therapy for the treatment of claudication (Class IIb).[2,24]

DISPOSITION AND FOLLOW-UP

Patients with acute or worsening chronic ischemia require further assessment and hospital admission or transfer to a center with vascular surgery capability. Patients with chronic peripheral arterial disease without an immediate threat to limb viability absent other acute illness can be discharged home to follow up with a vascular surgeon or primary care physician. Instruct patients to return immediately for worsening of symptoms. Prescribe aspirin (81 milligrams daily after first dose of 325 milligrams) if there are no contraindications.

PRACTICE GUIDELINES

Guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic)[2] are available at http://circ.ahajournals.org/cgi/reprint/113/11/e463.

SPECIAL CONSIDERATIONS

UPPER EXTREMITY ISCHEMIA

Acute arterial occlusion in the upper extremities is much less common than in the lower limbs, and due to well-developed collateral circulation around the shoulder and elbow, is better tolerated. Ischemic pain at rest and gangrene, in the absence of distal embolization, are rare in the upper limb. Causes of upper limb ischemia include vasospasm, arteritis, trauma, atherosclerotic plaque rupture, embolism, iatrogenic injury (e.g., during brachial artery access for cardiac catheterization), thoracic outlet syndromes, aneurysms, and hypercoagulable states. After clinical examination, further investigation of suspected ischemia is done with segmental blood pressure measurements above and below the elbow, Doppler evaluation, duplex US, and arteriography. Treatment of acute limb-threatening ischemia of the hand and forearm includes heparin (Table 61-6) and emergent surgical thromboembolectomy.

SECTION 8

Pulmonary Disorders

CHAPTER 62

Respiratory Distress

John Sarko
J. Stephan Stapczynski

GENERAL APPROACH TO RESPIRATORY DISTRESS

INTRODUCTION

Dyspnea is a subjective feeling of difficult, labored, or uncomfortable breathing, which patients often describe as "shortness of breath," "breathlessness," or "not getting enough air."[1] Dyspnea is frequently associated with other respiratory symptoms or signs. **Tachypnea** is rapid breathing. **Orthopnea** is dyspnea in the recumbent position. It is most often the result of left ventricular failure, but can also be seen with diaphragmatic paralysis or chronic obstructive pulmonary disease. **Paroxysmal nocturnal dyspnea** is orthopnea that awakens the patient from sleep, prompting an upright posture in order to resolve breathlessness. **Trepopnea** is dyspnea associated with only one of several recumbent positions. Trepopnea can occur with unilateral diaphragmatic paralysis, with ball-valve airway obstruction, or after surgical pneumonectomy. **Platypnea** is the opposite of orthopnea: dyspnea in the upright position. Platypnea results from the loss of abdominal wall muscular tone and, in rare cases, from right-to-left intracardiac shunting, as occurs from a patent foramen ovale. **Hyperpnea** is essentially hyperventilation and is defined as minute ventilation in excess of metabolic demand. **Respiratory distress** is a term used by the physician, combining the patient's subjective sensation of dyspnea with signs indicating difficulty breathing. **Ventilatory or respiratory failure** occurs when the lungs and ventilatory muscles cannot move enough air in and out of the alveoli to adequately oxygenate arterial blood and eliminate carbon dioxide.

PATHOPHYSIOLOGY

Dyspnea is a complex sensation that arises from the interaction of multiple pathophysiologic mechanisms.[1,2] Sensory information about respiratory activity generated by multiple afferent receptors is integrated within the CNS at both the subcortical and cortical levels. The current explanation for the sensation of dyspnea is when imbalance exists among the inspiratory drive, efferent activity to the respiratory muscles, and feedback from these afferent receptors.

CLINICAL FEATURES

Dyspnea is a feature of several disorders seen in the ED (**Table 62-1**). The presence or degree of dyspnea is difficult to measure, although categorical scales (e.g., the Borg or Fletcher scales) and visual analog scales can be used to gauge response to therapy.[1,3] Assess for evidence of impending respiratory failure: marked tachypnea and tachycardia; stridor; use of the accessory respiratory muscles, including the sternocleidomastoid, sternoclavicular, and intercostals; inability to speak normally as a consequence of breathlessness; agitation or lethargy as a consequence of hypoxemia; depressed consciousness due to hypercapnia; and paradoxical abdominal wall movement when the abdominal wall retracts inward with inspiration, indicating diaphragmatic fatigue. In patients with these signs, give oxygen and be prepared for more advanced measures (discussed elsewhere). Lesser degrees of dyspnea allow for a more detailed medical history, physical examination, and indicated ancillary tests.

DIAGNOSIS

Ask about recent infectious and environmental exposures that may impair respiratory function. Carefully question patients who require daily medications for symptom control about compliance and possible drug interactions.

Dyspnea is a prominent symptom of heart failure,[4] and differentiating heart failure from pulmonary causes of dyspnea is an important and frequently difficult task. Treatment and prognosis differ, and embarking down the wrong pathway of treatment can have adverse consequences.[5] Several findings can assist in this differentiation, although few of them are definitive by themselves (**Table 62-2**).[6-8]

An S_3 gallop on physical examination or pulmonary venous congestion/interstitial edema (especially with concomitant cardiomegaly) on chest x-ray strongly suggest heart failure as the cause of the dyspnea (**Figure 62-1**).[6] The physician's overall gestalt of the diagnosis, the presence of jugular venous distention on examination, and alveolar edema on chest x-ray suggest heart failure. Wheezing, dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and leg edema are not useful in discriminating between cardiac and pulmonary causes. Conversely, the absence of these findings does not exclude heart failure.

LABORATORY TESTING AND IMAGING

Pulse oximetry provides a rapid assessment of arterial oxygen saturation but is an insensitive screening test for disorders of gas exchange. Arterial blood gas analysis is more sensitive for detecting impaired gas exchange but cannot evaluate the work of breathing. Arterial blood gas testing can find the rare patient with dyspnea or tachypnea who exhibits no evidence of hypoxemia or pulmonary disease, suggesting hyperventilating from metabolic acidosis.

Bedside spirometric analysis (e.g., peak expiratory flow), especially if performed before and after bronchodilator therapy, can be used to diagnose dyspnea resulting from asthma or chronic obstructive pulmonary disease, but spirometry requires voluntary effort that might be difficult for dyspneic patients.

Negative inspiratory force can assess strength of the diaphragm and inspiratory muscles. Other potentially useful tests include an ECG and measuring the hemoglobin level. In most ED patients, the cause of dyspnea can be identified by the history, the physical examination, and these ancillary tests.

B-type natriuretic peptide (BNP) is a polypeptide secreted by ventricular myocytes in response to volume expansion and pressure overload; BNP elevates with any cause of overload, including heart failure, myocardial ischemia, pulmonary embolism, sepsis, chronic obstructive pulmonary disease, or any right heart strain. Serum levels of BNP or its precursor, N-terminal pro-BNP, are measured using two methods: an enzyme-linked immunosorbent assay and a radioimmunoassay; the enzyme-linked immunosorbent assay is more accurate than the radioimmunoassay.[9]

A normal BNP (<100 picograms/mL) or N-terminal pro-BNP (<500 picograms/mL) excludes heart failure in low and moderate pretest probability patients outside of "flash" settings.[6,9,10] A high level (BNP >500 picograms/mL or N-terminal pro-BNP >2000 picograms/mL)

TABLE 62-1 Common Causes of Dyspnea in the ED

Most Common Causes	Most Immediately Life-Threatening Causes
Obstructive airway disease: asthma, chronic obstructive pulmonary disease	Upper airway obstruction: foreign body, angioedema, hemorrhage
Decompensated heart failure/ cardiogenic pulmonary edema	Tension pneumothorax
Ischemic heart disease: unstable angina and myocardial infarction	Pulmonary embolism
Pneumonia	Neuromuscular weakness: myasthenia gravis, Guillain-Barré syndrome, botulism
Psychogenic	Fat embolism

is moderately useful for establishing the diagnosis of heart failure, although these elevations are rarely unsuspected after a careful history, exam, and chest radiograph.[10,11] Overall, BNP measurement offers limited real help in assessing dyspneic patients,[12] especially when values between 100 and 500 picograms/mL occur, which is common in the patient without a clear clinical syndrome.[11,13,14]

A chest radiograph may find a pulmonary abnormality, infiltrate, effusion, and pneumothorax.

Bedside lung US is an important tool in the assessment of acute dyspnea. It can differentiate acute decompensated heart failure from noncardiac causes of acute dyspnea with a sensitivity and specificity of about 97% and is superior to chest x-ray and natriuretic peptide determination.[15,16] Bedside US can identify pleural effusion, pneumothorax, cardiac tamponade, cardiac functional abnormalities, pulmonary consolidation, and intravascular volume status (**Figures 62-2 to 62-4**).[17,18]

TREATMENT

In severe dyspnea, the initial treatment goal is maintenance of the airway and oxygenation, seeking a partial pressure of alveolar oxygen (Pao_2) > 60 mm Hg and/or arterial oxygen saturation (Sao_2) ≥90%. Next, or in those with lesser dyspnea, treat the underlying disorder. Rarely are opioids or benzodiazepines used as dyspnea therapy, except in near terminal states for patient comfort.[1,19]

TABLE 62-2 Factors Supporting Heart Failure as the Cause of Dyspnea[6]

Finding	LR+ (95% CI)	LR– (95% CI)
Clinical gestalt	4.4 (1.8–10.0)	0.45 (0.28–0.73)
History		
Heart failure	5.8 (4.1–8.0)	0.45 (0.38–0.53)
Myocardial infarction	3.1 (2.0–4.9)	0.69 (0.58–0.82)
Coronary artery disease	1.8 (1.1–2.8)	0.68 (0.48–0.96)
Symptoms		
Paroxysmal nocturnal dyspnea	2.6 (1.5–4.5)	0.70 (0.54–0.91)
Orthopnea	2.2 (1.2–3.9)	0.65 (0.45–0.92)
Edema	2.1 (0.92–5.00)	0.64 (0.39–1.10)
Dyspnea on exertion	1.3 (1.2–1.4)	0.48 (0.35–0.67)
Physical examination		
S_3 gallop	11.0 (4.9–25.0)	0.88 (0.83–0.94)
Jugular venous distention	5.1 (3.2–7.9)	0.66 (0.57–0.77)
Hepatojugular reflex	6.4 (0.81–51.00)	0.79 (0.62–1.00)
S4	1.6 (0.47–5.50)	0.98 (0.93–1.00)
Wheezing	0.52 (0.38–0.71)	1.3 (1.1–1.7)
Chest x-ray		
Pulmonary venous congestion	12.0 (6.8–21.0)	0.48 (0.28–0.83)
Interstitial edema	12.0 (5.2–27.0)	0.68 (0.54–0.85)
Alveolar edema	6.0 (2.2–16.0)	0.95 (0.93–0.94)
Cardiomegaly	3.3 (2.4–4.7)	0.33 (0.23–0.48)
ECG		
Atrial fibrillation	3.8 (1.7–8.8)	0.79 (0.65–0.96)
Any abnormal finding	2.2 (1.6–3.1)	0.64 (0.47–0.88)

Abbreviations: CI = confidence interval; LR = likelihood ratio.

FIGURE 62-1. Pulmonary edema. Cardiomegaly is present, the pulmonary vasculature is engorged, and cephalization of flow is present.

HYPOXIA AND HYPOXEMIA

Hypoxia is insufficient delivery of oxygen to the tissues. The amount of oxygen available to the tissues is a function of the arterial oxygen content (Cao_2) comprising a small portion dissolved in plasma and a larger portion bound to Hb:

$$Cao_2 = 0.0031 \times Pao_2 + 1.38 \times Hb \times Sao_2 \qquad \textbf{[Formula 1]}$$

Oxygen delivery (Do_2) is a product of arterial oxygen content and cardiac output (CO):

$$Do_2 = Cao_2 \times CO \qquad \textbf{[Formula 2]}$$

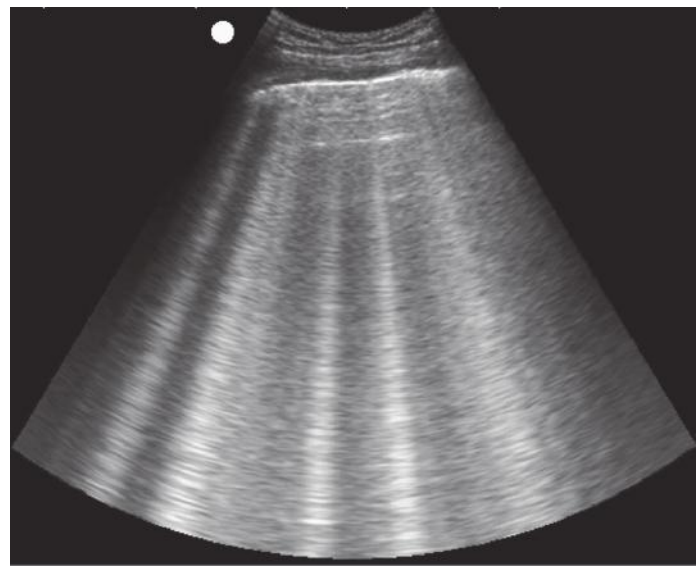

FIGURE 62-2. B lines of pulmonary edema. [Reproduced with permission from Silva FR, Mills L: Chapter 7. Pulmonary, in Ma OJ, Mateer JR, Reardon RF, et al (eds): *Ma and Mateer's Emergency Ultrasound*, 3rd ed. New York: McGraw-Hill Education; 2014. Fig. 7-4, Part B, p. 176.]

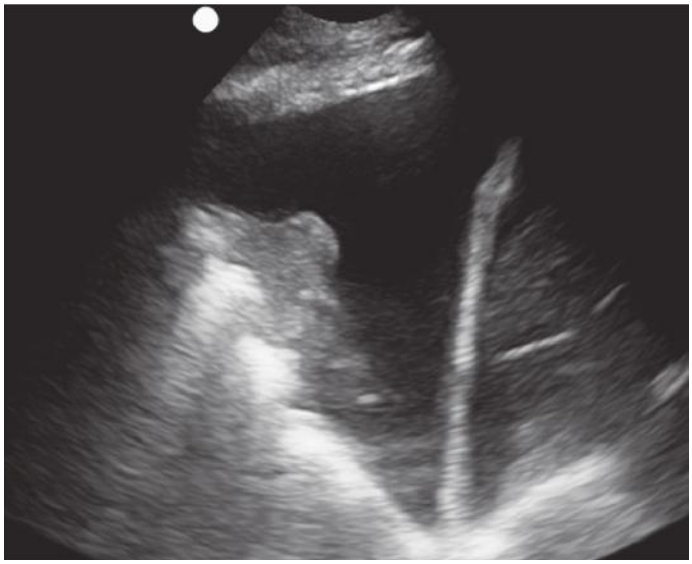

FIGURE 62-3. Pleural effusion. [Reproduced with permission from Silva FR, Mills L: Chapter 7. Pulmonary, in Ma OJ, Mateer JR, Reardon RF, et al (eds): *Ma and Mateer's Emergency Ultrasound*, 3rd ed. New York: McGraw-Hill Education; 2014. Fig. 7-4, Part D, p. 177.]

Tissue hypoxia occurs in states of low cardiac output, low Hb concentration, or low Sao_2. The level of oxygen saturation in arterial Hb is, in turn, dependent on the Pao_2, as determined by the oxygen-Hb dissociation curve. **Hypoxemia** is an abnormally low arterial oxygen tension (defined as a Pao_2 <60 mm Hg). While hypoxemia is the most common cause of hypoxia, *hypoxia* and *hypoxemia* are not interchangeable; one can occur without the other. For example, in states of low Pao_2 (hypoxemia) with concomitant polycythemia, the patient may have no tissue hypoxia. Alternatively, severely anemic patients may suffer tissue hypoxia despite a normal Pao_2.

Relative hypoxemia is the term used when the arterial oxygen tension is lower than expected for a given level of inhaled oxygen. The degree of relative hypoxemia can be assessed by calculating the alveolar arterial (A-a) oxygen partial pressure gradient, [$P(A\text{-}a)O_2$], which measures efficiency of oxygen transfer from the lungs to the circulation. Alveolar oxygen partial pressure is determined by the inhaled oxygen concentration (21% for room air), atmospheric pressure (760 mm Hg at sea level), and displacement by water vapor (47 mm Hg for full saturation) and carbon dioxide (CO_2). Gas in the alveolus is fully saturated with water vapor, and the amount of alveolar oxygen is further reduced by CO_2 that freely diffuses from the pulmonary capillaries in an amount determined by the ratio between oxygen consumption and CO_2 production, termed the *respiratory quotient* (R), which is affected by diet. On a typical mixed diet, the R is 0.8. Alveolar oxygen breathing room air at sea level has a:

$$P_{AO_2} = 0.21 \times (760 - 47) - Paco_2/0.8 \qquad \textbf{[Formula 3]}$$

The A-a gradient at sea level for room air is a:

$$P(A\text{-}a)O_2 = 149 - Paco_2/0.8 - Pao_2 \qquad \textbf{[Formula 4]}$$

A simplified formula often used is:

$$P(A\text{-}a)O_2 = 145 - Paco_2 - Pao_2 \qquad \textbf{[Formula 5]}$$

A normal $P(A\text{-}a)O_2$ is <10 mm Hg in young, healthy patients and increases with age, predicted by the formula:

$$\mathbf{P(A\text{-}a)O_2 = 2.5 + 0.21\ (age\ in\ years)\ (\pm\ 11)} \qquad \textbf{[Formula 6]}$$

This normal A-a gradient is for healthy, asymptomatic individuals measured in an upright or sitting position. The supine position alone, as well as many chronic cardiac or pulmonary diseases, may raise the A-a gradient. The supine position is a common ED patient position, impairing the assessment.

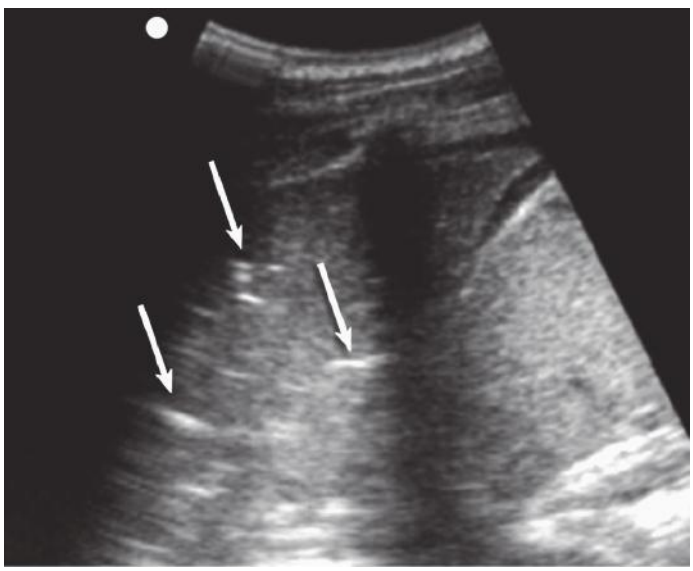

FIGURE 62-4. *Arrows* point to areas of pulmonary consolidation. [Reproduced with permission from Silva FR, Mills L: Chapter 7. Pulmonary, in Ma OJ, Mateer JR, Reardon RF, et al (eds): *Ma and Mateer's Emergency Ultrasound*, 3rd ed. New York: McGraw-Hill Education; 2014. Fig. 7-4, Part C, p. 177.]

PATHOPHYSIOLOGY

Hypoxemia results from any combination of five mechanisms.

1. *Hypoventilation.* Hypoxemia from hypoventilation alone has an increased $Paco_2$ and a normal A-a O_2 gradient. The additional CO_2 displaces inhaled oxygen in the alveolus. However, the remaining alveolar oxygen diffuses and mixes normally into the arterial blood, displaying a normal A-a O_2 gradient as long as there is no alveolar or interstitial disease.
2. *Right-to-left shunt.* Right-to-left shunting occurs when blood enters the systemic circulation without traversing ventilated lung. There is always a small degree of right-to-left shunting because of the direct left atrial return of deoxygenated blood from both the coronary veins and the bronchial arteries. Increased right-to-left shunting occurs in a variety of conditions, including congenital cardiac malformation and acquired pulmonary disorders (pulmonary consolidation, pulmonary atelectasis). Regardless of the specific cause of the right-to-left shunt, it is always associated with an increase in the A-a O_2 gradient. **A hallmark of significant right-to-left shunting is the failure of arterial oxygen levels to increase in response to supplemental oxygen.** Although a small improvement may be observed with supplemental oxygen, hypoxemia is never fully eliminated because of the mixing of deoxygenated blood in the systemic circulation.
3. *Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch.* Ideal pulmonary gas exchange depends on a balance of ventilation and perfusion. Any abnormality resulting in a regional alteration of either ventilation or perfusion can adversely affect pulmonary gas exchange, resulting in hypoxemia. There are many causes of $\dot{V}/\dot{Q}$ mismatch, including pulmonary emboli, pneumonia, asthma, chronic obstructive pulmonary disease, and even extrinsic vascular compression. Regardless of cause, hypoxemia from ventilation-perfusion mismatch is associated with an increased A-a O_2 gradient, and hypoxemia improves with supplemental oxygen.

4. *Diffusion impairment.* Pulmonary gas exchange requires diffusion across the alveolar–blood barrier. Regardless of the specific cause of the diffusion impairment, the A-a O_2 gradient is increased, and hypoxemia improves with supplemental oxygen.
5. *Low inspired oxygen.* Decreased ambient oxygen pressure results in hypoxemia. This is commonly seen at high altitude (including commercial air travel) or in nonobstructive asphyxia. The A-a O_2 gradient is normal, and hypoxemia improves with supplemental oxygen. For example, Denver, at 5400 ft (1646 m) above sea level, has an atmospheric pressure of 620 mm Hg and an inhaled P_{O_2} of only 0.21 × 620 = 130 mm Hg, as opposed to 160 mm Hg at sea level.

There are three distinct acute compensatory mechanisms for hypoxemia. Initially, minute ventilation increases. Next, pulmonary arterial vasoconstriction decreases perfusion to hypoxic alveoli. Although vasoconstriction balances ventilation and perfusion to restore arterial oxygenation, it may also cause acute right heart failure and is ineffective with diffuse lung disease. Finally, sympathetic tone increases and improves oxygen delivery by increasing cardiac output, usually with an increased heart rate. Chronic compensatory mechanisms include an increased red blood cell mass and decreased tissue oxygen demands. These compensatory mechanisms appear to be activated at different levels of hypoxemia among different individuals. However, the acute compensatory mechanisms are always activated when Pa_{O_2} reaches 60 mm Hg, and compensatory mechanisms fail when Pa_{O_2} falls below 20 mm Hg.

CLINICAL FEATURES

The signs and symptoms of hypoxemia are nonspecific. CNS manifestations include agitation, headache, somnolence, coma, and seizures. Although tachypnea and hyperventilation are often present, by the time Pa_{O_2} is <20 mm Hg, there is a central depression of respiration. **Cyanosis, the blood or tissue discoloration associated with a lowered arterial oxygenation saturation, is not a sensitive or specific indicator of hypoxemia.** Patients with chronic compensatory mechanisms may display polycythemia or alterations in body habitus (e.g., pulmonary cachexia).

DIAGNOSIS AND TREATMENT

Hypoxemia is defined as a Pa_{O_2} <60 mm Hg, so formal diagnosis requires arterial blood gas analysis. Although pulse oximetry is useful for screening purposes and decreased Sa_{O_2} readings accurately predict significant hypoxemia, clinically acceptable pulse oximetry saturation readings (>90%) do not exclude hypoxemia. If certain hemoglobin abnormalities exist (e.g., methemoglobin or carboxyhemoglobin), pulse oximetry analysis may overestimate oxygen saturation and under measure the response to supplemental oxygen (see the section "Cyanosis," below). Regardless of the specific cause of hypoxemia, the initial approach remains the same: ensuring a patent airway and providing supplemental oxygenation with a goal of maintaining a Pa_{O_2} >60 mm Hg. **Except in patients with right-to-left shunts, arterial oxygenation responds to supplemental oxygen.**

HYPERCAPNIA

Hypercapnia is exclusively caused by alveolar hypoventilation and is defined as a Pa_{CO_2} >45 mm Hg. Alveolar hypoventilation has many causes, including rapid shallow breathing, small tidal volumes, underventilation of the lung, or reduced respiratory drive. **Hypercapnia never results from increased CO_2 production alone (Table 62-3).**

PATHOPHYSIOLOGY

A portion of each tidal volume remains in the non–gas-exchange portion of the respiratory system—termed the *dead space*—that is determined by the anatomic size of the conducting airways (trachea and bronchi). The portion of the tidal volume that reaches the alveoli is that which remains after the dead space volume is subtracted:

$$Ta\ (\text{alveolar volume}) = V_T\ (\text{tidal volume}) - Td\ (\text{dead space}) \quad \textbf{[Formula 7]}$$

Alveolar ventilation (V_A) per minute is the alveolar volume multiplied by the respiratory rate:

$$V_A = Ta \times R = (V_T - Td) \times R \quad \textbf{[Formula 8]}$$

Alveolar hypoventilation can result from a decrease in respiratory rate, a decrease in V_T, or an increase in dead space. Dead space volume can increase above that due to the anatomic size of the conducting airways, such as seen as a result of ventilation of lung portions with deficient or absent perfusion; these ventilated portions do not participate fully in gas exchange because of inadequate blood flow.

Medullary chemoreceptors stimulate both respiratory rate and V_T in response to increased CO_2, so that alveolar ventilation is finely controlled relative to CO_2 production and Pa_{CO_2} is maintained within a narrow range. Decreased respiratory drive is associated with CNS lesions and toxic depression (Table 62-3). Thoracic cage and neuromuscular disorders produce hypoventilation by slowing respiratory rate and/or decreasing V_T relative to the production of CO_2. Intrinsic lung diseases, such as chronic obstructive pulmonary disease, produce alveolar hypoventilation because of an increase in dead space.

TABLE 62-3 Causes of Hypercapnia

Depressed central respiratory drive
Structural CNS disease: brainstem lesions
Drug depression of respiratory center: opioids, sedatives, anesthetics
Endogenous toxins: tetanus
Thoracic cage disorders
Kyphoscoliosis
Morbid obesity
Neuromuscular impairment
Neuromuscular disease: myasthenia gravis, Guillain-Barré syndrome
Neuromuscular toxin: organophosphate poisoning, botulism
Intrinsic lung disease associated with increased dead space
Chronic obstructive pulmonary disease
Upper airway obstruction

CLINICAL FEATURES

The signs and symptoms of hypercapnia depend on the absolute value of Pa_{CO_2} and its rate of change. Acute elevations result in increased intracranial pressure, and patients may complain of headache, confusion, or lethargy. Severe hypercapnia can produce seizures and coma. Extreme hypercapnia can result in cardiovascular collapse, but this is usually seen only with acute elevations of Pa_{CO_2} >100 mm Hg. As opposed to acute hypercapnia, chronic hypercapnia, even >80 mm Hg, may be well tolerated.

DIAGNOSIS

Diagnosis of hypercapnia requires arterial blood gas analysis, and pulse oximetry assessment can be normal. With acute hypercapnia, the serum bicarbonate level increases slightly as a result of mass action through the CO_2–bicarbonate (HCO_3^-) equilibrium: HCO_3^- increases about 1 mEq/L for each increase of 10 mm Hg in the Pa_{CO_2}. Patients with chronic hypercapnia have an elevated serum HCO_3^- concentration and normal pH due to the renal retention of bicarbonate in response to increased Pa_{CO_2}: the serum HCO_3^- concentration increases about 3.5 mEq/L for each increase of 10 mm Hg in the Pa_{CO_2}.

TREATMENT

Hypercapnia is treated by increasing minute ventilation, both the respiratory rate and the V_T, as appropriate. This involves ensuring a patent airway and may require noninvasive ventilation, mechanical ventilation, the use of an antidote to reverse drug toxicity, or, rarely, the use of a respiratory stimulant such as doxapram.[20] **Do not withhold oxygen required to maintain minimum saturation levels in any chronic lung disease patient in an effort to stimulate ventilation and reduce hypercapnia.**

The disposition of hypercapnic patients depends primarily on the underlying cause and severity. In general, patients with hypercapnia with new acidosis or that causes CNS symptoms should be hospitalized. Also, patients with neuromuscular disease—either congenital or acquired—who present with acute hypercapnia should be hospitalized. Some chronic obstructive pulmonary disease patients have chronic hypercapnia and do not require admission provided they are stable. Conversely, patients with chronic obstructive pulmonary disease who display worsening hypercapnia despite maximal outpatient therapy require hospital admission.

WHEEZING

Wheezes are "musical" adventitious lung sounds produced by airflow through the central and distal airways.[21] The duration is prolonged, typically >80 milliseconds. Wheezes differ from the other two main adventitial lung sounds: rhonchi and crackles (rales). Rhonchi are a series of damped sinusoidal sounds of lower frequency (<300 Hz) and prolonged duration (>100 milliseconds). Crackles or rales are a series of intermittent individual sounds, typically <20 milliseconds in duration. Wheezing is usually more prominent on exhalation, in contrast to upper airway stridor, which is more prominent during inspiration.

The current theory is that wheezes are produced by airway flutter and vortex shedding from the central and distal airways, although movement of airway secretions may play a small role. Airway obstruction comes from bronchial smooth muscle contraction (bronchospasm), smooth muscle hypertrophy, increased mucus secretion, and peribronchial inflammation.

Wheezing is usually associated lower airway disease such as with asthma or other obstructive pulmonary diseases with muscular spasm and inflammation (**Table 62-4**). Upper airway obstruction causes stridor, which is loudest during inspiration. An occasional wheeze is normal during forced expiration in some normal children and adults, and conversely, patients with severe airflow obstruction may not have audible wheezes.

Diagnosis and treatment of the different causes of wheezing are discussed in specific chapters in the Adult and Pediatric sections of this book. Treatment of wheezing is directed to the underlying disorder.

TABLE 62-4 Differential Diagnosis of Wheezing

Upper airway (more likely to be stridor, may be hard to separate from wheezing)
Angioedema: allergic, angiotensin-converting enzyme inhibitor, idiopathic
Foreign body
Infection: croup, epiglottis, tracheitis
Lower airway
Asthma
Transient airway hyperreactivity (usually caused by infection or irritation)
Bronchiolitis
Chronic obstructive pulmonary disease
Foreign body
Cardiovascular
Cardiogenic pulmonary edema ("cardiac asthma")
Noncardiogenic pulmonary edema (acute respiratory distress syndrome)
Pulmonary embolus (rare)
Psychogenic

COUGH

Cough is a protective reflex for clearing secretions and foreign debris from the tracheobronchial tree.[22] Coughing is initiated by stimulation of irritant receptors located largely in the larynx, trachea, and major bronchi. These receptors are stimulated by inhaled irritants (e.g., dust), allergens (e.g., ragweed pollen), toxic substances (e.g., gastric acid), hypo- or hyperosmotic liquids, inflammation (e.g., asthma), cold air, instrumentation, and excess pulmonary secretions. Minor cough receptors located in the upper respiratory tract (sinuses and pharynx) and chest (pleura, pericardium, and diaphragm) may stimulate coughing. Signals from these receptors travel by means of the vagus, phrenic, and other nerves to the cough center in the medulla.

Once stimulated, the cough center initiates the stereotypical cough pattern: a deep inspiration followed by attempted expiration against a closed glottis that suddenly opens, providing for a forceful exhalation of gas, secretions, and foreign debris from the tracheobronchial tree. The coughing sound is generated at the larynx and resonates in the nasal cavity and the lungs.

CLINICAL FEATURES

Acute cough is cough lasting <3 weeks and is usually associated with self-limited infectious upper respiratory or bronchial infections (Table 62-5).[23] Subacute cough lasts 3 to 8 weeks and is most commonly postinfectious, but causes of subacute cough overlap with causes of acute and chronic cough. **Chronic cough is cough present for >8 weeks.**[23]

ACUTE COUGH

Acute cough is most often caused by upper respiratory tract infection, lower respiratory tract infection, and allergic reactions.[23] Common upper respiratory infections are associated with a combination of rhinorrhea, sinusitis, pharyngitis, and laryngitis, with the cough a result of drainage from the nasopharynx onto cough receptors in the pharynx and larynx. A productive cough is the hallmark of acute bronchitis. Although pneumonia generally produces a cough, pulmonary secretions may be scant and the cough nonproductive. Pertussis in adults has been associated with acute cough lasting 1 to 6 weeks.[24] The observed increased incidence of pertussis in adolescents and young adults is thought to be due to waning vaccine immunity with increasing age.

SUBACUTE COUGH

Postinfectious cough is the most likely cause of subacute cough. The mechanisms include postviral airway inflammation with bronchial hyperresponsiveness, mucus hypersecretion, upper airway cough syndrome (postnasal discharge), or asthma.

TABLE 62-5 Differential Diagnosis of Cough

Acute	Chronic	Chronic: Less Common
Upper respiratory infection: rhinitis, sinusitis, pertussis	Smoking and/or chronic bronchitis	Heart failure
Lower respiratory tract infection: bronchitis, pneumonia	Upper airway cough syndrome (postnasal discharge syndrome)	Bronchiectasis
Allergic reaction	Asthma: reactive airways disease	Lung cancer or other intrathoracic mass
Asthma	Gastroesophageal reflux	Emphysema
Environmental irritants	Angiotensin-converting enzyme inhibitor	Occupational and environmental irritants
Transient airway hyperresponsiveness	Angiotensin II receptor blocker	Recurrent aspiration or chronic foreign body
Foreign body	Postinfectious; pertussis	Psychiatric
		Miscellaneous: cystic fibrosis, interstitial lung disease

CHRONIC COUGH

The most common causes of chronic cough are (1) smoking, often with chronic bronchitis; (2) upper airway cough syndrome (formerly postnasal discharge); (3) asthma; (4) gastroesophageal reflux; and (5) angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB) therapy (Table 62-5).[25,26] Smoking-induced coughing is usually worse in the morning and, with chronic bronchitis, usually productive. Upper airway cough syndrome, formerly called *postnasal discharge syndrome*, is associated with mucus drainage from the nose, a history of "allergies or sinus problems," and frequent clearing of the throat or swallowing of mucus.[27] The postnasal drainage itself may not only directly stimulate a cough, but the conditions producing postnasal drainage (e.g., allergic rhinitis) may also cause irritation or inflammation of upper airway structures that directly stimulates cough receptors independently of the drainage. Chronic cough associated with asthma is usually worse at night, exacerbated by irritants, and associated with episodic wheezing and dyspnea.[28] Asthma can be exacerbated by β-blocker therapy and also presents with nocturnal coughing. Cough associated with gastroesophageal reflux often has a history of heartburn, is worse when lying down, and improves with anti-acid therapy (antacids, H_2 blockers, or proton pump blockers).[29]

The incidence of ACE inhibitor cough is approximately 10% to 12%, although higher values have been reported.[30] All ACE inhibitors and ARBs can induce cough, although ARBs appear to have a lower reported incidence.[31] ACE inhibitor cough is thought to result when the blockade of ACE leads to accumulation of bradykinin and substance P, which stimulate the pulmonary cough receptors and enhance the formation of irritating prostaglandin metabolites. ACE inhibitor cough is highly variable in (1) onset (as early as 1 week to as late as 1 year after starting treatment), (2) severity (only slightly bothersome to debilitating symptoms), and (3) variation during the day. Cough typically resolves in 1 to 4 weeks after ACE or ARB therapy is stopped but may linger up to 3 months.[30] See chapter 14, "Anaphylaxis, Allergies, and Angioedema," for further discussion.

DIAGNOSIS AND TREATMENT

Most causes of acute cough do not warrant ancillary tests. A chest radiograph is wise for patients with purulent sputum and/or fever, and spirometry can document the presence of airflow obstruction in patients with asthma. Pertussis is a clinical diagnosis in patients with subacute cough as the commonly available culture, and polymerase chain reaction tests have decreasing sensitivity after the third week of coughing.[14]

ACUTE COUGH

In addition to disease-specific therapy,[32] patients with acute cough may benefit from antitussives, which block the cough reflex at various locations.[33,34] Demulcents, part of most proprietary cough preparations, soothe the pharynx and somewhat suppress the cough reflex. Of the herbal agents, menthol and the pungent spices (e.g., pepper, mustard, garlic, radish, and onions) have an antitussive effect.[35] Naproxen reduces coughing in patients with acute bronchitis.[36,37] In both children and adults, acute coughing illnesses can last up to 3 weeks.[38,39] For intractable coughing paroxysms in the ED, some patients respond to 4 mL of 1% or 2% preservative-free lidocaine (40 or 80 milligrams) by nebulization. This will cause transient suppression of the gag reflex due to posterior pharyngeal anesthesia.

SUBACUTE AND CHRONIC COUGH

Determine if the subacute cough is postinfectious—one following a recent respiratory infection. If postinfectious, then assess for transient bronchial hyperresponsiveness, asthma, pertussis, upper airway cough syndrome, pneumonia, or an acute exacerbation of chronic bronchitis. Treatment is then directed at the presumed cause. If subacute cough is not postinfectious, it is evaluated and treated in the same manner as a chronic cough.

Chronic cough is most often the result of a few common disorders, so an algorithmic approach to treatment using sequential steps is effective[25,26,40] (**Figure 62-5**):

- Reduce exposure to lung irritants (e.g., smoking) and discontinue ACE inhibitors, ARBs, and β-blockers.

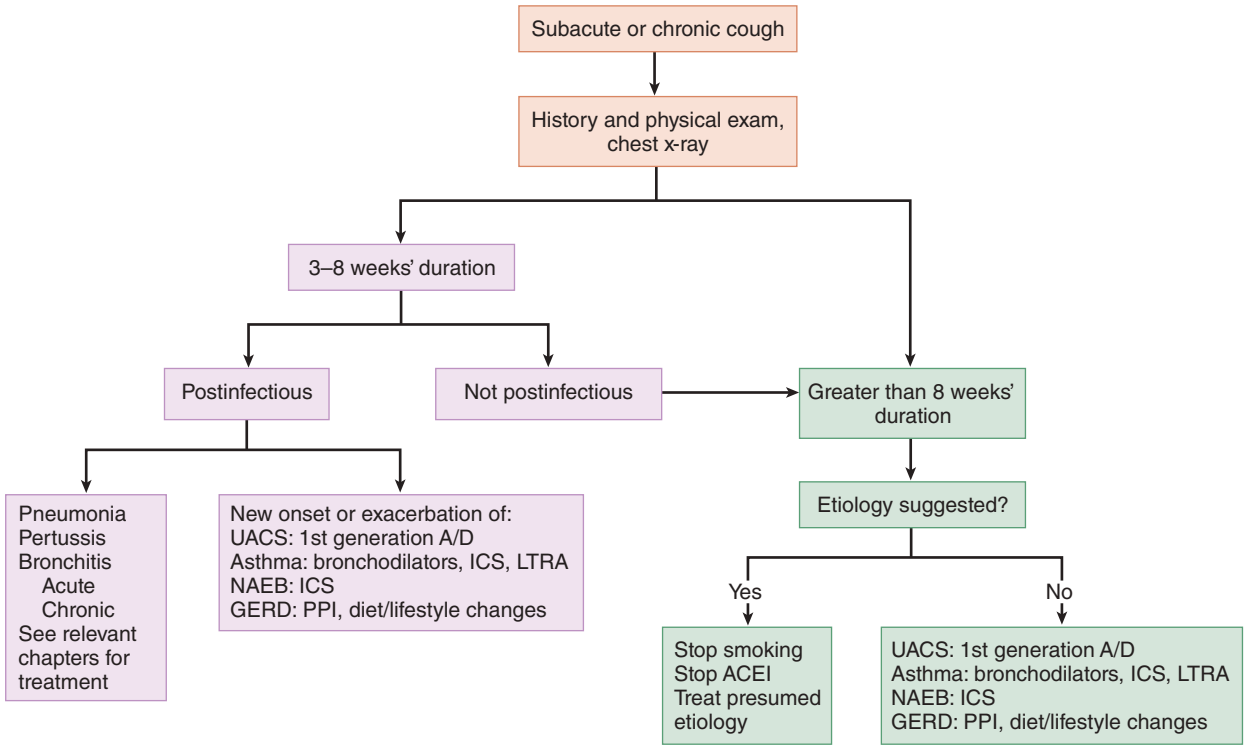

FIGURE 62-5. Evaluation of subacute and chronic cough for patients 15 years of age and older.[23] ACEI = angiotensin-converting enzyme inhibitor; A/D = antihistamine/decongestant; GERD = gastroesophageal reflux disease; ICS = inhaled corticosteroids; LTRA = leukotriene receptor antagonist; NAEB = nonasthmatic eosinophilic bronchitis; PPI = proton pump inhibitor; UACS = upper airway cough syndrome.

- Treat for postnasal discharge with an oral first-generation antihistamine/decongestant with or without an inhaled nasal steroid. If the cough improves, continue treatment and evaluate for sinus disease with imaging studies.
- Evaluate and treat for asthma.
- Obtain chest and sinus imaging if not already done.
- Evaluate and treat for gastroesophageal reflux.
- Refer the patient for specialist evaluation, for CT of the chest and evaluation for pulmonary and nonpulmonary causes of cough, or bronchoscopy.

By using a sequential approach, >95% of patients achieve resolution of their cough.[40] Opioid and nonopioid antitussives may help some patients who remain symptomatic.[41]

HICCUPS

Hiccup, or singultus, is involuntary spastic contraction of the inspiratory muscles. Hiccups have no specific protective purpose.[42]

PATHOPHYSIOLOGY

The afferent arm of the hiccup reflex consists of the phrenic and vagus nerves as well as the thoracic sympathetic chain. Normally, glottis closure inhibits inspiration and prevents aspiration during swallowing. Conversely, inspiration normally inhibits glottic closure and maintains an open airway. The hiccup reflex disrupts the connection between these two processes so that 30 to 40 milliseconds after the onset of inspiration, glottic closure is stimulated. In most cases in which a specific cause can be assigned, hiccups appear to result from stimulation, inflammation, or injury to one of the nerves of the reflex arc.

CLINICAL FEATURES

Hiccups are classified as benign and self-limited or persistent and intractable (**Table 62-6**).[42]

Benign hiccups are generally initiated by gastric distention from food, drinking (especially carbonated beverages), or air. Alcohol ingestion appears to precipitate hiccups by relaxing the relationship between inspiration and glottic closure, making it easier for other stimuli to trigger the reflex.

Persistent hiccups are usually a result of injury or irritation to a branch of the vagus or phrenic nerves. One rare but readily treatable stimulus is a foreign body (often a hair) in the external auditory canal that is pressing against the tympanic membrane and stimulating the auricular branch of the vagus nerve. Several drugs—usually steroids and benzodiazepines—are implicated in inducing hiccups, but the evidence is weak.[43]

DIAGNOSIS AND TREATMENT

Determine whether a specific triggering event exists (Table 62-6). Ask if the hiccups persist during sleep; resolution during sleep suggests a psychogenic cause, although this distinction is not absolute. Look in the external auditory canal for a foreign body. A chest radiograph should be done to evaluate for intrathoracic pathology. Fluoroscopy can evaluate for unilateral versus bilateral diaphragmatic movement during hiccups but is not part of the ED evaluation. Unilateral movement suggests focal injury to the phrenic nerve on the affected side.

A variety of physical maneuvers and medications have been used to terminate an acute episode of hiccups (**Tables 62-7 and 62-8**).[44,45]

Many of these physical maneuvers are based on the concept that stimulating the pharynx will block the vagal portion of the reflex arc and abolish the hiccups.[44] No one method appears to be more effective than another. Swallowing a teaspoon of dry granulated sugar is about as effective as others and does not involve the infliction of noxious or painful stimulation.

Drug treatment (Table 62-8) also works by inhibiting the reflex arc.[44] Several agents are described as effective, but mostly only through case reports.[45] Of the recommended drugs, only chlorpromazine has U.S. Food and Drug Administration approval for treatment of intractable hiccups. Chlorpromazine and metoclopramide take effect within 30 minutes. Adverse effects include extrapyramidal symptoms with both agents and hypotension with chlorpromazine. Nifedipine, valproate, baclofen, and gabapentin[46] are second-line outpatient options usually started by the primary care physician.

CYANOSIS

Cyanosis is a bluish color of the skin and mucous membranes resulting from an increased amount of reduced Hb (deoxyhemoglobin) or Hb derivatives. The detection of cyanosis is subjective and is not a sensitive indicator of the state of arterial oxygenation; cyanosis is determined by the absolute amount of deoxygenated Hb in the blood, not the amount of oxygenated Hb. Cyanosis is divided into central or peripheral categories (**Table 62-9**). **Central cyanosis is cyanosis of mucous membranes and tongue due to inadequate pulmonary oxygenation or an abnormal Hb. Peripheral cyanosis is cyanosis of the fingers or extremities from vasoconstriction and diminished peripheral blood flow.** All conditions that cause central cyanosis also result in peripheral cyanosis.

TABLE 62-6 Differential Diagnosis of Consequence: Hiccups

Acute: Benign, Self-Limited	Chronic: Persistent, Intractable
Gastric distention	CNS structural lesions
Alcohol intoxication	Vagal or phrenic nerve irritation
Excessive smoking	Metabolic: uremia, hyperglycemia
Abrupt change in environmental temperature	General anesthesia
Psychogenic	Surgical procedures: thoracic, abdominal, prostate and urinary tract, craniotomy
	Foreign body in ear touching tympanic membrane (especially hair)

TABLE 62-7 Treatment of Hiccups: Physical Maneuvers

Remove foreign body from ear
Swallow a teaspoon of sugar
Sip ice water
Drink water quickly

TABLE 62-8 Treatment of Hiccups: Drug Treatment

Drug	Initial Dose	Maintenance Dose
Chlorpromazine	25–50 milligrams IV, repeat in 2–4 h if needed	25–50 milligrams PO three to four times a day
Metoclopramide	10 milligrams IV or IM	10–20 milligrams PO three times a day for 10 d
Haloperidol	2–5 milligrams IM	1–4 milligrams PO three times a day
Nifedipine	10–20 milligrams PO	10–20 milligrams PO three to four times a day
Valproate	15 milligrams/kg PO	15 milligrams/kg PO three times a day
Baclofen	10 milligrams PO	10 milligrams PO three times a day
Gabapentin	100 milligrams	100 milligrams PO three times a day

TABLE 62-9 Differential Diagnosis of Cyanosis

Central Cyanosis	Peripheral Cyanosis
Hypoxemia	Reduced cardiac output
Decreased fraction of inspired oxygen: high altitude	Cold extremities
Hypoventilation	Maldistribution of blood flow: distributive forms of shock
Ventilation–perfusion mismatch	Arterial or venous obstruction
Right-to-left shunt: congenital heart disease, pulmonary arteriovenous fistulas, multiple intrapulmonary shunts	
Abnormal hemoglobin	
Methemoglobinemia: hereditary, acquired	
Sulfhemoglobinemia: acquired	
Carboxyhemoglobinemia	

CLINICAL FEATURES

Cyanosis is usually visible when deoxygenated Hb exceeds 5 grams/dL, but individuals with sensitive vision in ideal circumstances may detect central cyanosis with deoxyhemoglobin concentration as low as 1.5 grams/dL. Various physiologic, anatomic, and physical factors other than the amount of reduced Hb may influence the appearance of cyanosis, making an accurate clinical detection of the degree or even the presence of cyanosis difficult (**Table 62-10**).

The tongue and buccal mucosa are thought to be sensitive sites for observing central cyanosis. Peripheral cyanosis is caused by the slowing of blood flow to an area and an abnormally large extraction of oxygen from normally saturated arterial blood. Peripheral vascular disease, shock states, heart failure, and cold exposure all create states of vasoconstriction and decreased peripheral blood flow, with cyanosis of the nail beds. Massage or gentle warming of a cyanotic extremity will increase peripheral blood flow and abolish peripheral, but not central, cyanosis.

Pseudocyanosis is a bluish or slate-gray skin discoloration due to drugs (chlorpromazine, minocycline, amiodarone, nicorandil) or heavy metals (gold, silver).[47,48] In pseudocyanosis, the lips and mucous membranes are of normal color, the abnormal skin discoloration does not blanch with pressure, and the discoloration tends to be more intense in sun-exposed areas. Focal areas of pseudocyanosis may be due to local contact with color dyes, gold, or silver.

DIAGNOSIS AND TREATMENT

Pulse oximetry can detect hypoxemia and provide an accurate oxygen saturation measurement. However, with hemoglobinopathy, standard pulse oximetry is often inaccurate. In methemoglobinemia, pulse oximetry will read 80% to 85% regardless of the oxygen level, thereby often overestimating the true oxygen saturation (it may be lower, but pulse oximetry will not read lower). **With carboxyhemoglobinemia, the pulse oximetry reads carboxyhemoglobin as oxyhemoglobin** reporting a higher percentage for oxygen saturation (see chapters 207, "Dyshemoglobinemias," and 222, "Carbon Monoxide"). **Arterial blood gas analysis using co-oximetry (a specific multi-wavelength measurement of oxygen saturation) is needed in the assessment of any patient with suspected cyanosis.** In central cyanosis, the oxygen saturation measured from the arterial blood gas is decreased because of the underlying hypoxemia. In peripheral cyanosis, the oxygen saturation should be normal. With methemoglobinemia or carboxyhemoglobinemia, arterial blood gas co-oximetry will show a normal Pao_2 (reflecting a normal amount of dissolved oxygen in the plasma), a normal calculated oxygen saturation (from the normal Pao_2), and a decreased measured oxygen saturation (because of a decreased number of oxygen-binding sites).

Give oxygen to all patients with central cyanosis; failure to improve suggests impaired circulation (shock), abnormal Hb, or pseudocyanosis.

PLEURAL EFFUSION

Pleural effusions result from fluid accumulating in the potential space between the visceral and parietal pleurae. Although pleural effusions can result from many causes, in developed countries, the most common causes are heart failure, pneumonia, and cancer (**Table 62-11**).[49-51]

PATHOPHYSIOLOGY

A continuous amount of fluid is secreted from the parietal pleura into the pleural space where it is absorbed by the visceral pleural microcirculation, averaging about 8 L/d in an adult. This fluid reduces friction between the pleural layers and allows for smooth lung expansion and contraction with respiration. Any process that increases fluid production or interferes with fluid absorption will result in accumulation in the pleural space. Pleural effusions are traditionally divided into exudates or transudates.[49-51] Exudative effusions result from pleural disease, usually inflammation or neoplasia that produces active fluid secretion or leakage with high protein content. Transudative effusions result from an imbalance between hydrostatic and oncotic pressures. This imbalance results in the production of an ultrafiltrate with low protein content into the pleural space.

CLINICAL FEATURES

A pleural effusion may be clinically silent or come to detection from either symptoms of an underlying disease, an increase in volume of the effusion with the production of dyspnea, or the development of inflammation and associated pain with respiration. Physical findings of a pleural effusion include percussion dullness and decreased breath sounds. Because pleural fluid typically pools in the dependent portions of the hemithorax, small or

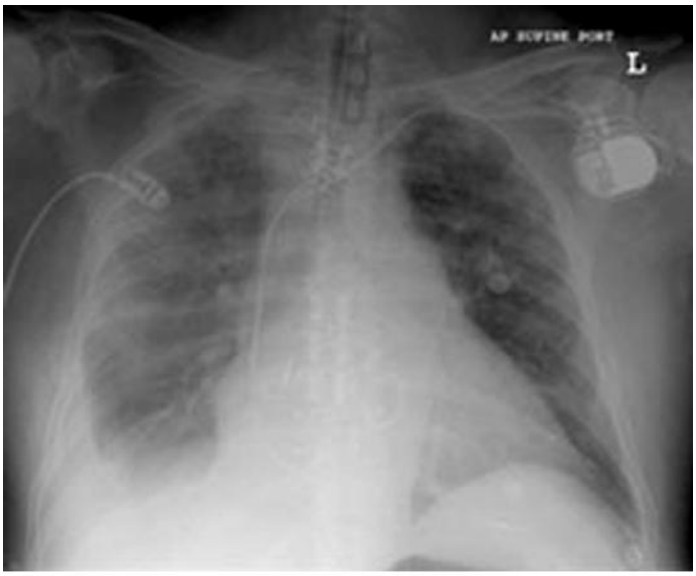
TABLE 62-11 Differential Diagnosis of Pleural Effusion

Common	Less Common
Transudates	
Heart failure	Cirrhosis with ascites
	Peritoneal dialysis
	Nephrotic syndrome
Exudates	
Cancer: primary or metastatic	Viral, fungal, mycobacterial, or parasitic infection
Bacterial pneumonia with parapneumonic effusion	Systemic rheumatologic disorders: systemic lupus erythematosus, rheumatoid arthritis
Pulmonary embolism	Uremia, pancreatitis
	Postcardiac surgery or radiotherapy
	Drug-related: amiodarone
Either transudates or exudates	
Transudates after diuretic therapy	Pulmonary embolism

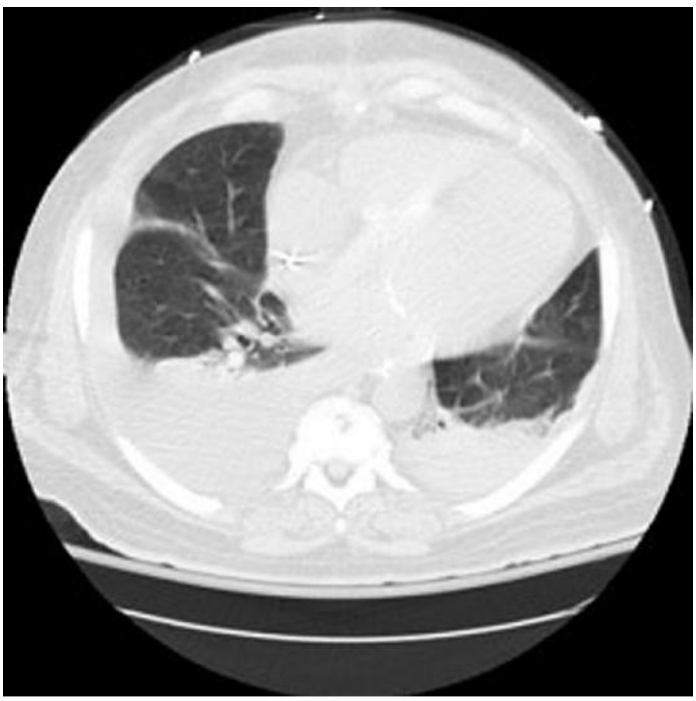
moderate-size effusions have percussion dullness and decreased breath sounds at the lung base with relatively normal lung findings above the level of fluid. With large or massive effusions, it may be impossible to distinguish a fluid level on clinical examination.

DIAGNOSIS

In an adult, 150 to 200 mL of pleural fluid in the hemithorax is required to be detectable on upright chest radiography. Supine chest radiographs may demonstrate only a hazy appearance of pleural fluid in the posterior pleural space (**Figure 62-6A**). CT scanning of the chest may clarify uncertain findings on chest radiograph (**Figure 62-6B**). Small free-flowing pleural effusions are better visualized on decubitus radiographic views (**Figure 62-7**). US can also identify a pleural effusion (Figure 62-3). **A significant pleural effusion is large enough to produce a pleural fluid strip >10 mm wide on lateral decubitus radiographic views or by ultrasonography.**[49]



A



B

FIGURE 62-6. A. Supine radiograph showing a right-sided pleural effusion. The right lung field is hazy compared to the left, and a small layer of fluid is noted inferiorly. B. CT scan of the same patient. A moderate pleural effusion is seen in the right lung field, and a small effusion not seen in the left lung field of the plain radiograph is present on the CT scan.

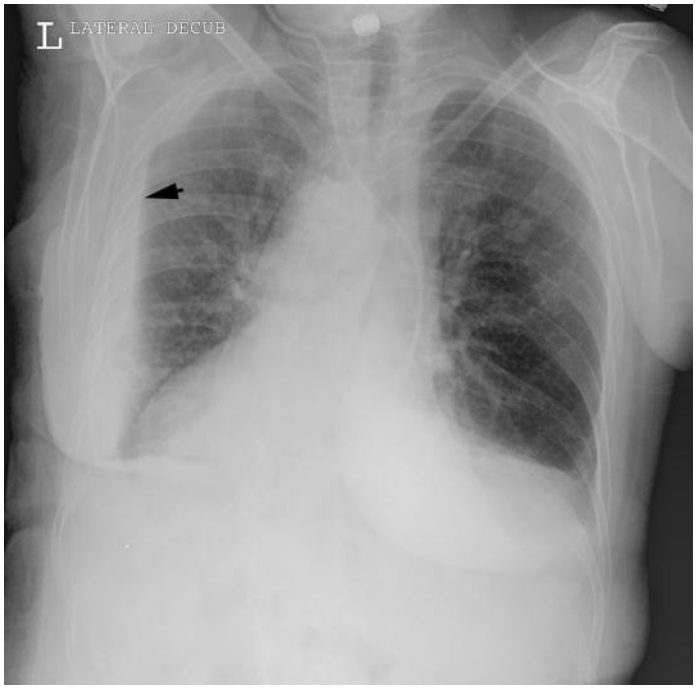


FIGURE 62-7. Left lateral decubitus radiograph showing a layering of a small pleural effusion. *Arrowhead* points to the layer of fluid.

Diagnostic thoracentesis is done to obtain pleural fluid for analysis in cases without a clearly evident cause, to confirm a suspected diagnosis, or to detect pleural space infection. For example, because the largest single cause of pleural effusion is heart failure, if a patient presents with a typical appearance (cardiomegaly, roughly equal in size bilateral effusions), then a period of treatment with monitoring for pleural fluid resolution is indicated, and routine thoracentesis is reserved for patients who do not experience resolution in 3 to 4 days. Otherwise, diagnostic thoracentesis and pleural fluid analysis are indicated.

Light developed the most widely used criteria to differentiate transudates from exudates using serum and pleural fluid protein and lactate dehydrogenase levels (**Table 62-12**).[52] Modifications to the original criteria have been proposed,[51,53] but the overall sensitivity for the detection of an exudative pleural effusion remains 98% to 99% with specificity from 65% to 86%. If the clinical circumstances suggest that the effusion is likely to be transudative, the only tests indicated are pleural fluid and serum protein content and lactate dehydrogenase levels. If the pleural effusion is exudative, additional tests are indicated (Table 62-12).[49-51]

The distinction between exudates and transudates may be obscured by the effect of diuretic therapy in patients with transudative pleural effusions.[49,50] During diuresis, the resorption of water is faster than that of protein, so the protein concentration rises into the range consistent with an exudative etiology. A serum to pleural albumin difference of >1.2 grams/dL has been proposed to help in this scenario, but this approach will reduce the sensitivity of exudative pleural effusion detection by >10%.[49,50,52]

TREATMENT

Therapeutic thoracentesis with drainage of 1.0 to 1.5 L of fluid is indicated if the patient has dyspnea at rest. Acute drainage of larger volumes is associated with reexpansion pulmonary edema, so large-volume

TABLE 62-12 Pleural Fluid Diagnostic Tests

Detection of exudative pleural effusion
Light criteria for pleural exudate: one or more of the following present:[49]
Pleural fluid/serum protein ratio >0.5
or
Pleural fluid/serum LDH ratio >0.6
or
Pleural fluid LDH greater than two thirds of the upper limit for serum LDH
Additional tests on exudative effusions
Gram stain and culture to detect bacterial infection
Cell count
Neutrophil predominance: parapneumonic, pulmonary embolism, pancreatitis
Lymphocytic predominance: cancer, tuberculosis, postcardiac surgery
Glucose: low glucose seen in parapneumonic, malignant, tuberculosis, and rheumatoid arthritis causes of pleural effusions
Cytology for malignancy: highest yield is with adenocarcinoma, much lower with squamous cell, lymphoma, or mesothelioma
Pleural fluid pH: normal pleural fluid pH around 7.64. In parapneumonic effusions, a pleural fluid pH <7.10 predicts development of empyema or persistence and indicates need for thoracostomy tube drainage.
Pleural fluid amylase: elevated in pleural effusions due to pancreatitis or esophageal rupture
Mycobacterial and fungal stains and cultures: as suggested clinically
Tuberculosis pleural fluid markers: polymerase chain reaction for mycobacterial DNA, pleural fluid adenosine deaminase, or pleural fluid interferon-γ

Abbreviation: LDH = lactate dehydrogenase.

drainage is to be avoided. Diuretic therapy typically resolves >75% of effusions due to heart failure within 2 to 3 days.

Patients with pleural empyema (gross pus or organisms on Gram stain) require drainage with large-bore thoracostomy tubes. Treatment of parapneumonic effusions is controversial (see chapter 66, "Lung Empyema and Abscess").[54-56] Clinical findings that suggest the need for thoracostomy tube drainage for parapneumonic effusion include comorbid disease, failure to respond to antibiotic therapy, anaerobic organisms, pleural fluid pH <7.10, and effusion involving >50% of the thorax or air-fluid level on the chest radiograph.[54]

CHAPTER 63

Hemoptysis

Troy Sims

INTRODUCTION AND EPIDEMIOLOGY

Hemoptysis is the expectoration of blood from the lungs or tracheobronchial tree. Severity ranges from mild to severe, and it can be difficult to stop. The challenge is to stabilize the patient while simultaneously determining the source and providing treatment. Most cases of hemoptysis are mild and resolve spontaneously; predicting which individual will develop large-volume bleeding is difficult. Determining the cause, location, and extent of hemoptysis requires a multidisciplinary approach.[1]

Assessing the amount of expectorated blood is difficult, because patients may either exaggerate or be unable to quantify the amount. The definition of **"massive" or "severe" hemoptysis** varies, with reported ranges from 100 mL per 24 hours to >1000 mL per 24 hours,[2,3] with a midpoint value of 600 mL per 24 hours accepted by many.[4] However, because even small volumes of blood can cause asphyxiation, any hemoptysis requires prompt attention.[5] Morbidity and mortality depend on the rate of bleeding, the ability of the patient to clear the blood, and the presence of underlying lung disease, which potentiates the effects of blood in the airways. We define **"minor" hemoptysis** as small-volume expectoration of blood in a patient with no comorbid lung disease, normal/stable oxygenation and ventilation, normal vital signs, and no risk factors for continued bleeding.

PATHOPHYSIOLOGY

Hemoptysis results from disruption of blood vessels within the walls of the airways, from trachea to bronchi, bronchioles, and the lung parenchyma (**Table 63-1**). The pulmonary arteries account for 99% of the

TABLE 63-1 Causes of Hemoptysis

Infectious
Acute bronchitis

Traumatic
Ruptured bronchus from deceleration injury
Lung contusion from blunt injury
Penetrating trauma
Miscellaneous
Nitrogen dioxide inhalation (ice arenas)
Cocaine inhalation
Catamenial (pulmonary endometriosis)

arterial blood flow to the lungs but are a low-pressure system and rarely the source of hemoptysis. The bronchial circulation accounts for only about 1% of the arterial blood flow to the lungs but 90% of the cases of hemoptysis because it is a high-pressure system.[6] The bronchial arteries typically branch off the thoracic aorta and are responsible for supplying oxygenated blood to the bronchi, pulmonary arteries and veins, and lung parenchyma. They follow the course of bronchi along their tortuous paths. Once the bronchial arteries reach the level of capillaries, three anastomoses occur: the larger bronchial arteries can merge directly with the alveolar microvasculature; the smaller bronchial arteries can merge with the veins of the pleural and pulmonary drainage system; and bronchial capillaries can merge directly with pulmonary capillaries.[7] These connections produce a physiological right-to-left shunt comprising 5% of the total cardiac output.

Many inflammatory and infectious processes can lead to hemoptysis. Coughing in the setting of transient airway inflammation (e.g., acute bronchitis) can lead to minor bleeding even in otherwise healthy lungs. In chronic inflammatory states like tuberculosis, cystic fibrosis, or chronic obstructive pulmonary disease (COPD), the bronchial arteries can proliferate and enlarge to enhance the delivery of blood to the alveoli. Such neoangiogenesis creates thin-walled, fragile vessels prone to rupture. Chronic disease states can lead to bronchiectasis (chronic bronchial wall inflammation), resulting in dilatation and destruction of the cartilaginous support, predisposing blood vessels to rupture. In the case of *Aspergillus* infection, there can be necrotic destruction of tissue, but more often there is a colonization of a previous area of pulmonary decay, resulting in cavitary **fungal balls**. Neoangiogenesis from bronchial artery branches occurs in the cavity walls.[5] A **Rasmussen's aneurysm** is a false aneurysm of dilated, tortuous branches of pulmonary arteries crossing the wall of a tuberculosis cavity. Although tumors can directly invade the bronchial and pulmonary arteries, they also promote neoangiogenesis. In particular, squamous cell carcinoma accounts for a large number of cases of massive hemoptysis.[5]

Traumatic causes of hemoptysis include deceleration injuries and penetrating trauma to the chest. Iatrogenic causes include direct arterial injury by pulmonary artery catheterization or biopsy of lung tissue during bronchoscopy. Biopsy of a carcinoid tumor can be associated with impressive hemoptysis.[5]

Hemoptysis secondary to fistulae between an aortic aneurysm or aortic inflammation and its primary branches can precipitate catastrophic hemoptysis. Tracheo-innominate fistulae result from erosion of a tracheostomy into the innominate artery that courses posterior to the upper sternum.

Arteriovenous fistulas forming between the low-pressure pulmonary arteries and pulmonary veins have thin walls that are easily ruptured. Osler-Weber-Rendu disease is associated with hemorrhagic telangiectasias of pulmonary arteriovenous fistulas as well as telangiectasias of the skin or mucous membranes.

Cardiac disease processes that elevate pulmonary pressure, such as mitral stenosis and congenital heart disease, can trigger hemoptysis. Distal pulmonary embolism can lead to infarction of lung tissue that results in edema and hemorrhage, which can be exacerbated by the use of anticoagulants.

Vasculitis and collagen vascular diseases such as Goodpasture's syndrome, systemic lupus erythematosus, and granulomatosis with polyangiitis (formerly Wegener's granulomatosis) damage the lung parenchyma predisposing to alveolar hemorrhage. Anemia can result from chronic diffuse alveolar hemorrhage.[9]

The cause of hemoptysis in up to 30% of the cases is undetermined.[1]

CLINICAL FEATURES

First, identify if the condition is truly hemoptysis, and exclude hematemesis and epistaxis. Upper GI (UGI) bleeding is identified by a history of dark stools, nausea or abdominal pain, and positive stool guaiac test. Epistaxis can be identified on examination. Expectorated blood is bright colored if the source is the upper airway or lungs.

HISTORY

If hemoptysis resolves prior to ED evaluation, history is then paramount for evaluation.

Patients give an accurate history regarding the source of bleeding about half the time. Ask about risk factors for hemoptysis; for example, smoking predisposes to chronic lung inflammation and vascular disruption and increases the risk of bronchogenic carcinoma. Tuberculosis is a leading cause of hemoptysis worldwide, so ask about a history of tuberculosis or emigration/travel from an endemic area. High-prevalence tuberculosis areas are Africa, inner-city New York, the Middle East, and Southeast Asia. Patients with previous venous thrombotic disease may have a pulmonary embolism as a cause. Ask about hematuria or known renal insufficiency given the link to Goodpasture's syndrome. Individuals with a connective tissue disease or suggestive symptoms such as arthralgias, myalgias, recurrent fevers, or rash may develop vasculitis and hemoptysis. Granulomatosis with polyangiitis is a more insidious vasculitis; look for saddle nose deformity from septal perforation. The lung fluke, *Paragonimus* spp., infects humans after eating infected crab and crayfish and can cause hemoptysis in chronic infection. The tapeworm, *Echinococcosis* spp., can lead to hydatid cysts within the lungs. Cyclical hemoptysis coordinating with a woman's menstrual cycle could indicate a catamenial source from pulmonary endometriosis.

Cocaine and heroin inhalation can trigger diffuse alveolar hemorrhage. Nitrogen dioxide exposure in indoor ice arenas may cause hemoptysis in hockey players. Finally, ask about use of anticoagulants and recent procedures such as Swan-Ganz catheter insertion and bronchoscopy.

PHYSICAL EXAMINATION

Examine the sputum to see if it is just blood-streaked or contains clots of blood. Patients often bring a sample of expectorated sputum to the ED, which helps assessment. Look for signs suggestive of major hemoptysis or underlying lung disease, such as tachypnea, tachycardia, hypotension, labored respirations, and hypoxemia.

If airway, breathing, and circulation are maintained, then focus on the physical exam. Evaluate the nares and posterior pharynx for evidence of epistaxis. Next, assess airway patency and potential difficulty of intubation. Auscultate the lungs for any wheezing suggesting airway inflammation or focally reduced breath sounds indicating a location of bleeding. Occasionally, crackles may be present, suggesting diffuse alveolar hemorrhage or heart failure. On the cardiac exam, auscultate for murmurs of valvular disease. Check for telangiectasia and petechiae on the skin exam.

DIAGNOSIS

Most patients with minor hemoptysis need no specific tests unless on anticoagulation medication. For patients with massive hemoptysis or recurring hemoptysis, obtain a metabolic assessment including electrolytes and renal function studies, CBC, coagulation studies, and urinalysis. Baseline hemoglobin concentration is often falsely elevated in acute, rapid bleeding, as equilibration may not occur for 6 hours. Thrombocytopenia and coagulopathy increase recurrence risk and morbidity from hemoptysis. Urinalysis and renal function tests help narrow the differential diagnosis that includes Goodpasture's syndrome and granulomatosis with polyangiitis, and can also identify those at risk for contrast nephropathy if imaging is contemplated.

IMAGING

Chest x-ray is the initial imaging modality and yields a diagnosis up to 50% of the time[1]; in massive hemoptysis, x-ray is rarely normal.

Diffuse alveolar hemorrhage manifests as scattered alveolar infiltrates on chest x-ray, whereas infiltrates, atelectasis, masses, and cavitation are localized as potential sources of hemoptysis.

Multidetector row CT delineates abnormal bronchial and nonbronchial arteries using reformatted images while limiting scan time and respiratory motion artifact. It can also identify bleeding from a pulmonary artery as in Rasmussen's aneurysm or from an anomalous vessel as in Dieulafoy's disease, a tortuous dysplastic artery within the submucosa. Bronchial arterial bleeding is almost always detected on multidetector row CT, whereas nonbronchial arterial sources can be identified more than half of the time.[10] Multidetector row CT is preferred over CT angiography. The limitation of CT evaluation for hemoptysis is that areas of bleeding can appear similar to infiltrate and tumor, and active bleeding can obscure a mass within the parenchyma.

TREATMENT: MILD HEMOPTYSIS

Hemoptysis promotes anxiety in the patient and their family members, so the goal is to identify the cause, reassure those with minor features and no threat of imminent harm, and provide an appropriate ED disposition. The amount of blood expectorated, respiratory status, and risk factors for continued bleeding dictate the disposition. Patients with mild hemoptysis can be assessed as described in **Figure 63-1**.

DISPOSITION AND FOLLOW-UP

Most cases of hemoptysis are mild and self-limited. For mild hemoptysis, arrange follow-up with a primary care physician, otolaryngologist, or pulmonologist. Choose a pulmonologist if lung cancer or structural disease is suspected. Treat acute bronchitis with appropriate antibiotics.

TREATMENT: SEVERE HEMOPTYSIS

Massive hemoptysis requires airway control and emergency bronchoscopy and often requires consultation with cardiothoracic surgery and interventional radiology (**Figure 63-2**) for definitive control of bleeding.

AIRWAY CONTROL

In patients with more severe bleeding, assessing and ensuring the airway patency and ongoing oxygenation are key. If the patient has a tracheostomy, look for a trachea-innominate fistula; this can be controlled with direct digital pressure on the anterior portion of the trachea against the posterior aspect of the sternum using the tracheostomy as the point of access. If the patient does not have a tracheostomy and requires airway control, proceed immediately with rapid sequence intubation,[10] using a larger-diameter endotracheal tube to allow for bronchoscopy. Once intubation is successful, place the patient so the affected lung is in a dependent position to prevent spilling of blood into the unaffected side. If bleeding is uncontrollable, you may preferentially intubate the main bronchus of the unaffected lung; and alternatively, to stop bleeding, some use a Fogarty catheter (14 French/100 cm) to tamponade the bronchus of the affected lung.[5] The latter can be accomplished by passing the Fogarty catheter adjacent to the endotracheal tube once the patient is intubated (**Figure 63-3**). If attempts at intubation fail, cricothyrotomy is an option.

Once the airway is stabilized, restore volume with crystalloid and transfusion of blood products to correct for anemia and coagulopathy as indicated.

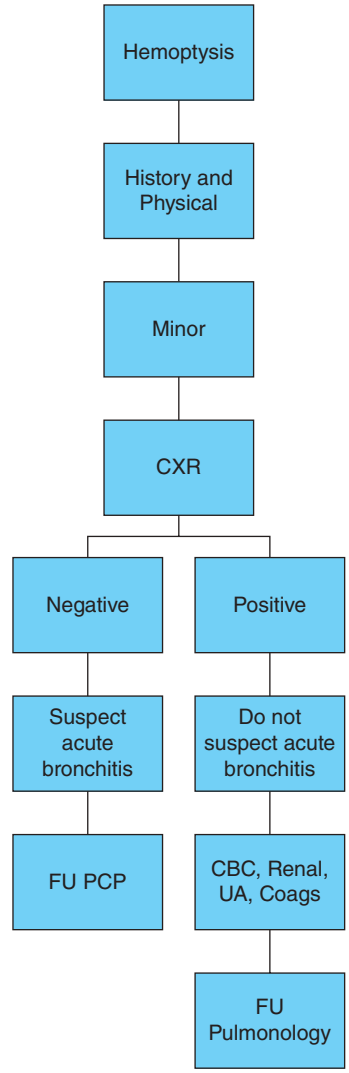

FIGURE 63-1. Diagnosis and management of minor hemoptysis. CXR = chest x-ray; FU = follow-up; PCP = primary care physician; UA = urinalysis.

BRONCHOSCOPY

Urgent bronchoscopy is needed in massive hemoptysis to identify the origin of bleeding and provide stabilizing treatment. Bronchoscopy may be performed in the ED by a consultant if the patient is unstable. Awake flexible, fiberoptic bronchoscopy provides visualization of the more peripheral and upper lobes but does not provide optimal suctioning and does not allow for local treatment. Rigid bronchoscopy usually requires general anesthesia but can be performed with deep sedation in skilled hands. Rigid bronchoscopy cannot fully view the upper lobes and peripheral lesions, but it offers greater suctioning ability than fiberoptic bronchoscopy and can provide treatment, such as the passage of Fogarty balloon catheters for tamponade of bleeding, epinephrine instillation, and ice water lavage. After rigid bronchoscopy, a flexible bronchoscope can be passed down the lumen of a rigid bronchoscope for more detailed inspection.

DEFINITIVE BLEEDING CONTROL

Definitive bleeding control may involve consultation with a cardiothoracic surgeon or an interventional radiologist.[9,11,12] Emergency surgery is often reserved for massive hemoptysis resulting from leaking aortic aneurysm, iatrogenic pulmonary artery injury, thoracic trauma, or

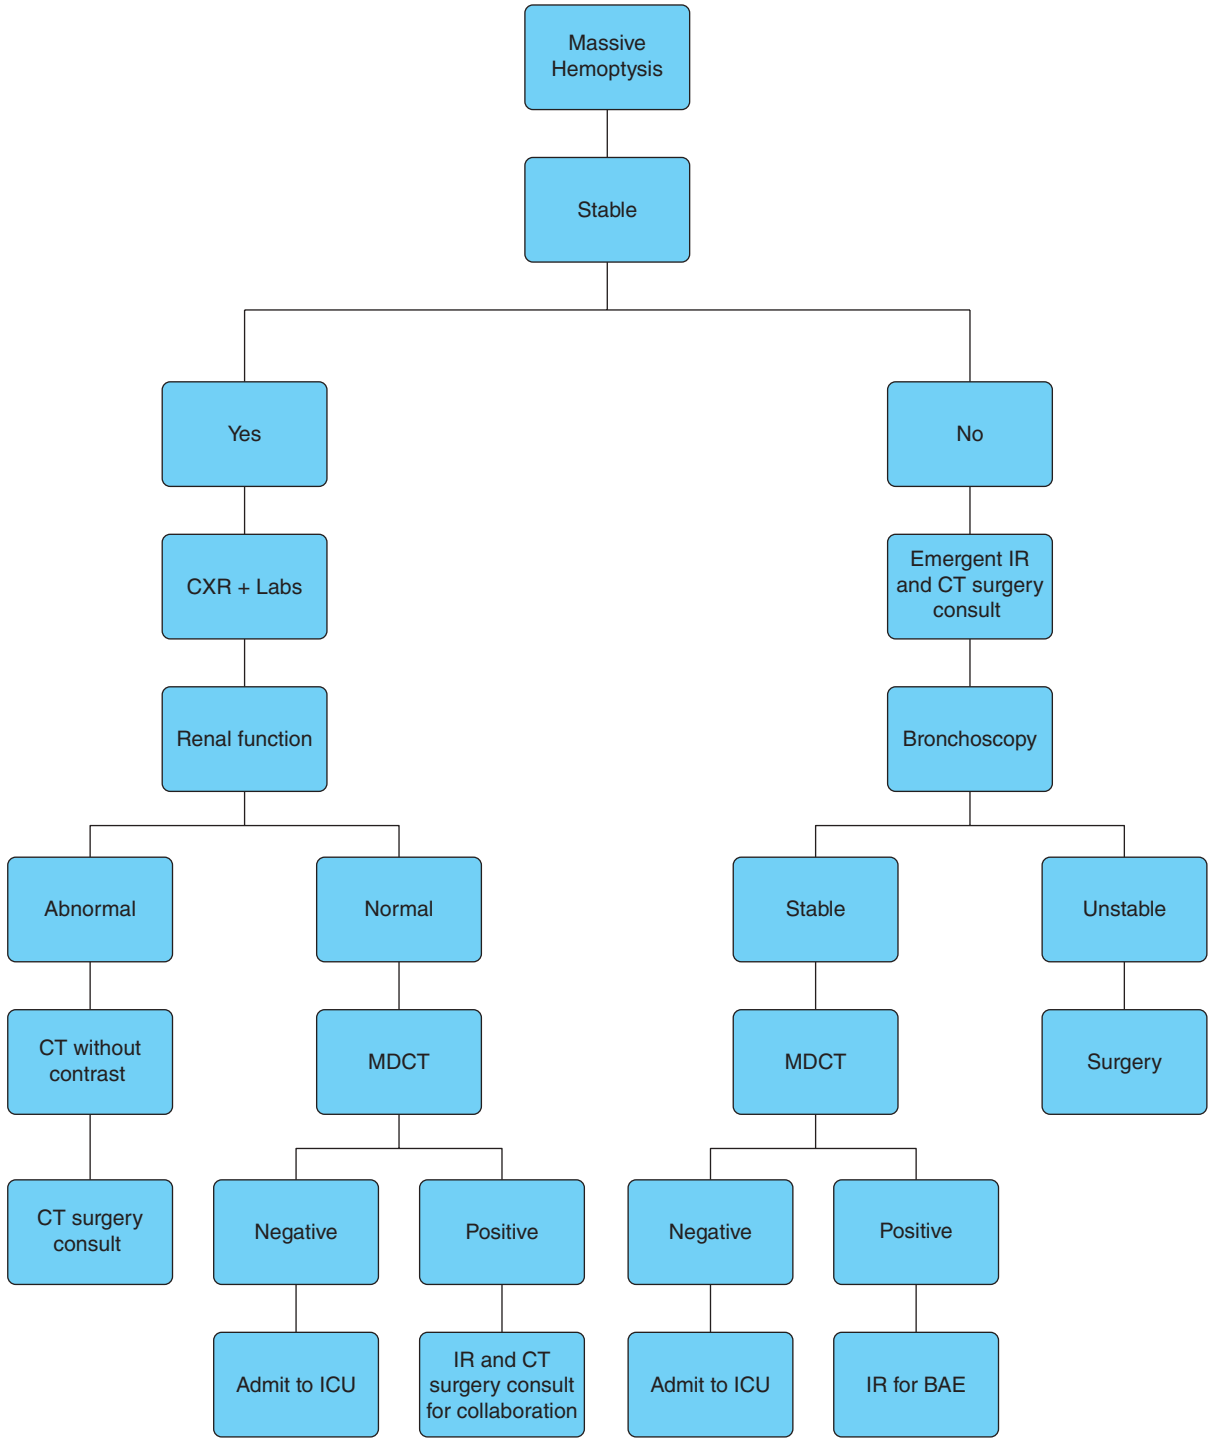

FIGURE 63-2. Algorithm for massive hemoptysis. bleeding from a tracheo-innominate artery fistula at a tracheostomy site.[9,12] In other causes of hemoptysis or if cause is uncertain, bronchial artery embolization is a common treatment of massive and recurrent hemoptysis.[9] Even in cases of mycetoma from aspergillosis, adenoma, hydatid cyst, and active tuberculosis, where surgery is still indicated as the ultimate treatment, embolization can temporize bleeding and stabilize patients for elective surgery.[12] Risks of bronchial artery embolization include transverse myelitis due to spinal cord ischemia and pulmonary artery infarction from spread of embolic material beyond its intended site.[10]

DISPOSITION

Admission to an intensive care setting or transfer to a tertiary care center is necessary for management of severe hemoptysis.

CHAPTER 64

Acute Bronchitis and Upper Respiratory Tract Infections

Cedric W. Lefebvre

INTRODUCTION AND EPIDEMIOLOGY

Bacterial and viral infections of the respiratory tract can result in a wide range of clinical syndromes including acute bronchitis, the common cold, influenza, and respiratory distress syndromes. Uniform definitions for the most common of these clinical syndromes are lacking because the symptoms associated with upper respiratory tract infections (URIs) frequently overlap and their causative pathogens are similar. The broad definition of acute bronchitis is as follows: **a self-limited inflammation of the large airways characterized by cough without evidence of pneumonia, without an alternative medical disorder to explain the symptoms, or without a history of chronic lung disease.**[1]

The **common cold** is a viral infection of the upper respiratory tract, primarily affecting the nasal mucosa, causing congestion, rhinorrhea, and sneezing. **Influenza**, or the "flu," is a respiratory illness caused by influenza viruses. Symptoms of influenza infection range from mild to severe and include fever, chills, myalgias, headache, malaise, cough, and fatigue. **Severe acute respiratory syndrome** is a unique respiratory illness that has clinical characteristics similar to other URIs but confers a high rate of mortality. Reported in 2012, **Middle East respiratory syndrome coronavirus** is novel viral respiratory infection that became a concern to the World Health Organization due to its fatality rate. Infections of the upper respiratory tract also cause specific clinical conditions like otitis media, pharyngitis, epiglottitis, bronchiolitis, laryngitis, tracheitis, and sinusitis (see corresponding chapters that discuss these diseases).

EPIDEMIOLOGY

In ambulatory care settings nationwide, URIs are the third most common diagnosis.[2] Annually, the estimated direct costs of noninfluenza viral URI in the United States is $17 billion, with indirect costs exceeding $22 billion.[3] Acute bronchitis is among the most commonly diagnosed outpatient illnesses in the United States every year, with an annual incidence of about 5%,[4] predominantly during fall and winter.[1] The disorder accounts for approximately 10 million office visits per year, or 10 ambulatory visits per 1000 people per year. Symptom relief is the primary reason for office visits among adults within the first 2 weeks of illness, and many of these visits result in the unnecessary prescription of antibiotics by clinicians.[5] The common cold afflicts adults three or three times every year, whereas children suffer up to eight colds annually.[6-8] The incidence of colds caused by rhinovirus peaks during autumn months.[9] Responsible for 22 million missed school days and 23 million lost work days, the common cold generates an enormous economic burden.[4]

Influenza affects millions of people worldwide every year during seasonal outbreaks (typically November through March in the northern hemisphere). An annual average of 41,000 Americans died from influenza infection from 1979 to 2001.[10] The Centers for Disease Control and Prevention reported influenza-associated annual death rates between 1976 and 2007 that ranged from 1.4 to 16.7 deaths per 100,000 persons. Deaths associated with influenza have increased in recent decades in the United States. With 90% of influenza-associated deaths occurring among people 65 years or older, influenza poses a particular threat to the elderly.[11,12] In 2009, an outbreak of swine-origin influenza A (H1N1) virus, known as "**swine flu**," occurred in Mexico and the United States.[13,14]

Influenza viruses are classified into three genera: A, B, and C. Of these, influenza A has the greatest impact on human populations and has the greatest potential to cause pandemics. Influenza A has many serotypes, including H1N1 and H3N2, both of which are currently active among humans. Influenza viruses are unique pathogens because their evolution involves a complex process of antigenic shifts and sporadic cross-species transmissions between humans, swine, and birds. The intensity of seasonal influenza varies from one year to the next, and localized influenza outbreaks can occur during interpandemic years.[15] Furthermore, seasonal influenza outbreaks tend to occur simultaneously in countries on similar latitudes. Population immunity against influenza can be achieved by natural infection or vaccination; however, antigenic shifts allow influenza viruses to survive from year to year and preserve their capacity to cause global pandemics.

ACUTE BRONCHITIS

PATHOPHYSIOLOGY

Etiologic studies of acute bronchitis are difficult to interpret because the disease lacks a precise definition and the cause is undetermined in 31% to 84% of cases vigorously tested.[16-23] Respiratory viruses are the most

common causative agents, with confirmed cases in 9% to 63% of patients studied, depending on the criteria used to make the diagnosis and the population.[16-23] Influenza A and B viruses are the most common cause, accounting for 6% to 35% of cases.[16-23] Parainfluenza virus, respiratory syncytial virus, coronavirus, adenovirus, rhinovirus, and human metapneumovirus combined account for another third of cases.[16-23] Bacterial causes of acute bronchitis range from less than 10%[16] to as much as 44% of cases in studies of older populations with comorbidities and severe symptoms.[21] *Streptococcus pneumoniae* (0% to 30% of cases), *Haemophilus influenzae* (0% to 9% of cases), and *Moraxella catarrhalis* (0% to 2% of cases) have been isolated in patients with acute bronchitis.[16-23] Atypical bacterial species such as *Bordetella pertussis* (0% to 1%),[24] *Chlamydia pneumoniae* (0% to 17%), and *Mycoplasma pneumoniae* (1% to 10%) also cause acute bronchitis.[16-23]

There are two overlapping sequential phases in the pathophysiology of acute bronchitis.[25] The first phase results from the direct inoculation of the tracheobronchial epithelium, yielding variable constitutional symptoms of fever, myalgias, malaise, and organism-specific upper respiratory symptoms, lasting 1 to 5 days, the severity of which depends on the infectious agent. The second phase is characterized by hypersensitivity of the tracheobronchial epithelium and airway receptors resulting in persistent, productive cough and lasting 1 to 3 weeks, peaking at 7 to 14 days. It is this second phase that best characterizes the illness. Sloughed epithelial cells and increased mucus produce sputum in most patients; sputum is not an indication of ongoing bacterial infection as frequently suspected by clinicians.[25] Inflammation and thickening of the bronchial and tracheal mucosa (**Figure 64-1**) result in airflow obstruction and decreased forced expiratory volume in 1 second, manifesting as wheezing and dyspnea in many patients.

CLINICAL FEATURES

The clinical manifestations of acute bronchitis depend on the infectious agent, especially in the first phase of the illness. Therefore, the initial symptoms are variable and may include fever, dyspnea, myalgias, malaise, sore throat, nasal congestion, and cough. The hallmark of acute bronchitis is cough (with or without phlegm production) persisting into the second phase of the illness lasing more than 5 days and up to 3 or 4 weeks.[1,25] The mean duration of cough is 18 days.[26] During this phase, the patient may or may not have dyspnea and/or chest discomfort. Physical exam may be completely normal, or the patient may have tachypnea, tachycardia, fever, wheezing, rhonchi, or rales. One important etiology of acute bronchitis to identify is *Bordetella pertussis,* because antibiotic treatment is recommended (see later discussion).[25,27] Suspect pertussis in patients with posttussive emesis or inspiratory whoop[27]; consider pertussis in any patient with cough lasting greater than 2 weeks if exposed to a known case or presenting during an epidemic.[1,25]

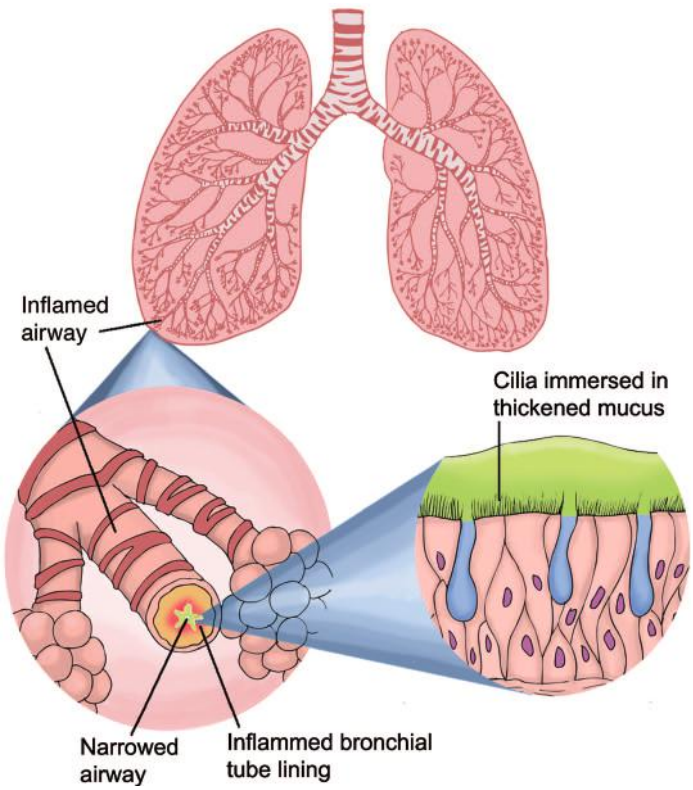

FIGURE 64-1. The respiratory epithelial infection of acute bronchitis leads to inflammation, thickening, and increased mucus production in the airways.

DIAGNOSIS

The diagnosis of acute bronchitis is made using clinical findings and historical information: when acute cough (dry or productive) is present for more than 5 days and when evidence of pneumonia, acute asthma, or an alternative explanation for the symptoms is are absent. Patients with chronic obstructive pulmonary disease are excluded from the diagnosis (see chapter 70, Chronic Obstructive Pulmonary Disease).

The primary objective in patient evaluation is carefully excluding pneumonia, either clinically or radiographically. Physicians are poor at differentiating patients with pneumonia from patients with bronchitis based on history and physical exam.[28-31] The addition of C-reactive protein testing does not improve diagnostic accuracy.[29,32] Identification of patients at low risk for pneumonia may be accomplished based on the absence of vital sign abnormalities and physical exam findings.[30,31,33] See **Table 64-1** for criteria suggesting pneumonia; patients meeting none of these criteria have a probability of pneumonia of 5% or less, and further testing is not required provided the patient has follow-up in the next 3 days and is able to return to the ED if symptoms worsen.[30,31,33] Patients with hypoxia or unstable vital signs (in the setting of respiratory symptoms) are at high risk for pneumonia and require further testing and treatment (see chapter 65, Pneumonia and Pulmonary Infiltrates). Obtain a chest radiograph in patients at intermediate risk for pneumonia. Although chest radiography remains the most common confirmatory test for pneumonia,[34,35] the sensitivity of a standard two-view chest film ranges from 69% in symptomatic patients suspected of pneumonia in the community,[36] to as low as 43.5% in patients being evaluated for pulmonary embolism in the ED[37] (both studies using high-resolution CT scan as the criterion reference). Therefore, if pneumonia is suspected on clinical grounds, treat accordingly regardless of a negative chest radiograph (see chapter 65) especially in the elderly, among whom distinctive signs and symptoms of pneumonia may be lacking.[1] Laboratory tests should be obtained if treatment for *B. pertussis* is being planned; tests include a culture, using a Dacron swab specimen, collected from the posterior nasopharynx; performing direct fluorescent antibody staining; collecting a polymerase chain reaction test; or testing for serum antibodies by enzyme-linked immunosorbent assays or Western blot.[27] Otherwise, further testing for acute bronchitis is not necessary unless alternative diagnoses require investigation. The differential diagnosis of cough is broad; see Table 64-5, Differential of Consequence: Cough, in chapter 62, Respiratory Distress.

TABLE 64-1 Clinical Criteria Suggesting Possible Pneumonia

Criteria	Clinical Finding
1	Heart rate >100 beats/min
2	Respiratory rate >24 breaths/min
3	Temperature of >38°C (100.4°F)
4	Chest examination findings of focal consolidation, egophony (increased resonance of voice sounds heard when auscultating the lungs), or fremitus (tactile vibrations felt over the chest when the patient repeats "boy oh boy")
5	Age > 64 y old

All five criteria must be absent in an individual patient to lower the probability of pneumonia to 5% or less.

TREATMENT

Case definitions of acute bronchitis that specify constitutional or respiratory symptoms including characteristics of sputum are used by research investigators and can define the spectrum of microbiologic causes but have not identified a patient subset that clearly benefits from antibiotics (see Acute Bronchitis, Treatment, later in this chapter).

Despite the fact that some patients with acute bronchitis have evidence of a bacterial infection in epidemiologic studies, antibiotics are not beneficial and are not indicated except in isolated cases.[1,5,38,39] A Cochrane analysis reviewed 15 randomized controlled trials, involving 2618 patients, including smokers and nonsmokers, comparing any antibiotic versus placebo or no treatment for acute bronchitis. At follow-up, patients receiving antibiotics were less likely to have cough (relative risk 0.64; 95% confidence interval 0.49 to 0.85), were less likely to have abnormal lung exam findings (relative risk 0.54; 95% confidence interval 0.41 to 0.70), experienced fewer days of feeling ill (mean difference −0.64; 95% confidence interval −1.16 to −0.13), and had fewer days with limited activity (mean difference −0.49; 95% CI −0.94 to −0.04).[39] Although the differences between these outcome measures reached statistical significance, the benefits demonstrated were modest (less than 1-day benefit in an illness lasting 10 to 21 days). Consider potential medication side effects, cost, and the potential for microbial resistance when using antibiotics to achieve these modest benefits for an otherwise self-limiting illness. Despite the lack of evidence supporting their use, the majority of acute bronchitis patients receive antibiotics, especially elderly patients and smokers.[1,5,38,40-42]

To counter public perception and patients' prior experiences with antibiotics, offer patient education.[43] Both printed and computer-assisted patient educational intervention reduce antibiotic prescriptions in the primary care setting.[44] Give azithromycin (500 milligrams on day 1, 250 milligrams on days 2 to 5) or similar macrolide for patients with presumed or confirmed *B. pertussis* infection to prevent transmission to contacts.[1,5,27] For influenza, if the patient presents very early in the course and influenza is suspected as the cause, consider influenza-specific antiviral therapy (see later section, Influenza).

There is little evidence to support the routine use of β_2-agonists for acute bronchitis in the absence of wheezing on physical exam.[1,5,39] A Cochrane Review reported no significant differences in daily cough scores or in duration of cough among adults with acute bronchitis who received β_2-agonists versus placebo or no treatment. Adults treated with β_2-agonists were more likely to report adverse effects such as tremor, shakiness, and nervousness (relative risk 7.94; 95% confidence interval 1.17 to 53.94).[45] However, among patients with evidence of airflow obstruction, β_2-agonists result in lower symptom scores and faster cough resolution.[45] Therefore, consider bronchodilators in acute bronchitis patients with wheezing.[46] Antihistamines do not reduce mean cough scores in acute bronchitis. Limited data are available on the efficacy of antitussives for acute bronchitis, and no data exist on the value of oral corticosteroids in nonasthmatics with acute bronchitis.[47] Dextromethorphan and codeine preparations may be no more effective than placebo in improving symptoms or reducing cough severity in acute bronchitis.[38] If used, limit antitussive therapy to those patients with a cough causing discomfort where inhibition of airway secretion clearance will not compromise breathing.[46]

COMMON COLD

PATHOPHYSIOLOGY

The pathogens responsible for causing the common cold include rhinovirus, adenovirus, parainfluenza virus, respiratory syncytial virus, enterovirus, and coronavirus. The rhinovirus, a species of the *Enterovirus* genus of the *Picornaviridae* family, is the most common cause of the common cold and causes up to 80% of all respiratory infections during peak seasons.[8,9,48] Dozens of rhinovirus serotypes and frequent antigenic changes among them make identification, characterization, and eradication exceedingly complex. After deposition in the anterior nasal mucosa, rhinovirus replication and infection are thought to begin upon mucociliary transport to the posterior nasopharynx and adenoids. As soon as 10 to 12 hours after inoculation, symptoms may begin. The mean duration of symptoms is 7 to 10 days, but symptoms can persist for as long as 3 weeks.[9] Nasal mucosal infection and the host's subsequent inflammatory response cause vasodilation and increased vascular permeability. These events result in nasal obstruction and rhinorrhea, whereas cholinergic stimulation prompts mucus production and sneezing.

CLINICAL FEATURES

Patients afflicted with the common cold can experience nasal congestion, rhinorrhea, sneezing, sore throat, cough, and malaise.[6] Clinical signs of rhinovirus infection include nasal discharge and hoarse voice. The consistency and purulence of nasal discharge in patients with the common cold do not necessarily indicate a bacterial infection. The high incidence of sinus abnormalities in patients with uncomplicated colds makes the identification of true bacterial sinusitis challenging. Sinusitis is estimated to complicate rhinovirus illness in 0.5% to 2% of cases (see chapter 244, Nose and Sinuses). Although fever is a common finding in children with rhinovirus infection, fever is uncommon in adults. Middle ear effusions may be noted, particularly among children, in whom acute otitis media occurs in up to 20% of viral URIs.[9]

DIAGNOSIS

The presence of classical features for rhinovirus infection, coupled with the absence of signs of bacterial infection or serious respiratory illness, is sufficient to make the diagnosis of the common cold. The common cold is a clinical diagnosis, and diagnostic testing is not necessary.

TREATMENT

The goal of treatment for the common cold is symptom relief. Decongestants and combination antihistamine/decongestant preparations can decrease cough, congestion, and other symptoms in adults.[43,49] Avoid cough preparations in children.[50,51] H_1-receptor antagonists may offer a modest reduction of rhinorrhea and sneezing during the first 2 days of a cold in adults.[6] First-generation antihistamines are sedating, so advise the patient about caution during their use. Topical and oral nasal decongestants (i.e., topical oxymetazoline, oral pseudoephedrine) have moderate benefit in adults and adolescents in reducing nasal airway resistance.[6,51] Evidence-based data do not support the use of antibiotics in the treatment of the common cold because they do not improve symptoms or shorten the course of illness.[6,51,52] There is also a lack of compelling evidence supporting the use of dextromethorphan for acute cough.

According to a Cochrane Review,[53] **vitamin C** used as daily prophylaxis at doses of ≥0.2 grams or more had a "modest but consistent effect" on the duration and severity of common cold symptoms (8% and 13% decreases in duration for adults and children, respectively). When taken therapeutically after the onset of symptoms, however, high-dose vitamin C has not shown clear benefit in trials.[53] *Echinacea* is an herbal remedy commonly used for treating the common cold; at this time, there is no clear evidence that echinacea is effective. Zinc has also been proposed for the treatment of common cold symptoms, and a meta-analysis found that oral zinc lozenges may shorten the course of symptoms in adults (no benefit in children), but nausea and altered taste were common, and the authors cautioned against a generalized recommendation.[54]

INFLUENZA

PATHOPHYSIOLOGY

The incubation period for influenza is 1 to 4 days, and the time interval between symptom onset among related household cases is estimated to be 3 to 4 days. Viral shedding can occur 1 day before the onset of symptoms. Shedding generally decreases by 3 to 5 days after illness in adults but can continue for more than 10 days after illness onset in children.[55] Understanding the routes of influenza transmission is critical to the development of effective infection control guidelines and for the planning of global, regional, and local pandemic responses. A debate exists over the route(s) of influenza virus transmission in mammals. It is believed that influenza can be transferred among humans by direct contact, indirect contact, droplets, or aerosolization. Short distances (<1 m) are generally required for contact and droplet transmission to occur

between the source person and the susceptible individual. Airborne transmission may occur over longer distances (>1 m). Experimental and observational studies support the possibility of influenza transmission by all of these routes. However, most evidence-based data suggest that direct contact and droplet transfer are the predominant modes of transmission for influenza.[56]

CLINICAL FEATURES

Influenza infection is characterized by abrupt onset of fever, headache, dry cough, sore throat, myalgias, and rhinitis. Oropharyngeal irritation and mild cervical lymphadenopathy may be present. Although the presence of fever can help distinguish influenza from the common cold, up to one third of H1N1 influenza cases in 2009 demonstrated flu symptoms without fever.[55] Hence, influenza can be difficult to distinguish from other viral URIs. Fever and intense myalgias are generally more prevalent in influenza infection than other viral URIs. Healthy individuals with uncomplicated influenza illness will generally experience resolution of symptoms in 3 to 7 days, although cough and malaise may persist beyond 2 weeks (see earlier section, Acute Bronchitis).

DIAGNOSIS

During seasonal influenza outbreaks, most cases of influenza can be diagnosed on clinical grounds alone. A retrospective analysis of 3744 subjects showed that the development of cough and fever are the best multivariate predictors of influenza infection with a positive predictive value of 79% (P <0.001).[57] During interpandemic periods, clinical signs and symptoms may be less predictive of sporadic influenza infection, and management decisions may be aided by diagnostic testing.

If the diagnostic test result for influenza will influence management decisions, certain patients should undergo testing. When signs of influenza infection are present *during an influenza outbreak*, perform testing on hospitalized patients, patients with high-risk conditions, and patients for whom a positive result would impact clinical care decisions. When a patient presents with signs of influenza infection at *any time of year*, consider testing for (1) healthcare personnel or visitors linked to an influenza outbreak presenting within 5 days of illness and (2) patients who are epidemiologically linked to an influenza outbreak presenting within 5 days of symptom onset.[58]

When testing for influenza, obtain specimens as close to symptom onset as possible. Nasal aspirates and swabs are the best specimens to obtain when testing infants and young children. For older children and adults, swabs and aspirates from the nasopharynx are preferred. Additional specimens from endotracheal aspirates and/or bronchoalveolar lavage fluid should be obtained from ventilated patients to allow testing of the lower respiratory tract.[58] Several influenza tests are available for clinical use (**Table 64-2**). Given their ability to provide results rapidly (<30 minutes), commercially available rapid influenza diagnostic tests are most practical in the ED. However, with reported sensitivities of these kits ranging from 10% to 80% (specificity 85% to 100%), negative rapid influenza tests do not completely exclude infection.[58,59]

TREATMENT

Early antiviral treatment for influenza infection shortens the duration of influenza symptoms, decreases the length of hospital stays, and reduces the risk of complications.[60] Recommendations for the treatment of influenza are updated frequently by the Centers for Disease Control and Prevention based on epidemiologic data and antiviral resistance patterns. The treatment of influenza infection is recommended as early as possible for any patient with confirmed or suspected influenza who (1) is at high risk for influenza complications (**Table 64-3**), (2) has severe, complicated or progressive illness, or (3) is hospitalized.[55,60]

A patient who does not meet the above criteria may still require treatment depending on clinical circumstances and clinician concern. Give antiviral therapy for influenza within 48 hours of symptom onset (or earlier), and do not delay treatment for laboratory confirmation if a rapid test is not available. Antiviral treatment can provide benefit even after 48 hours in pregnant and other high-risk patients.[61,62] Therefore, consider antiviral treatment even 3 or 4 days after onset of illness in certain high-risk populations.[60]

TABLE 64-2 Influenza Testing Modalities

Test	Time to Results	Comments
Rapid influenza test–antigen detection (EIA)	10–20 min	70%–90% sensitivity in children, <40%–60% sensitivity in adults, follow-up testing with RT-PCR should be considered to confirm negative result
Rapid influenza test–neuraminidase detection assay	20–30 min	Detects but does not distinguish between influenza A and B
RT-PCR	2 h	High sensitivity and specificity, highly recommended test for influenza
Immunofluorescence	2–4 h	Direct and indirect immunofluorescent antibody staining detects and distinguishes between influenza A/B and other viruses
Viral culture–shell vial Viral culture–cell culture isolation	48–72 h 3–10 d	Viral isolation/cultures are not screening tests; highest specificity, moderately high sensitivity; useful for confirming screening tests and surveillance purposes

Abbreviations: EIA, enzyme immunoassay, RT-PCR, reverse transcription polymerase chain reaction.

Copyright Oxford University Press.

For the 2012 to 2013 influenza season, the neuraminidase inhibitors zanamivir and oseltamivir were recommended by the Centers for Disease Control and Prevention for the prevention and treatment of influenza infection[55,60] (see **Table 64-4** for dosing recommendations). The recent development of resistance among several influenza strains to the neuraminidase inhibitors emphasizes the importance of following updated epidemiologic reports and recommendations by the Centers for Disease Control and Prevention and other health agencies.

Vaccination is the most effective method of preventing influenza illness. Antiviral chemoprophylaxis is also helpful in preventing influenza (70% to 90% effective) and should be considered as an adjunct to vaccination in certain scenarios or when vaccination is unavailable or not possible. Generally, antiviral chemoprophylaxis is used during periods of influenza activity for (1) high-risk persons who cannot receive vaccination (due to contraindications) or in whom recent vaccination does not, or is not expected to, afford a sufficient immune response; (2) controlling outbreaks among high-risk persons in institutional settings; and (3) high-risk persons with influenza exposures.[58,60] For more information about the indications for antiviral chemoprophylaxis, consult the Centers for Disease Control and Prevention website

TABLE 64-3 Persons at Higher Risk for Complications of Influenza Infection[34]

Children <5 y (especially <2 y)
Adults ≥65 y
Persons with chronic illnesses and/or conditions*
Persons with immunosuppression, including secondary to human immunodeficiency virus infection or medications
Women who are pregnant or postpartum (within 2 weeks of delivery)
Persons <18 y receiving long-term aspirin therapy
Residents of nursing homes and other chronic care facilities
Persons who are morbidly obese (body mass index ≥40)
American Indians/Alaska Natives

*Includes persons with chronic pulmonary (including asthma, cystic fibrosis), cardiovascular (except hypertension alone), renal, hematologic (including sickle cell disease), and hepatic diseases; metabolic disorders (including diabetes mellitus); cancers; or neurologic and neurodevelopment conditions including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy (seizure disorders), stroke, intellectual disability (mental retardation), moderate to severe developmental delay, muscular dystrophy, or spinal cord injury.

TABLE 64-4 Neuraminidase Inhibitor Dosing Recommendations[60]

	Oseltamivir (Tamiflu®)	
	Treatment	**Chemoprophylaxis**
Adults	75 milligrams twice daily × 5 d*	75 milligrams once daily × 7 d†
Children‡		
<15 kg	30 milligrams twice daily × 5 d*	30 milligrams once daily × 7 d
15–23 kg	45 milligrams twice daily × 5 d*	45 milligrams once daily × 7 d
24–40 kg	60 milligrams twice daily × 5 d*	60 milligrams once daily × 7 d
>40 kg	75 milligrams twice daily × 5 d*	75 milligrams once daily × 7 d
	Zanamivir (Relenza®)	
	Treatment	**Chemoprophylaxis**
Adults	10 milligrams (2 inhalations) twice daily × 5 d*	10 milligrams (2 inhalations) once daily × 7 d†
Children‡		
≥5 y old#	N/A	10 milligrams (2 inhalations) once daily
≥7 y old	10 milligrams (2 inhalations) twice daily × 5 d*	10 milligrams (2 inhalations) once daily × 7 d†

*Longer courses can be considered for patients who remain severely ill after 5 days of treatment.

†For controlling outbreaks in long-term care facilities, the Centers for Disease Control and Prevention recommend a minimum of 2 weeks of chemoprophylaxis and up to 1 week after the last identified case, and 7 days after most recent known exposure in other cases.

‡Antiviral medications are not Food and Drug Administration approved for treatment or prophylaxis of influenza in children age <12 months. Limited data are available in this age group. Oseltamivir was used in infants during the 2009 influenza A (H1N1) pandemic under Emergency Use Authorization (expired June 2010).

#Zanamivir is approved for treatment of influenza in children age ≥7 years and for influenza chemoprophylaxis in children age ≥5 years.

(http://www.cdc.gov/flu). Widespread and routine use of chemoprophylaxis is discouraged due to the possibility of promoting resistance and depleting supplies for high-risk or critically ill patients during influenza outbreaks.

DISEASE COMPLICATIONS

Complications of influenza infection include primary influenza viral pneumonia; secondary bacterial pneumonia; sinusitis; otitis media; coinfection with bacterial agents; and exacerbation of preexisting medical conditions, particularly asthma and chronic obstructive pulmonary disease. Pneumonia is one of the most common complications of influenza illness in children and contributes significantly to morbidity and mortality. Children with influenza-associated pneumonia are more likely than children admitted for influenza illness to develop respiratory failure (11% vs. 3%), require intensive care unit admission (21% vs. 11%), and die (0.9% vs. 0.3%).[63]

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

Severe acute respiratory syndrome is a rapidly progressive illness caused by a coronavirus, the severe acute respiratory syndrome coronavirus. Emerging in China in November 2002, severe acute respiratory syndrome quickly became a global health concern by early 2003. The World Health Organization reported 8096 probable severe acute respiratory syndrome cases worldwide through April 21, 2004. Deaths attributed to severe acute respiratory syndrome totaled 774 during that time period (9.6% case fatality rate).[64] Isolation procedures for suspected severe acute respiratory syndrome patients include airborne, droplet, and contact isolation. Healthcare providers should wear an N95 or higher respiratory facemask when caring for patients with severe acute respiratory syndrome, in addition to glove, gown, and eye protection.

Although severe acute respiratory syndrome shares many clinical features with viral URIs, its clinical characteristics are ill-defined, and case definitions were updated frequently during its emergence. The clinical features of coronavirus infection include fever (99% frequency), nonproductive cough, dyspnea, myalgias, headache, and diarrhea. Many cases progress to a moderate-severe condition characterized by hypoxia and dyspnea at rest. Respiratory failure requiring mechanical ventilation occurs in 10% to 20% of hospitalized patients with severe acute respiratory syndrome. Risk factors for death in coronavirus infection include age >60 years, diabetes mellitus, and hepatitis B infection.[65]

Consider the diagnosis of severe acute respiratory syndrome on clinical grounds when the patient has been exposed to known cases or has traveled to regions with severe acute respiratory syndrome activity. Chest radiographs may show subtle peripheral pulmonary infiltrates. Chest CT demonstrates ground-glass consolidation during early phases of illness. Lymphopenia, thrombocytopenia, elevated lactic dehydrogenase, liver enzymes, and creatine phosphokinase levels have been reported but are not pathognomonic for severe acute respiratory syndrome.[66] When severe acute respiratory syndrome is suspected, collect two specimens (from different locations) for polymerase chain reaction testing and obtain serum for serologic testing. To date, several diagnostic tests are available to detect coronavirus, but each has substantial limitations in sensitivity, specificity, or clinical practicality. Treatment for severe acute respiratory syndrome is largely supportive. When lopinavir-ritonavir was added to standard therapy (ribavirin and corticosteroids) for severe acute respiratory syndrome during a nonrandomized, open-label study in Hong Kong, a significant reduction in death rate was noted. Limitations in this study, however, make it difficult to derive definitive conclusions about its efficacy.[65]

MIDDLE EAST RESPIRATORY SYNDROME CORONAVIRUS (MERS)

In the summer of 2012, in Jeddah, Saudi Arabia, a novel coronavirus was isolated from the sputum of a patient with pneumonia and renal failure.[67] Since that time, the virus has been named the Middle East respiratory syndrome coronavirus. As of August 30, 2013, there have been 108 reported cases (several still hospitalized at that time) and 50 deaths.[68] All cases have been directly or indirectly linked to one of four countries: Saudi Arabia, Qatar, Jordan, and the United Arab Emirates, with the largest number from Saudi Arabia.[69] The original source is suspected to have come from bats.[70] Median age of patients is 56 years (range 2 to 94 years). All patients had respiratory symptoms, and some had GI symptoms including abdominal pain and diarrhea. The majority of patients experience severe acute respiratory disease requiring hospitalization; the case fatality rate has been reported as 56%. In addition to respiratory failure, renal failure and septic shock are common causes of death. Several patients had significant preexisting comorbidities, including immunosuppression. Cases have included healthcare workers and family contacts. A documented patient-to-patient nosocomial transmission has been reported in France.[71] Treatment is supportive and frequently requires mechanical ventilation, dialysis, and extracorporeal membrane oxygenation. Nonspecific antiviral drugs have been used, such as ribavirin, lopinavir, and type I interferon, but their efficiency is still unclear.[72] Patients should be isolated in an airborne infection isolation room.[73] Healthcare workers should wear personal protective equipment including gloves, gown, eye protection, and a fit-tested N95 respirator facemask.[73]

PERTUSSIS

Pertussis, or "whooping cough," is an acute respiratory infection in humans caused by the aerobic gram-negative rod, *B. pertussis*. Pertussis toxins cause respiratory epithelial and mucosal injury and interfere with immune cell function. Pertussis pneumonia can occur in children, but in school-age children, adolescents, and adults, URIs are the rule.

IMMUNIZATION

Although pertussis is often considered a disease of infants (primarily in those <1 year old who have not completed three doses of vaccination) and a disease in developing countries where immunization is not universal, in North America, the disease is now more common in school-age children and adults. School-age children are the usual sources of infection, and adults may serve as carriers of disease. Cyclical outbreaks occur every 3 to 5 years despite widespread immunization practices.

There are two types of vaccines, whole-cell and acellular. Whole-cell pertussis vaccination is effective for about 10 years and is used in developing nations. The acellular diphtheria, tetanus, and pertussis vaccine (DTaP), developed to remove toxins from the cell membrane, does not protect as long as the whole-cell vaccine and is typically used in the developed world.[74] The typical immunization schedule is at 2, 4, 6, and 18 months of age and a booster at age 5. Adolescents should receive a DTaP booster. **Pregnant women** should receive a booster of DTaP to protect neonates and infants and to prevent infection in the mother. For the unimmunized elderly (>65 years old), one dose of DTaP is recommended.[75] Although the vaccine is specifically not registered for the elderly,[76] a study of nearly 120,000 individuals ≥65 years old did not demonstrate any increase in inflammatory or allergic events in those receiving DTaP compared with those receiving only the tetanus and diphtheria vaccine.[77] There is no lifelong immunity after a clinical episode of pertussis.

CLINICAL FEATURES

Clinical features in adults are those of the common cold, but after 1 week, prolonged, paroxysmal, and sleep-disturbing cough develops. Whooping is uncommon in adults. Consider pertussis in situations of chronic cough >2 weeks in duration. Cough may last for several months. Since pertussis is highly communicable, with an attack rate of about 20% even in the immunized, suspect pertussis if there is contact with other individuals with prolonged cough. Except in the elderly, pertussis in adults is not associated with pneumonia. Clinical or radiologic evidence of pneumonia in adults or the elderly suggests secondary bacterial infection.

DIAGNOSIS

Diagnosis is often clinical, especially during epidemics. Definitive diagnosis is usually by polymerase chain reaction of nasopharyngeal secretions or serologic detection of antibodies. Other causes of respiratory illnesses with prolonged cough include *Mycoplasma*, *Chlamydophila*, influenza virus, and other respiratory viruses. In adults, chronic cough can be associated with angiotensin-converting enzyme inhibitors, gastroesophageal reflux, or asthma.

TREATMENT

Treatment of pertussis is azithromycin, 500 milligrams PO on day 1 and 250 milligrams PO on days 2 to 5. Trimethoprim-sulfamethoxazole, 160 milligrams/800 milligrams twice a day for 14 days (check renal dosing), is an alternative to those allergic to, or unable to tolerate, macrolides. Treatment is best if started early, in the first week. After that, antibiotic treatment does not alter the duration of cough. Chemoprophylaxis is typically given for household contacts, although the evidence base for such treatment is weak.

CHAPTER 65

Pneumonia and Pulmonary Infiltrates

Gerald Maloney
Eric Anderson
Donald M. Yealy

PNEUMONIA

EPIDEMIOLOGY

Pneumonia is an infection of the alveoli (the gas-exchanging portion of the lung) emanating from different pathogens, notably bacteria and viruses, but also fungi. Community-acquired pneumonia occurs in 4 million people and results in 1 million hospitalizations per year in the United States.[1,2] Pneumonia is the eighth leading cause of death, particularly among older adults,[3] and is the most common trigger for sepsis. Those who develop hospital- or other healthcare-associated pneumonia (acquired after placement in a care facility) often have infection from resistant organisms (**Table 65-1**).[4,5]

TABLE 65-1 Acquisition Environment Classification for Pneumonia

Classification	Criteria
Community-acquired pneumonia	Acute pulmonary infection in a patient who is not hospitalized or residing in a long-term care facility 14 or more days before presentation
Hospital-acquired pneumonia	New infection occurring 48 or more hours after hospital admission
Ventilator-acquired pneumonia	New infection occurring 48 or more hours after starting mechanical ventilation
Healthcare-associated pneumonia	Patients hospitalized for 2 or more days within the past 90 days
	Nursing home/long-term care residents
	Patients receiving home IV antibiotic therapy
	Dialysis patients
	Patients receiving chronic wound care
	Patients receiving chemotherapy
	Immunocompromised patients

PATHOPHYSIOLOGY

Pathogenic lung organisms are usually aspirated, especially in the hospital or healthcare setting (where eating is often not done sitting upright for dubious reasons), although inhalation is another potential route. *Staphylococcus aureus* and *Streptococcus pneumoniae* can produce pneumonia from hematogenous seeding. Patients most at risk for pneumonia are those with a predisposition to aspiration, impaired mucociliary clearance, or risk of bacteremia (**Table 65-2**).

Some forms of pneumonia produce an intense inflammatory response within the alveoli that leads to filling of the air space with exudate and white blood cells. Bacterial pneumonia results in an intense inflammatory response and tends to cause a productive cough. Atypical organisms often trigger a less intense inflammatory response and create a milder or nonproductive cough.

In about half of patients with community-acquired pneumonia, no specific pathogen is identified. When an organism is identified, the pneumococcus is still the most common, followed by viruses and the atypical agents *Mycoplasma*, *Chlamydia*, and *Legionella*. Most patients with severe community-acquired pneumonia who were otherwise healthy have *S. pneumoniae* and *Legionella* as pathogens.

In up to 5% of cases, more than one pathogen exists. In nursing home residents, alcoholics, and those with human immunodeficiency virus (HIV) infection and depressed CD4 counts, all the common pathogens exist along with others rarely seen in other patients.

CLINICAL FEATURES

Patients with pneumonia frequently will present with cough (79% to 91%), fatigue (90%), fever (71% to 75%), dyspnea (67% to 75%), sputum production (60% to 65%), and pleuritic chest pain (39% to 49%).[6] Despite described patterns of presentation, the variability in the individual symptoms and physical findings can make clinical diagnosis and differentiation from bronchitis and other upper respiratory tract disease difficult.[7,8] Many types of pneumonia do not have a sudden and characteristic presentation, and many patients with pneumonia have an antecedent viral upper respiratory infection with coryza, low-grade fever, rhinorrhea, or nonproductive cough. Weight loss, malaise, dizziness, and weakness may be associated with pneumonia. Some of the atypical agents are associated with headache or GI illness. Occasionally, pneumonia is associated with

TABLE 65-2 Risk Factors for Pneumonia

Aspiration risk
Swallowing and esophageal motility disorders
Stroke
Nasogastric tube
Intubation
Seizure and syncope
Bacteremia risk

Chronic diseases
Diabetes
Renal failure
Liver failure
Valvular heart disease
Congestive heart failure
Pulmonary disorders
Chronic obstructive pulmonary disease
Chest wall disorders
Skeletal muscle disorders
Bronchial obstruction
Bronchoscopy
Viral lung infections

extrapulmonary symptoms, including joint pain, hematuria, or skin rashes. **Table 65-3** lists common pathogen and clinical feature correlations, all of which can vary or be absent in an individual patient.

The physical examination in a patient with acute pneumonia may show evidence of alveolar fluid (rales), consolidation (bronchial breath sounds), pleural effusion (dullness and decreased breath sounds), or bronchial congestion (rhonchi and wheezing).[7,8] Radiologic findings in pneumonia sometimes provide a specific pathogenic diagnosis (Table 65-3).

Pneumococcal Pneumonia The elderly, children <2 years old, minorities, children who attend group day care centers, and those with immune-depressing comorbid conditions (e.g., previous splenectomy, transplantation, HIV infection, sickle cell disease) are at highest risk for pneumococcal pneumonia. Classically, patients with pneumococcal pneumonia present with sudden onset of disease with rigors, bloody sputum, high fever, and chest pain with lobar infiltrates (**Figure 65-1**); 25% will have parapneumonic pleural effusions. Patients with chronic lung disease, nursing home patients, or otherwise healthy elderly patients tend to have a slower progression of pneumonia, with symptoms of malaise with minimal cough or sputum production.

Laboratory findings in pneumonia include leukocytosis, elevation of the serum bilirubin or hepatic enzymes, and hyponatremia; none is diagnostic of the infection, but all detail the other organ involvement that can occur.

Pneumococcal pneumonia responds to a variety of antibiotics, although there is an increased incidence of penicillin-, macrolide-, and fluoroquinolone-resistant pneumococci.[9] Penicillin resistance ranges from 5% to 80%, depending on location, with increasing resistance reported in Spain, Italy, and Eastern Europe. Resistance is also increasing to tetracycline and trimethoprim-sulfamethoxazole. Patients with intermediate penicillin-resistant pneumococci may still be effectively treated with routine antibiotics so long as an adequate dose is administered.[10] However, the bacteriologic agent is rarely known to clinicians at the start of therapy. Patients with highly penicillin-resistant pneumococci require treatment with vancomycin, imipenem, a newer respiratory fluoroquinolone, or ketolide.

TABLE 65-3 Clinical Characteristics of Common Bacterial Pneumonias

Organism	Symptoms	Sputum	Chest X-Ray
Streptococcus pneumoniae	Sudden onset, fever, rigors, pleuritic chest pain, productive cough, dyspnea	Rust-colored; gram-positive encapsulated diplococci	Lobar infiltrate, occasionally patchy, occasional pleural effusion
Staphylococcus aureus	Gradual onset of productive cough, fever, dyspnea, especially just after viral illness	Purulent; gram-positive cocci in clusters	Patchy, multilobar infiltrate; empyema, lung abscess
Klebsiella pneumoniae	Sudden onset, rigors, dyspnea, chest pain, bloody sputum; especially in alcoholics or nursing home patients	Brown "currant jelly"; thick, short, plump, gram-negative, encapsulated, paired coccobacilli	Upper lobe infiltrate, bulging fissure sign, abscess formation
Pseudomonas aeruginosa	Recently hospitalized, debilitated, or immunocompromised patient with fever, dyspnea, cough	Gram-negative coccobacilli	Patchy infiltrate with frequent abscess formation
Haemophilus influenzae	Gradual onset, fever, dyspnea, pleuritic chest pain; especially in elderly and COPD patients	Short, tiny, gram-negative encapsulated coccobacilli	Patchy, frequently basilar infiltrate, occasional pleural effusion
Legionella pneumophila	Fever, chills, headache, malaise, dry cough, dyspnea, anorexia, diarrhea, nausea, vomiting	Few neutrophils and no predominant bacterial species	Multiple patchy nonsegmented infiltrates, progresses to consolidation, occasional cavitation and pleural effusion
Moraxella catarrhalis	Indolent course of cough, fever, sputum, and chest pain; more common in COPD patients	Gram-negative diplococci found in sputum	Diffuse infiltrates
Chlamydophila pneumoniae	Gradual onset, fever, dry cough, wheezing, occasionally sinus symptoms	Few neutrophils, organisms not visible	Patchy subsegmental infiltrates
Mycoplasma pneumoniae	Upper and lower respiratory tract symptoms, nonproductive cough, headache, malaise, fever	Few neutrophils, organisms not visible	Interstitial infiltrates, (reticulonodular pattern), patchy densities, occasional consolidation
Anaerobic organisms	Gradual onset, putrid sputum, especially in alcoholics	Purulent; multiple neutrophils and mixed organisms	Consolidation of dependent portion of lung; abscess formation

Abbreviation: COPD = chronic obstructive pulmonary disease.

FIGURE 65-1. Lobar pneumonia.

Other Bacterial Pneumonias ***S. aureus*** pneumonia is a consideration in patients with chronic lung disease, patients with laryngeal cancer, immunosuppressed patients, nursing home patients, or others at risk for aspiration pneumonia. *S. aureus* pneumonia may occur in otherwise healthy patients after viral illness, such as during an influenza epidemic, although pneumococcal pneumonia is still more common. Patients with staphylococcal pneumonia typically have an insidious onset of disease with low-grade fever, sputum production, and dyspnea. The chest radiograph usually demonstrates extensive disease with empyema, pleural effusions, and multiple areas of infiltrate (**Figure 65-2**). If leucocidin excretion by the organism accompanies this infection (rare and not predictable), rapid progression and death are common even with adequate therapy. Patients with healthcare-acquired pneumonia are at risk for infection with methicillin-resistant *S. aureus*.[5,11]

Klebsiella pneumonia often occurs in compromised patients: those at risk of aspiration, alcoholics, the elderly, and those with chronic lung disease. In contrast to *S. aureus,* patients with *Klebsiella* have acute onset of severe disease with fever, rigors, and chest pain. Patients with *Klebsiella* may develop pulmonary abscesses, although more commonly radiographs show a lobar infiltrate.

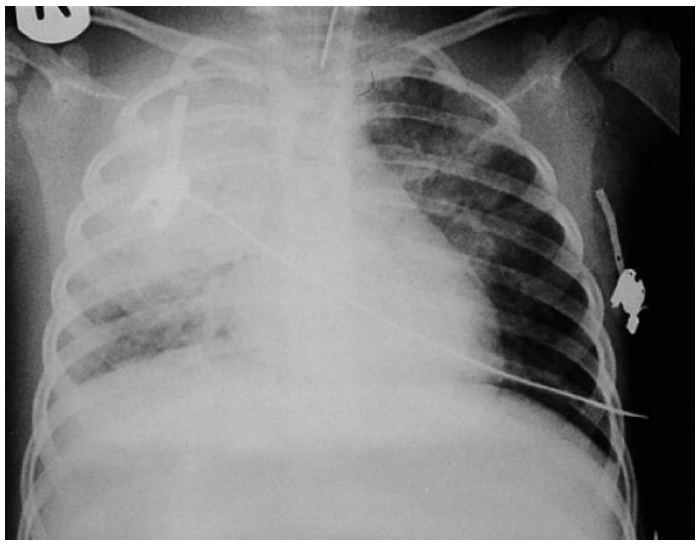

FIGURE 65-2. Staphylococcal pneumonia with extensive infiltration and effusion or empyema.

Pseudomonas causes a severe pneumonia with cyanosis, confusion, and other signs of systemic illness. The chest radiograph may show bilateral lower lobe infiltrates, occasionally associated with empyema. *Pseudomonas* is not a typical cause of community-acquired pneumonia, more often seen in patients with a prolonged hospitalization, who have received broad-spectrum antibiotics or high-dose steroid therapy, who have structural lung disease (including cystic fibrosis), or who are nursing home residents.

Haemophilus influenzae pneumonia occurs in any age, although it most commonly occurs in the elderly, or in those with chronic lung disease, sickle cell disease, or immunocompromised disorders and in alcoholics and diabetics. Since the onset of routine vaccination of children, the incidence of *H. influenzae* pneumonia in children has markedly dropped. Patients with this type of community-acquired pneumonia may either have a gradual progression of disease with low-grade fever and sputum production or occasionally the sudden onset of chest pain, dyspnea, and sputum production. Bacteremia may be seen in older adults. Pleural effusions and multilobar infiltrates are common findings in *H. influenzae* pneumonia.

Moraxella catarrhalis pneumonia has clinical features similar in spectrum to those of *H. influenzae.* Typically, patients with *M. catarrhalis* present with an indolent course of cough and sputum production, with fever and pleuritic chest pain are common. The chest radiograph usually shows diffuse infiltrates.

Pneumonia from Atypical Bacteria and Viruses The atypical bacteria are *Legionella*, *Chlamydophila*, and *Mycoplasma*. Because these agents lack a cell wall, they do not respond to β-lactam antibiotics but respond to macrolides or a respiratory fluoroquinolone.

Legionella can cause a range of illness from benign self-limited disease to multisystem organ failure with acute respiratory distress syndrome. Patients at particular risk include cigarette smokers, patients with chronic lung disease, transplant patients, and the immunosuppressed. **There is no seasonality to *Legionella* pneumonia, making it a more prominent cause of pneumonia in the summer when other pathogens decline in frequency.** *Legionella* pneumonia is commonly complicated by GI symptoms, including abdominal pain, vomiting, and diarrhea**.** In addition, *Legionella* can affect other organ systems, causing sinusitis, pancreatitis, myocarditis, and pyelonephritis. The chest radiograph frequently shows a patchy infiltrate, with the occasional appearance of hilar adenopathy and pleural effusions (**Figure 65-3**).

Infection with *Chlamydophila* usually causes a mild illness with sore throat, low-grade fever, and nonproductive cough, although occasionally patients have a more severe course. Patients with *Chlamydophila* pneumonia frequently have rales or rhonchi. The chest radiograph usually shows a patchy subsegmental infiltrate, overlapping with the appearance of *Legionella* pneumonia. Chlamydial infection is linked to adult-onset asthma.

Mycoplasma pneumonia also occurs year-round, although it tends to cluster in epidemics every 4 to 8 years. *Mycoplasma* may cause a subacute respiratory illness with cough, sore throat, and headache. *Mycoplasma* pneumonia is also frequently associated with retrosternal chest pain. Unlike *Legionella, Mycoplasma* usually is not associated with GI symptoms. Like the other atypical pathogens, chest radiograph often shows patchy infiltrates, commonly with hilar adenopathy or pleural effusions. *Mycoplasma* occasionally causes extrapulmonary symptoms, including rash, neurologic symptoms, arthralgia, hematologic abnormalities, or rarely acute kidney injury. Bullous myringitis is not at all specific for *Mycoplasma* infection but is associated with many other causes of otitis media.

Viruses cause pneumonia, often severe; influenza is the most common viral pneumonia and is seasonal. The outbreak of severe acute respiratory syndrome and the Middle East respiratory syndrome, both from coronaviruses, demonstrates how a local infection can be rapidly transmitted worldwide.[12] The most recent pandemic viral infection has been H1N1 in 2009. Varicella, typically benign in most childhood infections, can lead to a virulent pneumonia in pregnant patients.

FIGURE 65-3. Classic diffuse, patchy infiltrates seen with *Legionella pneumonia*.

Further discussion of life-threatening viral infections is covered elsewhere (see chapter 153, "Serious Viral Infections").

DIAGNOSIS

Suspect pneumonia from symptoms and signs (often fever, cough, dyspnea, or weakness with rales or rhonchi), while recognizing that each individual symptom or finding lacks high accuracy. When symptoms suggest a possibility, order a chest radiograph; if clinical findings suggest pneumonia (with or without an infiltrate on chest x-ray), treat emprically.[13] No single set of recommendations for diagnostic testing applies to all patients, requiring clinical judgment. In otherwise healthy, mildly ill, ambulatory patients, no further ancillary testing may be necessary. To optimally risk-stratify anyone over 50 years old or more than mildly ill, seek evidence of other organ affliction; this is done by including CBC, serum electrolytes, BUN, creatinine, and glucose levels. Pulse oximetry is needed in all cases because a saturation on room air of <91% is associated with more complications. An arterial blood gas analysis is reserved for those appearing ill, with underlying lung disease, with oxygen desaturation, or in respiratory distress.

Most patients do not require identification of a specific organism through blood or sputum analysis to direct antibiotic treatment. The incidence of positive blood cultures in nonhospitalized patients with community-acquired pneumonia is low, pathogen identification usually does not alter treatment, and the majority of patients respond to empiric antibiotic treatment. The value of sputum culture is similar to the value of blood cultures and often limited by poor sampling, with less than 15% being adequate and helpful.[14] Atypical agents may be detected by evaluation of titers from acute and convalescence sera or by direct fluorescent antibody testing.

In hospitalized community-acquired pneumonia patients, the incidence of positive blood cultures increases along with increasing disease severity.[15] For this reason, **obtain blood cultures in those admitted to the intensive care unit and in those with leukopenia, cavitary lesions, severe liver disease, alcohol abuse, asplenia, or pleural effusions.**[16] In any admitted patient, a **sputum culture and Gram stain are options if an adequate sample can be obtained.** *Legionella* urine antigen tests are useful in intensive care unit patients, alcoholics, those with classic findings, and those with a recent (within the past 2 weeks) travel history.

The differential diagnosis of patients with cough and radiographic abnormality includes lung cancer, tuberculosis, pulmonary embolism, chemical or hypersensitivity pneumonitis, connective tissue disorders, granulomatous disease, and fungal infections. Because radiographic signs of pneumonia vary, it is difficult to predict the causative microorganism by its radiographic appearance. In general, patients with bacterial pneumonia are more likely to have unilobar or focal infiltrates than patients with viral or atypical pneumonia. Hilar adenopathy is more common in patients with atypical pneumonia. Pleural effusions can accompany bacterial, viral, or atypical pneumonia. Cavitary lesions occur in patients with bacterial pneumonia or tuberculosis. Lung abscesses are rare complications of pneumonia in the antibiotic era, usually due to *S. aureus* or *Klebsiella.* Pneumococcal and staphylococcal pneumonia may mimic a lung mass, along with other atypical pneumonias, such as Q fever and tularemia.

PNEUMONIA IN SPECIAL POPULATIONS

Pneumonia in Alcoholics Alcoholics have a higher risk than the normal population for many lung diseases, including pneumonia, tuberculosis, pleurisy, bronchitis, empyema, and chronic obstructive pulmonary disease. Alcoholics are more likely than the general population to be undernourished, to develop aspiration pneumonitis, to be heavy smokers, and to have sequelae of alcoholic cirrhosis and portal hypertension. Compared with the nonalcoholic, the alcoholic has greater oropharyngeal colonization with gram-negative bacteria, and also has depressed granulocyte and lymphocyte counts with impaired neutrophil delivery.

***S. pneumoniae* is the most common pathogen causing pneumonia in alcoholics, but *Klebsiella* species and *Haemophilus* species are also important agents of infection.** In general, rates of pneumonia and subsequent mortality are higher in alcoholics compared with nonalcoholic patients.

Pneumonia in Diabetics Diabetic patients between the ages of 25 and 64 years old are four times more likely to have pneumonia and influenza, and diabetics are two to three times more likely than nondiabetics to die with pneumonia and influenza as an underlying cause of death. **Pathogens that occur with increased frequency in diabetic patients include *S. aureus*, gram-negative bacteria, mucormycosis, and *Mycobacterium tuberculosis*.** Infections due to *S. pneumoniae*, *Legionella pneumophila*, and influenza are associated with increased morbidity and mortality in diabetic patients.

Pneumonia in Pregnant Women Community-acquired pneumonia in pregnancy is one of the most serious nonobstetric infections, with maternal mortality of approximately 3%. Pregnancy does not alter the course of bacterial pneumonia, but the prognosis of viral pneumonia during pregnancy is more serious than in the nonpregnant patient. Pregnant woman are at risk for developing severe influenza-associated pneumonia, and antivirals are often used in this patient group (see chapter 153, "Serious Viral Infections").

Pregnant women who develop varicella pneumonia are more often smokers and have skin lesions suggestive of the disease on exam. **Obtain a chest radiograph and pulse oximetry measure in any pregnant woman with symptoms of respiratory tract infection and varicella exposure.** Empiric IV acyclovir is often used, although there is little evidence that the timing of administration affects outcome.

Pneumocystis jiroveci pneumonia is the most common cause of acquired immunodeficiency syndrome–related death in pregnant women in the United States, with a mortality of approximately 50%; over half receive mechanical ventilation during hospitalization. Combination treatment with pentamidine, steroids, and eflornithine improves survival compared with patients treated with trimethoprim-sulfamethoxazole alone.

Pneumonia in the Elderly Pneumonia is the most common serious elderly infection, representing the fifth leading cause of death.[17] The incidence of lower respiratory tract infection in the elderly ranges from 25 to 44 cases per 1000 in the general population, with a mortality rate

approaching 40%. Chronic obstructive pulmonary disease, congestive heart failure, cardiovascular and cerebrovascular disease, lung cancer, dementia, diminished gag reflex, and other aspiration risks make the elderly susceptible to infection.

Those over age 65 years are three times more likely to have pneumococcal bacteremia than younger patients. Atypical pathogens are still more common in younger populations but occur in the elderly. *Legionella* is the most common atypical agent in the elderly and is responsible for up to 10% of cases of community-acquired pneumonia. **Influenza is the most common serious viral infection in the elderly. Postinfluenza bacterial pneumonia, whether following H1N1 or other seasonal influenza, is most commonly caused by *S. pneumoniae*, *S. aureus*, or *H. influenzae*.** This usually presents as a worsening of respiratory symptoms after days of improvement.

Elderly patients with pneumonia may present with nonpulmonary symptoms like falls, weakness, tremulousness, functional decline, abdominal complaints, delirium, or confusion. Elderly patients are more likely to be afebrile on presentation but are more likely than younger adults to have a serious bacterial infection when the temperature is higher than 38.3°C (100.9°F).

Age alone does not confer a poor prognosis until extremes (over 85 years), but age does interact with other organ dysfunction to increase mortality and morbidity. Up to one third of elderly patients with community-acquired pneumonia will not manifest leukocytosis. Poor prognostic indicators for pneumonia in the elderly include hypothermia or a temperature >38.3°C (100.9°F), leukopenia, immunosuppression, gram-negative or staphylococcal infection, cardiac disease, bilateral infiltrates, and extrapulmonary disease. Elderly pneumonia patients frequently require hospitalization, and 10% receive intensive care.

Pneumonia in Nursing Home Patients Pneumonia is a major cause of morbidity, mortality, and hospitalization among nursing home residents.[17,18] Nursing home patients are less likely than those living independently to have a productive cough or pleuritic chest pain, but more likely to be confused and have poorer functional status and more severe disease.[18] Eight findings are independent predictors of pneumonia in nursing home patients: increased pulse rate, respiratory rate ≥30 breaths/min, temperature ≥38°C (100.4°F), somnolence or decreased alertness, presence of acute confusion, lung crackles on auscultation, the absence of wheezes, and an increased leukocyte count.[19] A patient with one of these features has a 33% chance of having pneumonia, whereas three or more features suggest a 50% likelihood of pneumonia.[19] Fewer than 10% of nursing home patients with pneumonia will have no respiratory symptoms. Fever, although nonspecific, is present in approximately 40% of cases of nursing home–acquired pneumonia.

The most frequently reported pathogens among patients with nursing home–acquired pneumonia are *S. pneumoniae*, gram-negative bacilli, and *H. influenzae*. Because nursing home patients live in close proximity to each other, residents are subject to outbreaks of influenza. Vaccination against influenza is 33% to 55% effective in preventing postinfluenzal pneumonia in nursing home patients. *M. pneumoniae* and *Legionella* are uncommon causes of pneumonia in nursing home patients.

Nursing home–acquired pneumonia is often treated in the hospital, but some patients can be treated in nursing homes with either intramuscular or oral antibiotics.[20] **Nursing home patients are at risk for the organisms linked to health care–associated pneumonia, so therapy should include coverage for gram-negative bacteria and methicillin-resistant *S. aureus*.[4]**

Pneumonia in Human Immunodeficiency Virus Patients Community-acquired pneumonia accounts for roughly three fourths of bacterial pneumonia diagnosed in patients hospitalized with HIV infection. Compared with HIV-seropositive patients hospitalized *without* pneumonia, those admitted *with* pneumonia generally have a lower CD4+ T-cell count, a higher Acute Physiology and Chronic Health Evaluation II score, a longer length of hospital stay, a greater chance of intensive care unit admission, and a higher case fatality rate.

***S. pneumoniae* is the most common cause of bacterial pneumonia in patients with HIV. *Pseudomonas aeruginosa* is also a common cause of bacterial pneumonia in HIV-positive patients.** HIV-positive patients with *P. aeruginosa* pneumonia, compared with HIV-negative patients, are more likely to have a lower leukocyte and CD4+ T-cell count and a longer hospital stay but a similar case fatality rate. (See chapter 154, "Human Immunodeficiency Virus Infection.")

TABLE 65-4 Therapy for Outpatient Treatment of Uncomplicated Patients*

Class	Examples	Comments
Macrolide	Azithromycin, 500 milligrams PO on day 1 and 250 milligrams on days 2–5	Respiratory fluoroquinolones reserved for those who cannot tolerate or have failed other therapy
	or	
	Clarithromycin XL, 1000 milligrams PO each day for 7 d	
Tetracycline-like macrolide	Doxycycline, 100 milligrams twice a day for 10–14 d	Second-line choice

*Other drugs may also be effective.

Pneumonia in Transplant Patients **Bacterial pneumonia is more common in patients receiving liver, heart, or lung transplants during the first 3 months after surgery, compared with other transplant and surgical patients.** Gram-negative bacilli (especially *P. aeruginosa* associated with mechanical ventilation), *S. aureus*, and *Legionella* predominate in the first 3 months posttransplantation. *K. pneumoniae*, *Escherichia coli*, and fungi may also cause pneumonia in this time period. These early-onset nosocomial bacterial pneumonias carry a substantial mortality rate, approximately 33%. Cytomegalovirus, *P. jiroveci*, and fungal infections, especially *Aspergillus* species, are opportunistic infections, which may be seen in the first 6 months after surgery. **After 6 months posttransplantation, typical community-acquired pneumonia bacteria (*S. pneumoniae*, *H. influenzae*) are common and less often fatal than earlier infections** (see chapter 297, "The Transplant Patient").

TREATMENT

Emergency physicians start community-acquired pneumonia therapy usually based on bedside features rather than culture data; the Infectious Diseases Society of America and the American Thoracic Society guidelines, along with the American College of Emergency Physicians (ACEP) Clinical Policy, help care decisions.[21] Pediatric recommendations are provided in the chapter 125, "Pneumonia in Infants and Children."

The drugs listed in Tables 65-4 through 65-9[4,16,22] are based on site acquisition and comorbidities but do not represent a comprehensive list. Other antibiotic regimens are effective and guided by local resistance patterns and availbility.[16] Outpatient treatments are listed in **Tables 65-4** and **65-5**. Inpatient treatments are listed in **Tables 65-6** through **65-9**.

TABLE 65-5 Therapy for Outpatient Management of Patients with Significant Comorbidities* without Criteria for Healthcare-Associated Pneumonia

Class	Examples	Comments
Fluoroquinolone	Levofloxacin, 750 milligrams daily for 5 d	Other respiratory fluoroquinolones may also be used.
	or	
	Moxifloxacin, 400 milligrams daily for 7–14 d	
β-Lactamase inhibitor penicillin derivative	Amoxicillin-clavulanate, 2 grams twice daily	A third-generation cephalosporin may be used instead of the aminopenicillin.
plus	*plus*	
Macrolide	Azithromycin, 500 milligrams PO on day 1 and 250 milligrams on days 2–5	

*Significant comorbidities include chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies; and asplenia. See text. Dosing may need adjustment for patients with renal insufficiency. Other therapies may also be effective.

TABLE 65-6 Inpatient Therapy for Non–Intensive Care Unit Patients* with Community-Acquired Pneumonia

Class	Examples	Comments
Fluoroquinolone	Levofloxacin, 750 milligrams IV	Other respiratory fluoroquinolones may also be used.
	or	
	Moxifloxacin, 400 milligrams IV	
Cephalosporin or penicillin class with β-lactamase inhibitor	Ceftriaxone, 1 gram IV or ampicillin/sulbactam 1.5 gram IV	Other third-generation cephalosporins may also be used in combination with other macrolides or doxycycline.
plus	*plus*	
Macrolide	Azithromycin, 500 milligrams IV	

*Other drugs may also be effective; dosing may need adjustment for patients with renal insufficiency. Oral therapy with selected drugs may be acceptable for non–intensive care unit patients.

TABLE 65-7 Empiric Therapy for Patients with Suspected Healthcare-Associated Pneumonia

Three-Drug Regimen Recommended

Class	Examples	Comments
Antipseudomonal cephalosporin	Cefepime, 1–2 grams every 8–12 h	An aminoglycoside may be substituted in place of the fluoroquinolone. Levofloxacin, 750 milligrams every 8 h, may be substituted for ciprofloxacin. Linezolid, 600 milligrams every 12 h, may be substituted for vancomycin.
	or	
	Ceftazidime, 2 grams every 8 h	
plus	*plus*	
Fluoroquinolone	Ciprofloxacin, 400 milligrams every 8 h*	
plus	*plus*	
Anti-MRSA drug	Vancomycin, 15 milligrams/kg every 12 h	
Antipseudomonal carbapenem	Imipenem, 500 milligrams every 6 h	An aminoglycoside may be substituted in place of the fluoroquinolone. Levofloxacin, 750 milligrams every 8 h, may be substituted for ciprofloxacin. Linezolid, 600 milligrams every 12 h, may be substituted for vancomycin.
	or	
	Meropenem, 1 gram every 8 h	
plus	*plus*	
Fluoroquinolone	Ciprofloxacin, 400 milligrams every 8 h*	
plus	*plus*	
Anti-MRSA drug	Vancomycin, 15 milligrams/kg every12 h	
β-Lactam/β-lactamase inhibitor	Piperacillin-tazobactam, 4.5 grams every 6 h	An aminoglycoside may be substituted in place of the fluoroquinolone. Levofloxacin, 750 milligrams every 8 h, may be substituted for ciprofloxacin. Linezolid, 600 milligrams every 12 h, may be substituted for vancomycin.
plus	*plus*	
Antipseudomonal fluoroquinolone	Ciprofloxacin, 400 milligrams every 8 h*	
plus	*plus*	
Anti-MRSA drug	Vancomycin, 15 milligrams/kg every 12 h	

Note: Healthcare-associated pneumonia risks include (1) patients hospitalized for 2 or more days within the past 90 days, (2) nursing home/long-term care residents, (3) patients receiving home IV antibiotic therapy, (4) dialysis patients, (5) patients receiving chronic wound care, (6) patients receiving chemotherapy, and (7) immunocompromised patients.

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus*.

*See text. Dosing may need adjustment for patients with renal insufficiency.

TABLE 65-8 Inpatient Therapy for Intensive Care Unit Patients*

Class	Example	Comments
Cephalosporin	Ceftriaxone, 1 gram IV	Other β-lactams may also be used in place of ceftriaxone. See Table 65-9 for additional recommendations.
plus	*plus*	
Macrolide	Azithromycin, 500 milligrams IV	
Cephalosporin	Ceftriaxone, 1 gram	Other β-lactams may also be used in place of ceftriaxone. See Table 65-9 for additional recommendations.
plus	*plus*	
Fluoroquinolone	Either moxifloxacin, 400 milligrams IV	
	or	
	Levofloxacin, 750 milligrams IV	
Fluoroquinolone	Moxifloxacin, 400 milligrams IV	Aztreonam is generally well tolerated in penicillin-allergic patients.
plus	*or*	
Either a monobactam	Levofloxacin, 750 milligrams IV	
or	*plus*	
Lincosamide	Either aztreonam, 1–2 grams IV	
	or	
	Clindamycin, 600 milligrams IV	
Anti-MRSA drug (add if HCAP or MRSA risk)	Vancomycin, 10–15 milligrams/kg IV	To be added to one of the above regimens for patients with MRSA or HCAP risk.
	or	
	Linezolid, 600 milligrams IV	

Abbreviations: HCAP = healthcare-associated pneumonia; MRSA = methicillin-resistant *Staphylococcus aureus*.

*Other combinations may also be used. Dosing may need adjustment for patients with renal insufficiency.

TABLE 65-9 Inpatient Therapy for Patients with Higher *Pseudomonas* Risk*

Class	Example	Comments
β-Lactam/β-lactamase inhibitor	Piperacillin-tazobactam, 3.375 milligrams IV	Other antipseudomonal cephalosporins or quinolones may be used. Carbapenems are also appropriate. Consider adding an aminoglycoside if substituting a macrolide.
plus	*plus*	
Fluoroquinolone	Ciprofloxacin, 400 milligrams IV	
Monobactam	Aztreonam, 1 gram IV	May be used for patients with penicillin allergy. Carbapenems and aminoglycosides may also be appropriate.
plus	*plus*	
Fluoroquinolone	*either* Moxifloxacin, 400 milligrams IV	
	or	
	Levofloxacin, 750 milligrams IV	
Anti-MRSA drug (add if HCAP or MRSA risk)	Vancomycin, 10–15 milligrams/kg IV	To be added to one of the above regimens for patients with MRSA or HCAP risk.
	or	
	Linezolid, 600 milligrams IV	

Abbreviations: HCAP = healthcare-associated pneumonia; MRSA = methicillin-resistant *Staphylococcus aureus*.

*Other combinations may also be used. Dosing may need adjustment for patients with renal insufficiency.

In **outpatients,** single-drug therapy is the common first choice, using a macrolide or a respiratory fluoroquinolone, with doxycycline as an alternative. Erythromycin is a cost-effective agent for community-acquired pneumonia but is associated with GI side effects in about 25% of adult patients and also causes photosensitivity. Clarithromycin has fewer GI side effects, although some patients may complain about a metallic taste. Azithromycin has the advantage of once-a-day dosing or single-dose therapy with the newer formulations. The newer fluoroquinolone agents, including moxifloxacin, levofloxacin, and gemifloxacin, extend coverage to both common bacterial agents and atypical agents, along with the advantage of once-a-day dosing. However, given concerns about resistance developing, **the Centers for Disease Control and Prevention recommends that fluoroquinolones be reserved for patients who cannot tolerate other agents, have documented pneumococcal resistance, or have failed other therapies. Fluoroquinolones should not be used in patients with myasthenia gravis.**

Patients who received broad-spectrum antibiotics within the previous 3 months are at risk for drug-resistant infection. In these patients, consider a respiratory fluoroquinolone or combination therapy using an aminopenicillin or a third-generation cephalosporin with a macrolide (including doxycycline). Patients with chronic cardiac, pulmonary, renal, or hepatic disease, severe diabetics, chronic alcoholics, patients on immunosuppressive therapy, or patients with asplenia may require therapy with more than one agent.

Inpatients not admitted to the intensive care unit benefit from coverage for both atypical and common organisms. Often, monotherapy using a respiratory fluoroquinolone is an option, although single-agent therapy with a macrolide or doxycycline is avoided. An aminopenicillin/β-lactamase or cephalosporin in combination with a macrolide or with a respiratory fluoroquinolone is common.

Treat patients admitted to the intensive care unit with a combination of agents, including an aminopenicillin or cephalosporin with either a respiratory fluoroquinolone or a macrolide. Penicillin-allergic patients could be treated with a respiratory fluoroquinolone with either aztreonam or clindamycin. For patients at risk for *Pseudomonas* infection, add at least two agents active against the organism. This may include an antipseudomonal β-lactam such as piperacillin-tazobactam or cefepime with a respiratory fluoroquinolone. Alternatively, a carbapenem, such as imipenem, along with either a fluoroquinolone or aminoglycoside is appropriate. In penicillin-allergic patients, use a monobactam along with a fluoroquinolone. If the combination does not include two drugs with antipseudomonal activity, consider adding an aminoglycoside. Patients admitted to the intensive care unit with healthcare-associated pneumonia should have coverage for methicillin-resistant *S. aureus* with drugs such as vancomycin or linezolid.[22]

Emergency physicians play a prominent role in the initiation of treatment for patients being hospitalized with community-acquired pneumonia, although the effect of delays in care are debated.[16,23,24] The Joint Commission currently recommends starting antibiotics within 6 hours of diagnosis. Although it is reasonable to not delay therapy, there is no single best time frame to optimize outcomes without overuse.

DISPOSITION AND FOLLOW-UP

Most patients with community-acquired pneumonia do not require hospitalization.[25] In general, physicians tend to overestimate the risk of pneumonia mortality. **It is best to use an illness severity or prognostic tool to better aid care site decisions**.

The best-tested tool is the **Pneumonia Severity Index (PSI),** which estimates the risk of short-term death and intensive care unit need in those with community-acquired pneumonia.[25-27] With the Pneumonia Severity Index, patients are assigned to one of five risk categories (class I to V) based on points (starting with age, adjusted for sex) and bedside features; **the lowest risk patients (<50 years old with minimal x-ray and vital sign/concomitant condition threats) need no further testing;** all others have labs tested to better assess prognosis and organ function. Nonhypoxemic (room air saturation of 91% or higher) Pneumonia Severity Index class I to III patients have <4% mortality and are candidates for outpatient therapy. The Pneumonia Severity Index was not designed to determine prognosis in patients with severe HIV, patients with other forms of pneumonia (ventilator or hospital-acquired), or pregnant patients. Other factors, such as social situation or unusual medical conditions, play a role in the admission decision. Also, one profound derangement should drive care (e.g., blood pressure <60 mm Hg systolic or presence of coma), irrespective of the class assigned. A brief hospitalization or observation is an alternative for class III patients with mild hypoxemia, and class IV and V patients are usually treated as inpatients. A free online Pneumonia Severity Index calculator is available at http://pda.ahrq.gov/clinic/psi/psicalc.asp, and a version that can be downloaded to a hand-held computer is obtainable from http://pda.ahrq.gov/clinic/psi/psi.htm.

The **CURB-65 rule** looks at the presence of *c*onfusion, *u*remia >7 mmol/L, *r*espiratory rate ≥30 breaths/min, age ≥65 years old, or abnormal *b*lood pressure (systolic <90 mm Hg or diastolic <60 mm Hg), with 1 point assigned for each factor.[20] The CRB-65 uses the same variables but eliminates the uremia measurement. Patients with a CURB-65 or CRB-65 score of <2 have a low mortality rate and are candidates for outpatient therapy.

The Pneumonia Severity Index and CURB scoring systems *inform* but do not *determine* care location. Some patients are better served based on social or medical factors not assessed by these scores. Nonetheless, the validated scoring tools help safely increase the number of appropriate patients treated on an outpatient basis and to limit unnecessary admissions.[26] Absent a structured approach, admission decision patterns for patients with community-acquired pneumonia among emergency physicians can vary widely, often unrelated to disease severity and socioeconomic states.

Once the decision to admit the patient is made, the next decision is to determine which patients require admission to the intensive care unit. Patients in septic shock or those requiring mechanical ventilation will be placed in an intensive care unit setting. Other criteria for intensive care unit admission include a markedly elevated respiratory rate, a partial pressure of arterial oxygen/fraction of inspired oxygen ratio ≤250, multilobar infiltrates, confusion, uremia with a BUN >20 milligrams/dL, leukopenia, thrombocytopenia, hypothermia, hyponatremia, lactic acidosis, and asplenia. No single criterion will mandate intensive care unit admission; consider intensive care unit or intermediate-care admission for patients with three or more of the criteria in **Tables 65-10** through **65-12.** Those with a PSI class of V or a CURB-65 of ≥3 often require intensive care.[20,25]

Most patients will achieve some resolution within 3 to 5 days after the initiation of antibiotics. Many hospitalized patients can be switched to oral antibiotics at approximately 3 days and then subsequently discharged to complete a course of therapy. After ED or hospital discharge, contact within 3 to 5 days may help avoid a need for repeat care. However, up to half of patients are still symptomatic at 30 days,

TABLE 65-10 Step 1 of Pneumonia Severity Index (PSI)

Step 1: Assess initial factors
Age (if <50 y old, move on to next features; if ≥50 y, go to Step 2)
Comorbid conditions—ask about:
Neoplastic disease
Cerebrovascular disease
Congestive heart failure
Renal disease
Liver disease
Physical examination
No altered mental status
Pulse <125 beats/min
Respiratory rate <30 breaths/min
Systolic blood pressure >90 mm Hg
Temperature >35°C (95°F) or <40°C (104°F)

If all negative, then assign to risk class I (lowest risk); if over 50 y or *any* abnormality present, go on to Step 2 testing and classification in Table 65-11.

TABLE 65-11 Step 2 of Pneumonia Severity Index: Assignment to Risk Classes II to V

Criteria	Points Given
Demographics	
Age	Men: Age (in years)
	Women: Age (in years) – 10
Nursing home resident	10
Coexistent illness (same as Step 1)	
Neoplastic disease	30
Congestive heart failure	10
Cerebrovascular accident	10
Renal disease	10
Liver disease	20
Physical examination (same as Step 1)	
Abnormal mental status	20
Pulse ≥125 beats/min	10
Respiratory rate >30 breaths/min	20
Systolic blood pressure (<90 mm Hg)	20
Temperature <35°C (95°F) or >40°C (104°F)	15
Ancillary studies	
Arterial pH <7.35 (may assume normal if clinical condition suggests)	30
BUN ≥30 milligrams/dL (11 mmol/liter)	20
Na <130 mEq/L	20
Glucose >250 milligrams/dL (14 mmol/liter)	10
Hematocrit <30%	10
Pa_{O_2} <60 mm Hg or O_2 saturation on room air <91%	10
Pleural effusion	10
Summary points risk assignment	
Sum of points <70 = risk class II	
Sum of points 71–90 = risk class III	
Sum of points 91–130 = risk class IV	
Sum of points >130 = risk class V	

with a significant minority of patients experiencing chest pain, malaise, or mild dyspnea even 2 to 3 months after treatment. Educate patients about smoking cessation and moderation of alcohol use, and provide information about rest, nutrition, hydration, follow-up, and the importance of pneumococcal and influenza vaccination.

Finally, not all radiographic infiltrates result from an infection. Congestive heart failure may present a radiographic picture that overlaps with pneumonia, and pulmonary embolism can be associated with segmental or lobar densities. A variety of cancers may mimic pneumonia, best detected by CT scan or repeat radiographs after therapy. Eosinophilic or fungal diseases often have transient or recurring infiltrates. Finally, obtain an occupational history to identify patients with hypersensitivity disorders or chemical pneumonitis.

TABLE 65-12 Prediction of Mortality from Pneumonia

Class	Points	Mortality (%)	Treatment Recommendation
I	No predictors	0.1	Outpatient
II	<70	0.6	Outpatient
III	71–90	2.8	Individualized; nonhypoxemic may be candidate for home therapy
IV	91–130	8.2	Inpatient
V	>130	29.2	Inpatient (often intensive care unit)

ASPIRATION PNEUMONIA

DEFINITIONS AND EPIDEMIOLOGY

Aspiration pneumonia results from the swallowing of colonized oropharyngeal contents into the lower respiratory tract with subsequent inflammation and infection. Aspiration pneumonitis is from exposure of sterile gastric contents into the lower respiratory tract. This results in a rapid chemical pneumonitis due to irritation of the pulmonary tissues from the acidic material. Aspiration pneumonia—infection occurring from the exposure—is often unwitnessed, especially in the elderly. Other aspiration syndromes include drowning, solid foreign body aspiration with or without asphyxia, and lipoid pneumonia. Sterile pneumonitis and aspiration pneumonia are difficult to distinguish from one another, even with bronchial lavage. When certain, the treatment of aspiration pneumonitis is largely supportive.[28]

Aspiration of small amounts of oropharyngeal content is common. Approximately half of healthy adults aspirate small amounts oropharyngeal secretions during sleep.[28] Silent aspiration is more common in patients with community-acquired pneumonia. Aspiration occurred in 71% of patients with pneumonia compared to 10% of control subjects.[29] Approximately 5% to 15% of community-acquired pneumonia cases result from aspiration,[30-32] and 30% of those in continuing care facilities with pneumonia have aspiration pneumonia.[30,33] Mortality rates differ for aspiration based on location, with mortality higher in nursing home patients with aspiration pneumonia (28.2%) compared with those with community-acquired aspiration pneumonia (19.4%).[30,33] The incidence of aspiration pneumonia in those who aspirate with acute stroke or chronic degenerative neurologic conditions is higher than in patients without those conditions.[30]

Risks for aspiration pneumonia include conditions that promote oropharyngeal colonization with pathogenic bacteria or conditions that impair the swallowing or gag mechanism (**Table 65-13**). The incidence of aspiration is highest in patients with dementia or stroke. The risk of

TABLE 65-13 Risk Factors for Aspiration Pneumonia

Intoxicants
Alcohol and illicit drugs
Therapeutic drug overdose
Sedative drug use
Procedural sedation
General anesthesia
Neurologic
Stroke, especially brainstem involvement with dysphagia
Seizure
Head trauma
Chronic debilitating neurologic condition, especially dementia
Oropharyngeal
Impaired glottic functions
Emergent intubation
Periodontal disease and poor oral hygiene
GI
High gastric pressures: prior meal, bag-mask ventilation
Gastroesophageal reflux
Esophageal dysmotility or obstruction
Nasogastric, orogastric, percutaneous gastric tube
Tracheobronchial fistula
Other
Chronic supine position
Rapid sequence intubation
Advanced age
Chronic debility
Extension neck contractures

infection is compounded by poor oral care, which leads to oropharyngeal colonization of the oral cavity. Placement of nasogastric or gastric feeding tubes and the use of sedative and neuroleptic drugs also increase the risk of aspiration.[34-38] Aspiration pneumonia is the most common cause of death in gastric tube–fed patients.[39]

Although many patients have clinical evidence of aspiration, along with dysphagia, emesis, or coughing while eating, up to one third of those who aspirate have "silent aspiration" without evidence of cough or gagging. Small bowel obstruction, gastroesophageal reflux, esophageal dysmotility, esophageal obstruction, and tracheoesophageal fistula are GI risk factors for aspiration. Chronic degenerative neurologic conditions such as Parkinson's disease, myasthenia gravis, amyotrophic lateral sclerosis, acute stroke, encephalopathy, seizures, and alteration of consciousness increase the risk of aspiration.

PATHOPHYSIOLOGY

The development of pneumonitis depends on the volume and pH of the aspirate, with consensus that gastric contents with pH <2.5 and an aspirated volume of 0.3 to 0.4 mL/kg (20 to 30 mL in adults) are required to develop aspiration pneumonitis.[32] The injury produced by acid aspiration is initially a direct caustic effect followed by an inflammatory response that peaks in 4 to 6 hours. Proinflammatory cytokines increase capillary permeability and cause fluid and inflammatory cells to enter the area of irritation. These reactions may manifest clinically as cough, pleuritic chest pain, fever, and radiographic findings. Aspiration of solid or viscous material blocking the airway may result in precipitous asphyxiation.

Typical bacterial species involved in aspiration pneumonia include *S. pneumoniae, S. aureus, H. influenzae*, and Enterobacteriaceae in community-acquired aspiration pneumonia.[32] Common bacterial species in hospital-acquired aspiration pneumonia include *P. aeruginosa* and gram-negative organisms.[32] Antibiotic therapy for typical aspiration syndromes should include coverage for anaerobic organisms.[40,41]

The posterior portions of the upper lobes and the upper portions of the lower lobes are most commonly involved in recumbent aspiration. In upright patients, the most dependent portions of the lungs are the basal segments of the lower lobes. The inflammatory injury may include bilateral patchy, interstitial or alveolar infiltrates, particularly in aspiration of large volumes seen with near drowning.[42]

CLINICAL FEATURES

Witnessed aspiration is a key feature in the diagnosis of aspiration pneumonitis or pneumonia. Typically those with noninfectious aspiration are younger, and the aspiration is witnessed. These patients will present giving a history of aspiration and coughing immediately afterward. "Silent aspirators" are typically older and have a chronic neurologic disorder and will present with a cough or fever or general malaise. Silent aspirators are more likely to be from a chronic care facility and have a history of prior pneumonia episodes. Historical features that suggest silent aspiration include general debility, recurrent cough, hoarseness, or dysphagia. History may be difficult to obtain in chronically debilitated or otherwise noncommunicative patients.

The clinical symptoms of aspiration pneumonia include fever, dyspnea, and productive cough. Other symptoms of systemic infection in the elderly and debilitated may be present, including a change in mental status, lethargy, and nausea or vomiting.[43] The physical examination may reveal signs classic for pneumonia, including tachycardia, tachypnea, fever, rales, or decreased breath sounds in an ill-appearing patient. Patients with underlying pulmonary disease may decompensate rapidly and have more symptoms and signs of respiratory distress.

DIAGNOSIS

Chest radiographs in aspiration pneumonia usually show unilateral focal or patchy consolidations in the dependent lung segments (**Figure 65-4**). Occasionally, a bilateral or interstitial pattern can be seen. The right lower lobe is the most common area of consolidation if the aspiration occurs when the patient is upright.

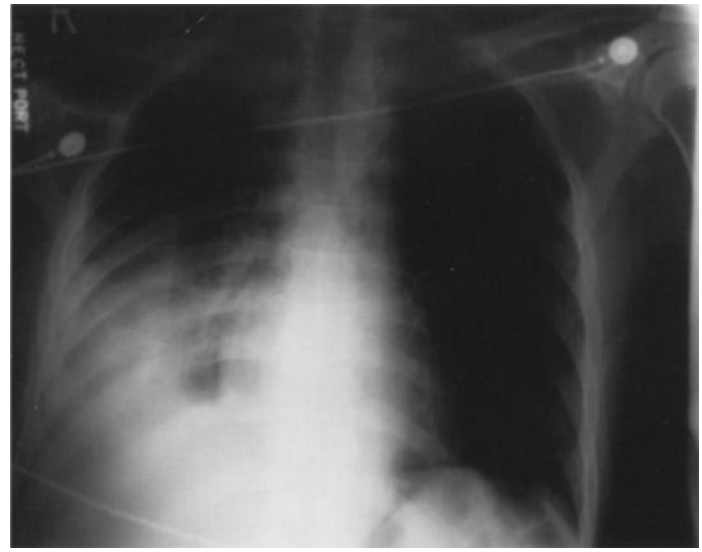

FIGURE 65-4. Aspiration pneumonia of the right lower lobe.

Early in the course, the white blood cell count may not be elevated. Arterial blood gases to identify hypoxemia or hypoventilation aid care and are best compared to previous values if chronic lung disease exists.

TREATMENT

Aspiration of large volumes of solid material, foods, nonfood objects, or very tenacious liquids may require suctioning of the tracheobronchial tree or bronchoalveolar lavage to clear the airway. Bronchodilators aid aspiration-induced bronchospasm.

Choice of antibiotics depends on the circumstances of the aspiration and the suspected bacterial etiology of the infection (**Table 65-14**).[32,44,45] Most patients with aspiration pneumonia are infected by gram-negative organisms and require broad-spectrum antibiotics, such as third-generation cephalosporins, fluoroquinolones, piperacillin-tazobactam, or carbapenems.[28] When methicillin-resistant *S. aureus* is suspected, consider the addition of vancomycin or linezolid.[28] In community-acquired aspiration pneumonia where the usual organisms are *S. aureus, S. pneumoniae,* and *H. influenzae*, levofloxacin and ceftriaxone are recommended.[46] Patients with severe periodontal disease, putrid sputum, or lung abscess require anaerobic coverage, such as piperacillin-tazobactam or imipenem or a combination of two drugs (levofloxacin, ciprofloxacin, or ceftriaxone plus clindamycin or metronidazole).[46]

TABLE 65-14 Initial Treatment for Presumed Aspiration Pneumonia

Acquisition Site	Empiric Therapy	Empiric Therapy for Penicillin Allergy
Community acquired	Ampicillin/sublactam *or* Amoxicillin/clavulanate *or* Levofloxacin *or* Moxifloxacin	Clindamycin
Hospital acquired or Severe periodontal disease, putrid sputum or alcoholism	Pipracillin-tazobactam +/– Vancomycin +/– gentamicin *or* Cefepime or ceftazidime *plus* Clindamycin or metronidazole *or* Levofloxacin + clindamycin	Ciprofloxacin + vancomycin

TABLE 65-15 Noninfectious Causes of Pulmonary Infiltrates

Disease	Pathophysiology	Chest Radiography Findings	Symptoms
Congestive heart failure	As pulmonary capillary hydrostatic pressure rises, fluid crosses into the interstitium. When the capacity of lymphatic drainage is exceeded, fluid accumulates in the interstitium and eventually collects in the alveoli.	With increasing atrial pressures, chest x-ray reveals cephalization, Kerley B lines (thickening of the interlobular septa), interstitial edema, thickening of fissures, and, ultimately, alveolar edema and pleural effusions.	See chapter 53, Acute Heart Failure.
Pulmonary embolism	Pulmonary artery occlusion, typically at multiple sites, with its secondary effects, including infarction.	Chest x-ray nonspecific or normal: cardiac enlargement (27%), normal (24%), pleural effusion (23%), elevated hemidiaphragm (20%).	See chapter 56, "Venous Thromboembolism."
Aspiration pneumonitis	After aspiration of gastric contents, an intense inflammatory reaction occurs; biphasic pattern, at 1–2 h, caustic effect of low pH of the aspirate on alveolar cells; at 4–6 h, infiltration of neutrophils into the alveoli and lung interstitium.	Alveolar infiltrates in the posterior segments of the upper lobes if aspiration occurs while the patient is in the supine position; infiltrates in the basal segments of the lower lobes if aspiration occurs while the patient is upright.	See "Aspiration Pneumonia" section earlier in this chapter.
Allergic bronchopulmonary aspergillosis	Allergic lung reaction to *Aspergillus fumigatus* that occurs most commonly in patients with asthma or cystic fibrosis. Eosinophils fill small airways and alveolar spaces due to inflammation. Bronchiectasis.	Branching band-like opacities may be seen, or may see alveolar infiltrates, peripheral and migratory.	Dyspnea, wheezing, productive cough; may have hemoptysis and occasionally fever.
Eosinophilic lung disease; chronic (Löffler's syndrome) and acute forms exist	The acute form leads to rapidly progressive respiratory failure. This is a reaction to the presence of infection, such as ascariasis, or in association with chronic conditions, such as asthma or atopic disease. Eosinophils accumulate in distal airways and alveolar and interstitial spaces.	Alveolar and interstitial infiltrates; classically, these are peripheral, but findings are proximal in equal numbers.	Mild or severe symptoms; dyspnea, fever, cough, and wheezing. In acute forms, hypoxia and potential for progression to respiratory failure.
Hypersensitivity pneumonitis (also called extrinsic allergic alveolitis)	Inflammation of the alveoli secondary to hypersensitivity in response to inhaled organic dust.	Diffuse micronodular interstitial infiltrates, may see ground-glass densities in the lower or mid-lung fields.	Fever, chills, malaise, cough, chest tightness, dyspnea, and headache.
Acute interstitial pneumonitis	Idiopathic.	Bilateral interstitial infiltrates, sometimes patchy alveolar densities and ground-glass appearance.	Progressive dyspnea over days to weeks.
Acute respiratory distress syndrome	Reaction of the lung to a number of precipitating causes, including sepsis, trauma, surgeries, transfusions, and therapeutically induced immunosuppression.	Classically, patchy peripheral infiltrates that extend to the lateral lung margins suggest the diagnosis.	Hypoxia, tachypnea, rales.
Drug-induced pneumonitis	Causes include chemotherapeutic, immunosuppressive, antimicrobial, and herbal agents.	Typically, bilateral interstitial infiltrates.	Cough, mild fever, dyspnea, and, potentially, hypoxia.
Sarcoidosis	Systemic granulomatous disease of unknown etiology.	Hilar lymph node enlargement and/or diffuse parenchymal interstitial pulmonary infiltrates. Occasionally may be peripheral.	Dyspnea, cough, weight loss; skin lesions may also be found. May be asymptomatic.
Bronchiolitis obliterans with organizing pneumonia	Inflammation of the bronchioles and surrounding tissues, leading to loss of the integrity of the bronchioles and organizing pneumonia without infection. Occurs in association with immunocompromise and connective tissue diseases, such as SLE.	Patchy alveolar infiltrates and, occasionally, cavitation.	Cough, dyspnea, fever.
Wegener's granulomatosis (granulomatosis with polyangiitis)	Inflammatory and granulomatosis disease involving the blood vessels of unknown etiology. The upper respiratory tract, lung parenchyma, and kidneys are typically affected.	Alveolar infiltrates, nodules, or cavities.	Cough and dyspnea; may see epistaxis and sinusitis.
Goodpasture's syndrome (antiglomerular basement antibody disease)	Autoimmune disease affecting the lungs and kidney.	Diffuse, bilateral, predominately alveolar densities.	Fatigue, dyspnea, cough with hemoptysis; may have simultaneous hematuria.
Churg-Strauss vasculitis (eosinophilic granulomatosis with polyangiitis)	Systemic vasculitis of unknown cause primarily affecting the lung and may eventually involve the skin, nervous system, kidney, GI tract, and heart.	Bilateral peripheral, patchy, alveolar infiltrates. May see nodules.	Cough, dyspnea, allergic rhinitis, may see symptoms related to skin, coronary, or intestinal involvement.
Radiation pneumonitis	Interstitial pulmonary inflammation seen in 5%–15% of patients with thoracic radiation treatment.	Subtle hazy ground-glass densities to marked patchy infiltrates or homogenous consolidation. Air bronchograms are commonly present.	Symptoms occur 1–6 mo after treatment: low-grade fever, cough, fullness in the chest.

(*Continued*)

TABLE 65-15 Noninfectious Causes of Pulmonary Infiltrates (*Continued*)

Disease	Pathophysiology	Chest Radiography Findings	Symptoms
Chemical pneumonitis	Inflammatory reaction to the presence of foreign substance, such as barium, petroleum distillates, pesticide, or irritating gases.	Diffuse, alveolar, and interstitial infiltrates.	History of exposure or aspiration of substance; acute dyspnea, cough, and, possibly, wheezing.
Alveolar cell carcinoma, often called bronchiolar carcinoma	Malignant pulmonary cancer originating in a bronchiole and spreading across the alveolar walls.	Classically, a butterfly distribution of alveolar infiltrates, but may be unilateral.	Often severe coughing, dyspnea, and copious sputum production.
Bronchoalveolar cell carcinoma	Adenocarcinoma that typically originates in the lung periphery and grows along alveolar walls.	Peripheral alveolar infiltrates that do not respond to antibiotics; may see a peripheral nodule or mass.	Symptoms like pneumonia but fails to respond to antibiotics. May lack fever or leukocytosis.
Fat emboli	ED presentations are typically after trauma, associated with long-bone fracture.	Interstitial prominence, suggesting interstitial edema. Radiographic findings may be delayed 1–2 d after trauma.	Dyspnea, cough, hemoptysis, and pleural pain. May be associated with confusion, stupor, delirium, and a petechial skin rash, most commonly on the chest.
Alveolar hemorrhage	In the setting of chemotherapy induction for leukemia and thrombocytopenia (<20,000/mL), hemorrhage filling alveoli is common from endobrachial and interstitial sources. Also seen with SLE.	Focal or diffuse alveolar infiltrates.	Dyspnea, hemoptysis; symptoms are frequently less severe than radiographic appearance would predict.
Leukemic infiltrates	Most common in myeloid leukemia when peripheral blast cell counts exceed 100,000/mL. Primitive myeloid leukemic cells invade through the endothelium of the lung capillary beds, yielding hemorrhage.	Interstitial or alveolar infiltrates. Diffuse infiltrates associated with hypoxia and need for intubation; focal infiltrates associated with coexistent pneumonia.	Respiratory distress, hypoxemia, and may progress to respiratory failure.

Abbreviation: SLE = systemic lupus erythematosus.

DISPOSITION

Healthy persons who aspirate small volumes of nontoxic material may be observed and, if stable and reliable, discharged to return for worsening symptoms. Antibiotic treatment is generally not needed for witnessed aspiration of a small amount of nontoxic liquid provided the patient's symptoms (cough, low-grade fever) resolve within 24 to 48 hours.[28] Patients should be able to identify worsening symptoms and have the ability to follow up if symptoms worsen.

Stable patients at risk for worsening (e.g., diabetes, advanced age, renal dialysis, recent stroke, chronic pulmonary disease, active cancer and HIV) are usually admitted to the hospital or an observation unit. Start antibiotics in the ED in those who have definite evidence of infection. Deliver supplemental oxygen as needed, and treat cardiopulmonary compromise. Noninvasive positive-pressure ventilation and endotracheal intubation are options if gas exchange is impaired (see chapters 28 "Noninvasive Airway Management" and 29 "Intubation and Mechanical Ventilation"). Admit all unstable patients to an intensive care unit.

NONINFECTIOUS PULMONARY INFILTRATES

Commonly, a noninfectious cause is suspected by the appearance of the chest radiograph or after antibiotics fail to improve the patient's symptoms. Noninfectious infiltrates occur in response to a wide variety of pathophysiologic processes involving the respiratory, cardiovascular, and immune systems or may be due to the infiltration of malignant cells.

CLINICAL FEATURES

The most important symptom of noninfectious pulmonary infiltrates is dyspnea, but some disorders present with hemoptysis, cough, chest pain, or fatigue. Fever can also be a symptom of autoimmune disease exacerbation; however, it may be impossible to clinically differentiate a noninfectious source from an infectious source of fever in the ED.

Table 65-15 lists the most common causes of noninfectious pulmonary infiltrates, their pathophysiology, chest radiograph findings, and symptoms.[45,47-52] Typical radiographic appearances help to prioritize the differential diagnosis. An interstitial infiltrate is classically described as fine, diffuse, linear density representing fluid or the accumulation of cells in the interstitial spaces. An alveolar infiltrate is a small ill-defined or reticular density representing fluid or abnormal cells in the alveoli. A ground-glass appearance is defined as multiple finely granular densities. Table 65-15 lists diseases that produce acute radiographic change, not diseases that produce chronic densities, such as fibrosis or scarring.

Patients with connective tissue diseases or on immunosuppression are at risk for bronchiolitis obliterans, organizing pneumonia, pneumonitis, and alveolar hemorrhage, often from therapy. Patients with atopic disease or asthma are at risk for eosinophilic lung disease.

DIAGNOSIS

Assess critically ill patients with CBC, renal function assessment, electrolytes, chest radiograph, and liver function tests, and add specimen cultures to look for complications of the acute disease process rather than establishing a new disease diagnosis. Newer high-sensitivity procalcitonin assays help differentiate infection from an exacerbation of a systemic inflammatory condition (very low values suggest a nonbacterial cause).[53] In many patients, an infectious cause of pulmonary infiltration cannot be excluded until bronchoscopy or lung biopsy. Therefore, the diagnostic plan can rarely be completed in the ED.

TREATMENT

Assess gas exchange with pulse oximetry in all, and use selective arterial blood gas analysis in those ill, hypoxemic, or with underlying chronic lung disease; use noninvasive or mechanical ventilation as needed. Prepare for possible subglottic stenosis with difficult airway equipment in patients with systemic inflammatory disease.[52] Broad-spectrum antibiotics, such as piperacillin-tazobactam (3.375 to 4.5 grams IV) and vancomycin (1 gram IV), or similar coverage, are recommended for critically ill patients with pneumonia and systemic inflammatory disease or immunocompromise.[48] Definitive treatment for noninfectious pulmonary diseases will occur after ED stabilization. Many of the disorders listed in Table 65-15 are treated acutely with corticosteroids such as methylprednisolone (0.5 to 1 gram IV).[52] Additional immunosuppressive drugs may be initiated by the admitting physician.

DISPOSITION AND FOLLOW-UP

Patients suspected of having a noninfectious cause of pulmonary infiltrate require testing beyond the capabilities of the ED. Hospitalization should be based on the severity of the medical illness, with attention to hypoxemia, hypercapnia, and work of breathing. In stable patients with mild symptoms, outpatient referral to a pulmonologist or another specialist is best.

PRACTICE GUIDELINES

Guidelines concerning the management of community-acquired pneumonia[16] and healthcare-associated pneumonia[4] are undergoing revision, but will be available online at the following address: http://www.thoracic.org/professionals/clinical-resources/disease-related-resources/pneumonia.php.

CHAPTER 66

Lung Empyema and Abscess

Eric Anderson
Sharon E. Mace

EMPYEMA

INTRODUCTION AND EPIDEMIOLOGY

Empyema is a pleural space infection with pus, a positive Gram stain or culture, or parapneumonic effusions without pleural fluid sampling. Causes of empyema include pulmonary infections, most commonly bacterial pneumonia (56%), complications of chest surgery (22%), trauma (4%), esophageal perforation (4%), complications of chest tube/thoracentesis (4%), an extension from a subdiaphramatic infection (3%), and other causes (7%), such as osteomyelitis or other near pleural infections or a hemothorax, chylothorax, or hydrothorax that becomes infected.[1]

Predisposing factors for empyema include aspiration pneumonia (and the conditions causing this event, notably neurologic disease altering swallowing), respiratory disease impairing ciliary function, immunocompromise, malignancy, and alcoholism. The common organisms in empyema stratified by associated pathology are listed in **Table 66-1**.[1]

CLINICAL FEATURES

Suspect empyema if symptoms of pneumonia (fever, cough, dyspnea, pleuritic chest pain, and malaise) do not resolve. The onset of empyema may be insidious, with patients appearing chronically ill with weight loss, anemia, and night sweats.

Physical examination findings include decreased breath sounds, dullness to percussion, decreased tactile fremitus, and on occasion a friction rub. Pain from an underlying effusion or empyema may cause splinting with respiration. If there is an underlying pulmonary infection, rales or rhonchi may be heard.

TABLE 66-1 Common Organisms in Empyema and Associated Pathology

Pathology	Organisms
Pneumonia	*Streptococcus pneumonia* *Staphylococcus aureus*
Pneumonia (unimmunized with *Haemophilus influenza* type B vaccine)	*Haemophilus influenza*
Lung abscess	Mixed oropharyngeal anaerobes
Aspiration pneumonia	*S. aureus*
Recent thoracotomy	Gram-negative bacilli
Pneumonia in the setting of human immunodeficiency virus	Tuberculosis Fungal infections
Chest trauma	*S. aureus* Gram-negative bacilli
Contiguous abdominal infection	Gram-negative bacilli Anaerobes
Esophageal rupture	Mixed oropharyngeal organisms

DIAGNOSIS

Diagnostic criteria for empyema are aspiration of grossly purulent material on thoracentesis and at least one of the following: thoracentesis fluid with a positive Gram stain or culture, pleural fluid glucose <40 milligrams/dL, pH <7.1, or lactate dehydrogenase >1000 IU/L. In countries where tuberculosis is a common cause of exudative effusions, the negative predictive value of adenosine deaminase is 99.9% and can exclude the disease.[2-4]

Empyema has three stages that impact treatment:

1. Exudative (may be very short, <48 hours; the free-flowing pleural effusion that is present is amenable to chest tube drainage)
2. Fibrinopurulent (fibrin strands form in the pleural fluid causing loculations; resolution of the empyema with single chest tube drainage is unlikely)
3. Organizational (takes several weeks; more extensive fibrosis; "pleural peel" restricts lung expansion)

TREATMENT

Treat any trigger, especially pneumonia or heart failure. Nonsteroidal anti-inflammatory drugs or opioids can aid the pleuritic pain. Thoracentesis can aid in therapy in a patient with respiratory or cardiac distress and can be used as symptomatic treatment in patients with dyspnea. The definitive treatment of an empyema is drainage and antibiotics.[1]

Initial antibiotic therapy for empyema targets the presumptive underlying pneumonia, lung abscess, or bronchiectasis. Recommended therapy includes piperacillin-tazobactam 3.375 to 4.5 grams every 6 hours IV or imipenem 0.5 to 1.0 gram IV every 6 hours. Add vancomycin for methicillin-resistant *Staphylococcus aureus* in those at risk. Those at risk for methicillin-resistant *S. aureus* include patients recently hospitalized, patients who have an invasive medical device, and patients residing in a long-term care facility. Those at risk of community-acquired methicillin-resistant *S. aureus* include participants in contact sports, those who live in crowded or unsanitary conditions, and men who have sex with men. Tailor antibiotics once culture results are available and the clinical course is apparent.[1]

Treat exudative empyema with chest tube thoracostomy in addition to antibiotics.[5] Consider intrapleural fibrinolytic agents for empyema in the fibropurulent stage in consultation with a thoracic surgeon or pulmonologist. Streptokinase, urokinase, and more recently, deoxyribonuclease (either streptococcal deoxyribonuclease or human recombinant deoxyribonuclease) and alteplase all have some reported success.[5,6] The decrease in the percentage of hemothorax occupied by pleural fluid is significantly greater for tissue plasminogen activator plus deoxyribonuclease (29.7%) versus tissue plasminogen activator alone (15.1%), saline (17%), or deoxyribonuclease alone (17.1%).[7] Video-assisted thoracoscopic surgery is useful in the treatment of loculated empyemas.[5] Surgical removal of the fibrous peel is required to treat empyema in the organizational stage.

LUNG ABSCESS

INTRODUCTION AND EPIDEMIOLOGY

Lung abscess is defined as a localized necrosis of the lung parenchyma, typically caused by suppurative microbial infection. This initial infection is usually caused by aspiration of oral contents. Lung abscess may also develop as a result of hematogenous spread of infectious material to the lung parenchyma or lung infarct. Other less common causes of pulmonary abscess include infection as a result of penetrating chest trauma, fungal and parasitic infections, primary and metastatic neoplasms, and inflammatory conditions such as Wegener's granulomatosis and sarcoidosis.

Primary lung abscess occurs in individuals in good health or in those prone to aspiration. Approximately 80% of lung abscesses are primary.[1] The in-hospital mortality rate is 10% to 15%. Secondary lung abscess is associated with malignancy, immunosuppression, extrapulmonary infection or sepsis, or complication of surgery; the mortality is higher than seen in primary lung abscess, often over 50%. Lung abscesses present for less than 1 month are acute, with the rest being considered chronic.[1]

The incidence of lung abscess and short-term mortality have both declined over the last four decades, presumably secondary to improved treatment regimens for pneumonia. The mortality rate for community-acquired (anaerobic) lung abscess is considerably lower than that of hospital-acquired (aerobic) lung abscess.

PATHOPHYSIOLOGY

Lung abscess typically is caused by a breakdown or overwhelming of the usual pulmonary defense mechanisms. This allows a parenchymal infection to evolve into an abscess. It takes approximately 7 to 14 days for aspiration pneumonia to develop into an abscess. Anaerobic bacteria are the most common isolates from lung abscess in immunocompetent patients.[8] Generally, both aerobic and anaerobic bacteria cause lung abscess, but anaerobes are more common.[1,9] Aerobic bacteria are found more commonly in lung abscesses in immunocompromised patients and include *S. aureus, Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Streptococcus pyogenes, Burkholderia pseudomallei, Haemophilus influenzae, Legionella pneumophila, Nocardia asteroides, Actinomyces* species, and rarely pneumococci. Aerobic infections are often hospital-acquired and have a higher mortality rate; anaerobic infections usually are community-acquired and associated with aspiration. Typical anaerobic lung abscess pathogens are pigmented *Prevotella*, *Porphyromonas*, *Bacteroides*, *Fusobacterium*, and *Peptostreptococcus* species.

Aspiration predisposes patients to developing pneumonia and lung abscesses. Conditions increasing the frequency of aspiration are chronic alcoholism, chronic debility with extension neck contractures, chronically depressed mental status, poor dentition and gingival disease, therapeutic or recreational drug overdose, and gastric and jejunostomy tubes. These risk factors are covered in more detail in the chapter on aspiration pneumonia.

Lung abscesses caused by hematogenous spread tend to be multilobar; risk factors include IV drug use, endocarditis, and tricuspid valve endocarditis. Jugular vein suppurative thrombophlebitis (Lemierre's syndrome) is a complication of tonsillitis that can spread to the lungs with *Fusobacterium necrophorum* bacterial seeding.[10,11]

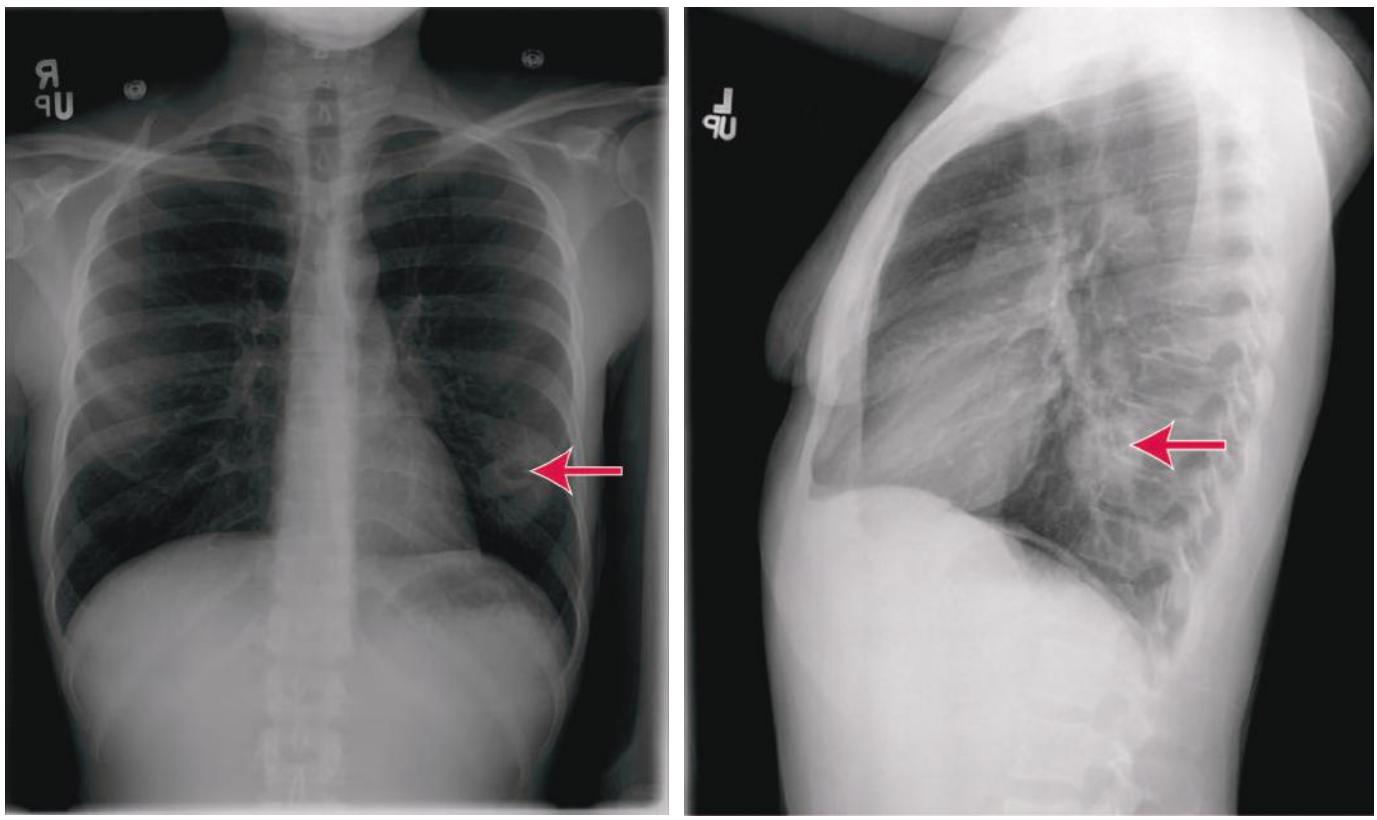
Lung abscesses typically occur in the basal segments of the lower lobes or the posterior segment of the upper lobes. When abscesses occur in the anterior lung, a neoplasm often underpins the infection. Cancer is associated with 8% to 18% of all lung abscesses; this rate increases to 30% in those older than 45 years.

CLINICAL FEATURES

Patients with lung abscess classically present with an indolent course of cough, fever, pleuritic chest pain, weight loss, and night sweats, often for 2 or more weeks. There may be cough productive of putrid sputum that layers out when allowed to stand. Hemoptysis occurs in up to 25% of cases. Because the infection is more indolent, tachycardia, tachypnea, and fever are often absent. Laboratory findings usually are nonspecific but commonly include an elevated WBC count and erythrocyte sedimentation rate.

DIAGNOSIS

The diagnosis is usually made by a chest radiograph showing an area of dense consolidation with an air-fluid level inside of a cavitary lesion, indicating that the abscess cavity communicated with a bronchiole. Bronchiole communication occurs in about three fourths of patients with lung abscesses (**Figure 66-1**). In the remaining quarter of patients, chest CT detects the cavitary lesion (**Figure 66-2**). Multiple abscesses are unusual but can be seen in septic emboli or Lemierre's syndrome (streptococcal sepsis from peritonsillar abscess).[10]



A B

FIGURE 66-1. Posteroanterior and lateral chest x-ray. **A.** Chest radiograph demonstrating air-fluid level of abscess cavity at arrow. **B.** Lateral chest radiograph showing air-fluid level of abscess cavity at *arrow*.

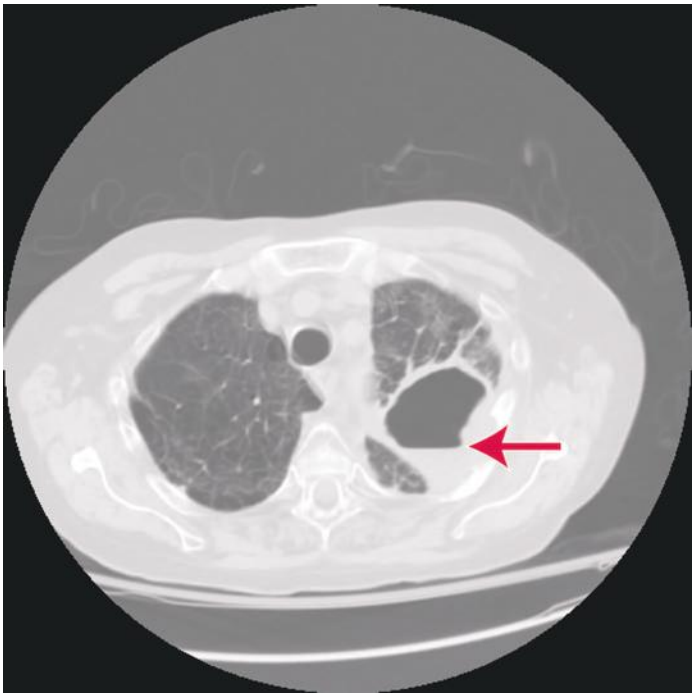


FIGURE 66-2. CT of the chest, demonstrating air-fluid level of abscess cavity at *arrow*.

The differential diagnosis of cavitary lesions includes infected bullae, pleural fluid collection with bronchopleural fistula, and loop of bowel extending through a diaphragmatic hernia. Infected bullae have thin walls. Pleural fluid collection with bronchopleural fistula will demonstrate an air-fluid level that extends to the chest wall and tapers at the apex. A loop of bowel extending through a diaphragmatic hernia may result in nausea, vomiting, and abdominal pain due to incarceration or audible bowel sounds in the chest on the side on the hernia (**Figure 66-3**). **Table 66-2** lists different causes of cavitary lung lesions.

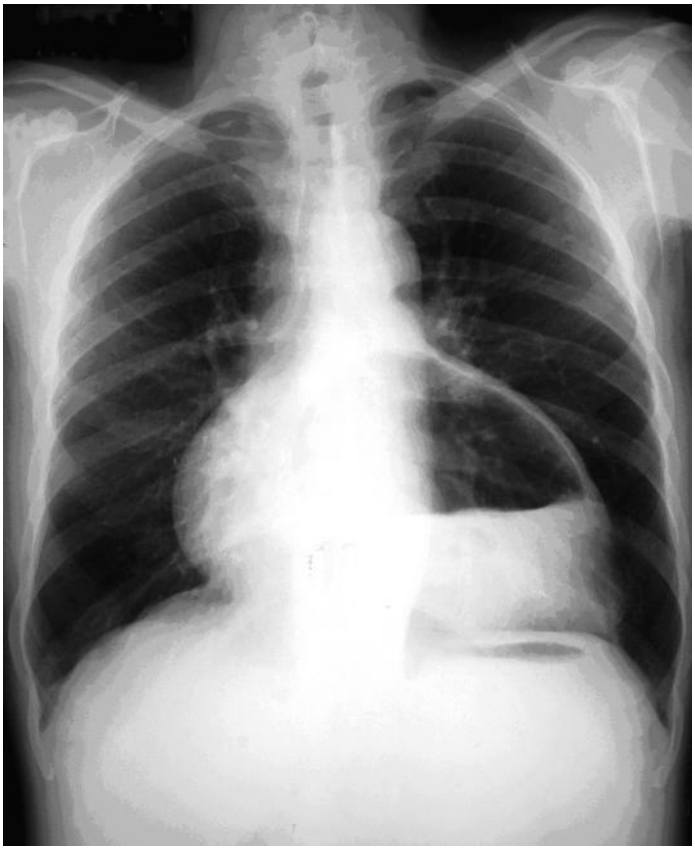

FIGURE 66-3. Hiatal hernia mimicking the appearance of cavity lesion.

TABLE 66-2 Cavitary Lung Lesions

Infectious	
Bacterial	Anaerobic abscess (immunocompetent)
	Aerobic abscess (immunocompromised)
	Infected bullae
	Tuberculosis
	Actinomycosis
	Pleural empyema
Fungal	Coccidioidomycosis
	Histoplasmosis
	Blastomycosis
	Aspergillosis
	Cryptococcus
Parasitic	Echinococcosis
	Amebiasis
Neoplastic	Bronchogenic carcinoma (squamous cell or adenocarcinoma)
	Metastatic cancer (colorectal or renal)
	Lymphoma or Hodgkin's disease
Inflammatory	Wegener's granulomatosis
	Sarcoidosis

TREATMENT

Medical management will resolve most lung abscesses. Initial treatment consists of clindamycin, 600 milligrams IV every 8 hours, or ampicillin-sulbactam, 1.5 to 3.0 grams IV every 6 hours, for those who cannot take clindamycin.[1,11] Alternative treatments include piperacillin-tazobactam, 3.375 grams IV every 6 hours, or meropenem or doripenem. Methicillin-resistant *S. aureus* infections are treated with linezolid, 600 milligrams IV every 12 hours, or vancomycin, 15 milligrams/kg IV every 12 hours (target trough level 15 to 20 μg/mL).[12]

Drainage usually occurs spontaneously from communication of the abscess cavity with the tracheobronchial tree. This is signaled by the development of an air-fluid level on the chest radiograph. Reasons for poor outcomes include aerobic infection, large abscess cavity, advanced age, debilitation, immunosuppression, malignancy, malnutrition, and sepsis. Reasons for failure of medical treatment include bronchial obstruction, nonbacterial cause of abscess, large cavity size, and concomitant empyema.

Surgical treatments for a nondraining lung abscess include image-guided percutaneous drainage or thoracotomy with pulmonary resection.

DISPOSITION

Admit patients with new lung abscess; hospitalization usually lasts several weeks. After resolution of symptoms, patients can be discharged on oral antibiotics for 4 to 8 weeks. Chest radiographic findings will lag behind clinical progress and will take more than 2 months to resolve.

COMPLICATIONS

Complications of lung abscess include empyema, massive hemoptysis, contamination of the uninvolved lung, and failure of the abscess cavity to resolve. Approximately 10% of bacterial lung abscesses require surgical intervention.[13]

CHAPTER 67

Tuberculosis

Vu D. Phan
Janet M. Poponick

INTRODUCTION AND EPIDEMIOLOGY

Tuberculosis remains an important worldwide infection, with more than one third of the overall population harboring the bacterium. It is the second leading cause of death among infectious diseases and a major cause of death among those with human immunodeficiency disease (HIV), especially in countries with limited resources.[1,2] Despite therapeutic progress over the past 20 years, drug resistance and HIV coinfection continue to challenge the global control of tuberculosis.[2]

Tuberculosis has been on the decline in the United States, with an average 3.8% decrease each year from 2000 to 2010.[3] This reduction is primarily due to tuberculosis control programs targeting high-risk individuals. In addition, improved infection control policies, increased vigilance among physicians, implementation of directly observed therapy, and standardized drug regimens all contributed to the decline of tuberculosis rates. Although overall national cases have decreased, the incidence in foreign-born patients remains 12 times that of U.S.-born persons.[3] In foreign-born patients, clinical tuberculosis is usually from reactivation of latent disease. Overall, reactivation of latent tuberculosis is responsible for 70% of active tuberculosis cases.[4]

Continued improvement in tuberculosis control and prevention requires recognition and treatment of high-risk populations (**Table 67-1**). Screening and treatment of latent infection in high-risk individuals are key to reducing tuberculosis in the United States.[4]

PATHOPHYSIOLOGY

Mycobacterium tuberculosis is a slow-growing aerobic rod that has a multilayered cell wall containing lipids that account for its acid-fast staining property. Because the organism is an obligate aerobe, it settles in areas of high oxygen content and blood flow. Transmission from person to person occurs through inhalation of droplet nuclei into the lungs. Persons with active tuberculosis who excrete mycobacteria in saliva or sputum are the most infectious.[5] Only 30% of patients actually become infected after a droplet exposure.[6]

PRIMARY AND LATENT INFECTION

Once the organisms reach the lungs, host defenses are activated. Some organisms survive and are transported to the regional lymph nodes, where the host cell-mediated immunity is activated to contain the infection. Granulomas, known as *tubercles*, form as a result of this process, which involves activated macrophages and T lymphocytes in addition to active bacteria in most cases. Tubercles are a sign of primary infection and may progress to caseation necrosis and calcification. In the lung, the **Ghon complex** (**Figure 67-1**) is a manifestation, appearing as calcified hilar lymph nodes.

If the tubercle fails to contain the infection, the mycobacteria may spread by hematogenous, lymphatic, or direct mechanical routes. The tendency is for survival in areas of high oxygen content or blood flow, such as the apical and posterior segments of the upper lobe and the superior segment of the lower lobe of the lung, the renal cortex, the meninges, the epiphyses of long bones, and the vertebrae. In these areas, the mycobacteria can remain dormant for years. During dormancy (or latent infection), the disease is detected by a positive tuberculin skin test. **The skin test generally becomes positive 1 to 2 months after initial exposure.** Only 1% to 13% of otherwise healthy patients will go on to develop active postprimary disease. However, children and HIV patients have a higher risk, approaching a 20% frequency of postprimary infection.[5,7]

TABLE 67-1 Patients with a High Prevalence of Tuberculosis (Highest to Lowest Risk)

Immigrants from high-prevalence countries
Patients with the human immunodeficiency virus
Residents and staff of prisons or shelters for the homeless
Alcoholics and illicit drug users
Elderly and nursing home patients

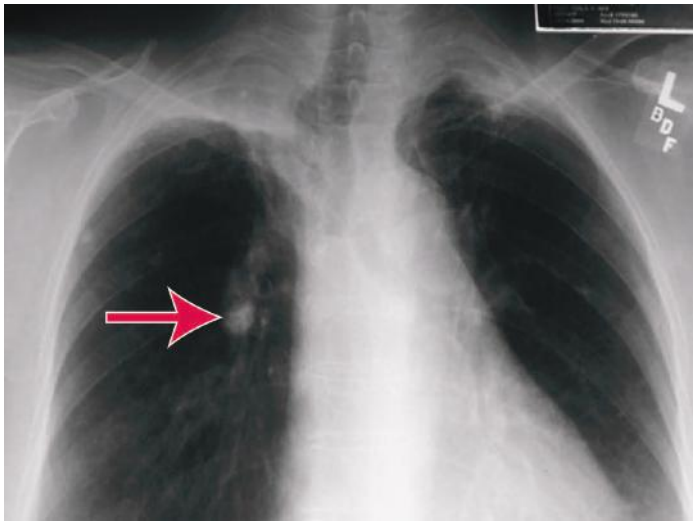

FIGURE 67-1. Primary Ghon complex (*arrow*).

REACTIVATION TUBERCULOSIS

Whether latent infection progresses to recurrently active (or "reactivation") tuberculosis is dependent on the immune status of the host.[5,6] As the host defense system weakens, it is no longer capable of containing the foci of previous hematogenous spread, and active tuberculosis may develop. The risk for reactivation is higher among HIV-infected persons and those more than 50 years old.[6] In 5% of persons, latent infection may progress to active disease within 2 years after initial exposure, with another 5% developing disease later in life.[5,7] In immunocompromised hosts, spread often occurs rapidly, and progression of early active disease is more frequent. HIV-infected patients are at particularly high risk, with progression reported at 7% to 10% per year.[5] Other groups at risk for developing tuberculosis activation include those immunocompromised from carcinoma of solid organs, leukemia, transplantation, or medications such as antagonists of tumor necrosis factor-α (etanercept or infliximab) or corticosteroids. Those with select chronic diseases such as diabetes, chronic renal failure requiring hemodialysis, psoriasis, and silicosis are also at increased risk for tuberculosis activation.[5,8]

CLINICAL FEATURES

PRIMARY TUBERCULOSIS

The initial infection is usually asymptomatic, often detected only by a positive screening tuberculin skin test or by abnormalities on chest radiograph. When the infection is primary and active, common symptoms include fever, malaise, weight loss, and chest pain.[5] Infrequently, a pneumonitis that is similar to a viral or bacterial infection appears. Hilar adenopathy is present but rarely massive. In some cases, especially in immunocompromised patients, the primary infection may be rapidly progressive and fatal.

REACTIVATION TUBERCULOSIS

When latent infection progresses to tuberculosis reactivation, symptoms may be systemic or pulmonary. The most common reactivation

symptoms are similar to those of primary tuberculosis and include fever, night sweats, malaise, fatigue, and weight loss. Productive cough, hemoptysis, dyspnea, and pleuritic chest pain develop as the infection spreads within the lungs. Physical examination is generally unremarkable, although rales may be noted in areas of pulmonary infection.

Although most cases of active tuberculosis involve the lungs, up to 20% of cases will have extrapulmonary manifestations.[5] The most common extrapulmonary site of tuberculosis is the lymphatic system—painless lymphadenopathy (i.e., scrofula, cervical lymphadenitis). Other extrapulmonary manifestations include abdominal pain due to hepatosplenomegaly, peritoneal tubercles, prostatitis, epididymitis, or orchitis; adrenal insufficiency; bone pain with arthritis, osteomyelitis, or Pott's disease (bony destruction, often in the spine); hematuria and sterile puree; and meningitis. Tuberculosis can also cause pericarditis, which can lead to tamponade and constrictive symptoms. One key extrapulmonary tuberculosis axiom is that it can mimic many other common diseases, especially in the elderly and HIV patients.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

With the aging population, consider tuberculosis in all patients over 50 years old with a pneumonia-like presentation or prominent respiratory complaint.[5,6] Similarly, consider the disease in those with HIV or on immunosuppressive medications (notably after transplantation or with a connective tissue disease). The variable clinical presentation and the time required to culture the organism make diagnosis in the ED challenging. The goal is to have considered and begun testing for tuberculosis and to start respiratory precautions while awaiting results.

The ED is the point of entry into the healthcare system for many patients.[9] Prehospital and ED personnel should think of potential tuberculosis in higher-risk patients with lung symptoms, institute appropriate respiratory precautions, and notify healthcare providers about the possibility of tuberculosis. Place patients with suspected tuberculosis in separate waiting areas, provide them with surgical masks, and instruct them to cover the mouth and nose when coughing. Immunocompromised patients with respiratory symptoms should be evaluated promptly and isolated until tuberculosis can be excluded based on a chest radiograph.[10] A negative-pressure room is ideal for isolation when available.

During triage or initial assessment, consider the diagnosis of tuberculosis in any patient with a persistent cough (weeks or months) that has not improved despite appropriate treatment. Tuberculosis can mimic community-acquired pneumonia; clues that suggest tuberculosis include hemoptysis, night sweats, and weight loss. On chest radiograph, look carefully for upper lung field involvement, fibrocalcific changes, pleural capping, or a calcified Ghon complex.[5]

Once tuberculosis is suspected, give empiric antibiotics for pneumonia, admit the patient to an isolation bed, and institute airborne precautions. The evaluation should include sputum culture and tuberculosis skin testing and should also include HIV testing if the patient's HIV status is unknown.

MANTOUX OR TUBERCULIN SKIN TEST

The most common method for screening for exposure to *M. tuberculosis* is a skin test. The Mantoux test uses intracutaneous injection of 0.1 mL of **purified protein derivative** into the forearm. The test relies on a delayed-type hypersensitivity reaction that is triggered in those with past infection or those with a significant recent exposure to tuberculosis. The test is read between 48 and 72 hours after administration by measuring the extent of skin induration at the test site; erythema or other skin changes are not assessed (**Table 67-2**).[10] All persons with a new positive skin test or recent conversion should be referred for treatment of latent tuberculosis.

In a few situations, a positive skin test is not diagnostic of tuberculosis. Those who received **Bacillus Calmette-Guérin (BCG)** immunization for tuberculosis prevention will often have a positive skin test response in absence of infection. Exposure to nontuberculosis mycobacteria also can result in a false-positive test. False-negative skin test results occur with improper administration or reading, very early in the disease, or with profound underlying immunosuppression (notably in HIV).[7,8,11]

TABLE 67-2 Interpretation of a Purified Protein Derivative Skin Test*

≥5-mm induration is positive in:
Patients with the human immunodeficiency virus
Patients with close contact with a tuberculosis-infected individual
Patients with abnormal chest radiograph suggestive of healed tuberculosis
Patients with organ transplants and other immunosuppressed patients receiving the equivalent of prednisone >15 milligrams per day for >1 month
≥10-mm induration is positive in patients not meeting the above criteria but who have other risks:
Injection drug users
High-prevalence groups (immigrants, long-term care facility residents, persons in local high-risk areas)
Patients with conditions that increase the risk of progression to active disease (silicosis, diabetes, carcinoma of the head, neck, or lung)
Children <4 y of age
≥15-mm induration is positive in all others
Detection of newly infected persons in a screening program:
≥10-mm induration increase within any 2-y period is positive if <35 y
≥15-mm induration increase within any 2-y period is positive if >35 y
If the patient is anergic, other epidemiologic factors must be considered

*A positive reaction does not necessarily indicate disease.

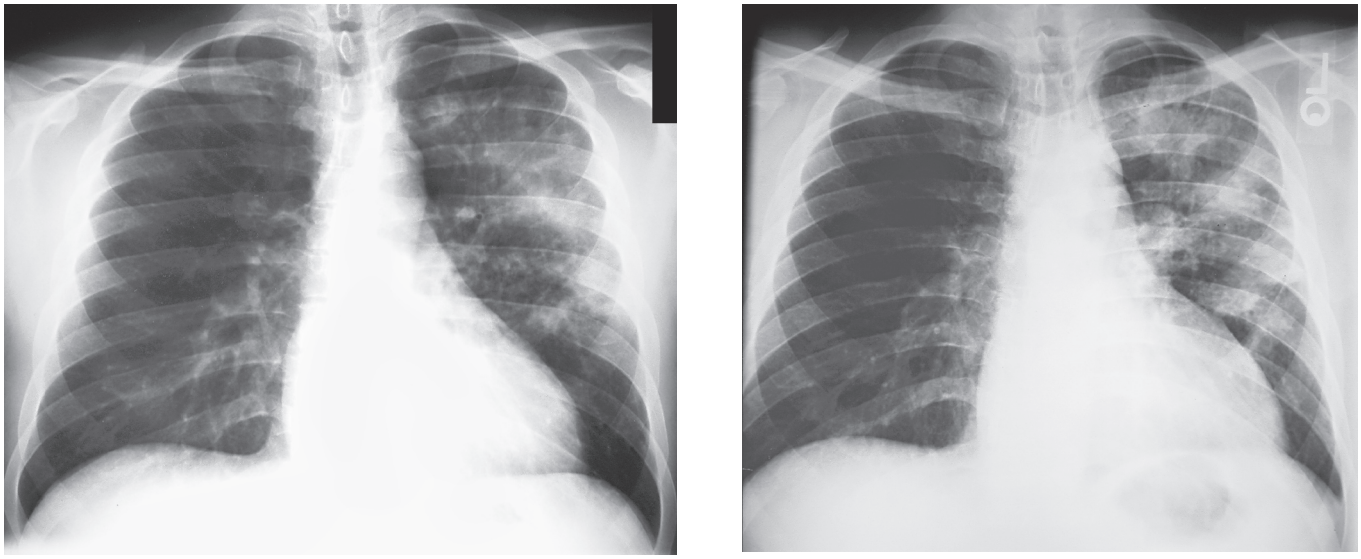
BLOOD TESTS

Interferon-gamma release assays (IGRA) are blood tests that indirectly assess for tuberculosis. The test seeks the response to peptides present in all *M. tuberculosis* proteins, which trigger the release of interferon-gamma by the infected host.[11] These proteins are absent in the BCG vaccine and in most nontuberculous mycobacteria, making IGRA more specific than skin testing.[8,11] IGRA is used in conjunction with a history, chest radiograph, and culture in those with suspected active tuberculosis.[11,12] Currently used IGRA tests give results in 16 to 24 hours. These tests are especially helpful when follow-up care compliance is a concern, notably in the homeless or drug-abusing patient, and can aid in those patients in whom skin testing is not helpful for the previously mentioned reasons or with known previous exposure (e.g., a healthcare worker).[8,11]

CHEST RADIOGRAPH

The chest radiograph is used to identify disease in those with pulmonary symptoms or after a positive skin test. No singular findings are pathognomonic for primary tuberculosis,[13] and the most common finding is a normal chest radiograph.[5] In primary infection, parenchymal infiltrates in any area of the lung may be found (**Figure 67-2**). Isolated ipsilateral hilar or mediastinal adenopathy is sometimes the only finding. Pleural effusions are usually unilateral and occur alone or in association with parenchymal disease. During primary infection, younger patients are more likely to have enlarged hilar lymph nodes, whereas adults more frequently have parenchymal abnormalities and effusions. The enlarged lymph nodes commonly encountered in children may cause external compression, leading to bronchial obstruction, atelectasis, and postobstructive hyperinflation. Because tuberculosis has a wide variety of appearances on chest radiographs, comparison with previous films is extremely helpful in determining the significance of an abnormal or unusual finding.[5,13]

In **latent tuberculosis**, nonspecific findings include upper lobe or hilar nodules and fibrotic lesions, which may be calcified. Other findings are bronchiectasis, volume loss, and pleural scarring. Healed primary areas of infection appear as Ghon foci, areas of scarring, and calcification (see Figure 67-1).



A B

FIGURE 67-2. Reactivation tuberculosis. **A.** This elderly patient was treated with antibiotics for community-acquired pneumonia. **B.** When the patient did not respond, a past history of asymptomatic exposure to tuberculosis was elicited. Infiltrates were noted to be worse on hospital day 5 when tuberculosis skin test turned positive, diagnosing reactivation pulmonary tuberculosis.

Reactivation infections often have the classic findings of tuberculosis: cavitary or noncavitary lesions in the upper lobe or superior segment of the lower lobe of the lungs (**Figures 67-3 and 67-4**).

The radiographic appearance of tuberculosis is often dependent on the integrity of the immune system rather than the stage of tuberculous disease, with classic findings seen in the immunocompetent patient. Thus, immunocompromised patients are more likely to have radiographic findings traditionally considered findings of primary disease.[13,14] The frequency of classic findings on chest radiographs is directly related to the degree of immunosuppression; those HIV patients with low CD4 counts have more atypical findings on radiographs. Normal radiographs occur in up to 22% of tuberculosis patients with advanced HIV.[14,15]

MICROSCOPY/CULTURES

Sputum is normally collected to detect the presence of *M. tuberculosis*. In the absence of a satisfactory sputum sample, gastric aspirates, pleural and other body fluids, or tissue samples may be used for culture and other diagnostic tests. The samples are typically stained with either a Ziehl-Neelsen stain or a fluorochrome procedure followed by exposure to an acidic agent. Mycobacteria will not lose the stain despite being rinsed with an acidic chemical. Hence, the term "**acid-fast bacilli**" is used to describe the appearance on microscopic smears. Unfortunately, the staining procedure is not sufficiently sensitive or specific to confirm or exclude the diagnosis of tuberculosis.[2] Negative smears are found in approximately 60% of culture-positive cases of tuberculosis. This number may be even higher in children and HIV patients.[13,15]

Cultures for *M. tuberculosis* are the best method of confirming diagnosis. Cultures also can aid detecting resistance to treatment regimens.

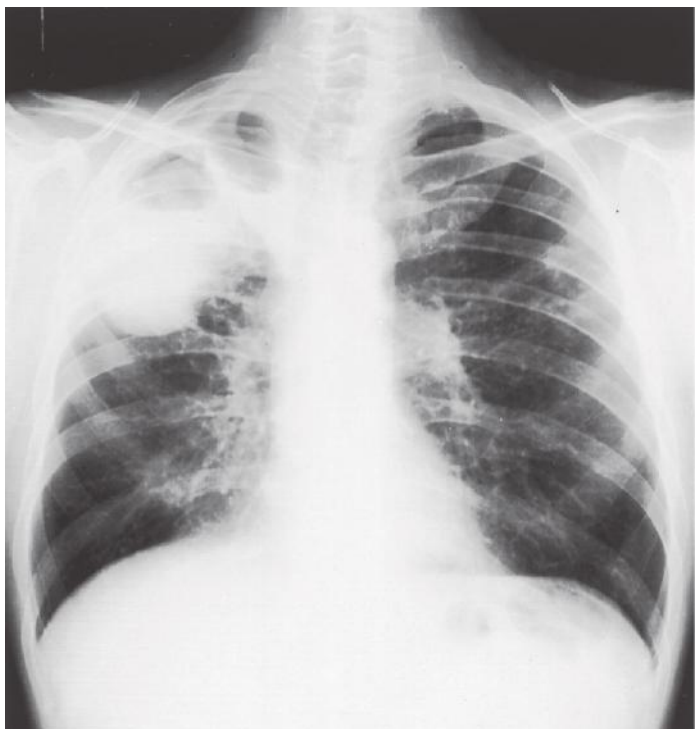


FIGURE 67-3. Cavitary tuberculosis of the right upper lobe.

FIGURE 67-4. Advanced pulmonary tuberculosis involving apex and upper lobe.

TABLE 67-3 Antituberculous Medications

First-Line	Second-Line
Isoniazid	Cycloserine
Rifampin	Ethionamide
Rifapentine	Fluoroquinolones
Ethambutol	Streptomycin
Pyrazinamide	Amikacin
Rifabutin	Capreomycin

However, culture results are not available for weeks, thus creating the need for newer adjunctive tests to expedite diagnosis and treatment. The **nucleic acid amplification test (NAAT)** can yield results within 1 day. In patients with positive smears, it has a reported sensitivity of greater than 95%. Patients with positive smears and positive NAAT should receive treatment pending culture results.[2] However, a negative NAAT result cannot rule out tuberculosis. For these cases, treatment may depend on further testing and should be guided by clinical suspicion and culture results.[13]

TREATMENT

TREATMENT OF ACTIVE TUBERCULOSIS

Active tuberculosis treatment requires the use of a combination of antituberculous medications to overcome resistance (**Table 67-3**).[12] Initial therapy includes first-line medications (isoniazid [INH], rifampin [RIF], pyrazinamide [PZA], ethambutol) for 8 weeks, followed by two-drug continuation treatment for 18 to 31 weeks based on culture results. Second-line medications are used for drug-resistant cases or when side effects from initial therapy are not tolerable. In the ED, patients are either admitted to the hospital to determine the need for antituberculous medications or referred to specialists in the community for follow-up if compliance is likely. In most cases, antituberculous medications will not be started in the ED unless done in consultation and for classic cases. The recommended Centers for Disease Control and Prevention regimens are as follows[12]:

- Daily four-drug (INH, RIF, PZA, ethambutol) therapy for 8 weeks, followed by either INH/RIF or INH/rifapentine for 18 weeks *OR*
- Daily four-drug therapy for 2 weeks, followed by two times per week for 6 weeks, with subsequent INH/RIF or INH/rifapentine for 18 weeks *OR*
- Three times weekly four-drug therapy for 8 weeks, followed by INH/RIF three times weekly for 18 weeks *OR*
- Daily three-drug therapy (INH, RIF, ethambutol) for 8 weeks followed by INH/RIF for 31 weeks

More prolonged therapy is recommended for immunocompromised patients or for those with extrapulmonary disease. Initial therapy may be modified once drug susceptibilities are available. The importance of directly observed therapy is paramount in select patients where compliance is a concern; the Centers for Disease Control and Prevention recommends that all regimens of two or three times per week be given by directly observed therapy.[2,12]

Although the standard medications used to treat tuberculosis are generally effective and safe, side effects or drug interactions may occur (**Table 67-4**). Hepatotoxicity, or hepatitis, is the major adverse effect of INH. Preexisting liver disease, pregnancy, ethanol use, HIV, and hepatitis C infection have been associated with an increased risk for hepatotoxicity from INH. Those with preexisting medical conditions requiring multiple medications may be at higher risk for drug interactions with antituberculous agents.[2,12,15]

A portion of patients being treated for tuberculosis will clinically worsen after the initiation of antituberculous medications.[10,15,16] This effect is called a ***paradoxical reaction*** or ***immune reconstitution syndrome*** and can be seen in any patient receiving treatment for tuberculosis, although it is more commonly seen in those with HIV infection. Signs and symptoms include fever, worsening respiratory status, lymphadenopathy, hepatosplenomegaly, ascites, meningitis, and new or worsening CNS lesions. **Hypercalcemia** is a unique finding in paradoxical reactions. Because treatment of tuberculosis and HIV both improve immune function, the paradoxical reaction is thought to be a result of improvement in the body's ability to mount an inflammatory response as mycobacteria are cleared. The dilemma is differentiating this from treatment failures, drug resistance, and medication noncompliance. (See the Special Populations section.)

TREATMENT OF LATENT TUBERCULOSIS

Treatment of latent infection with INH alone is started in those with recent asymptomatic skin test conversion (see Table 67-2), any person in close contact with an actively infected patient, and anergic patients with known tuberculosis contact.[11,12] Unless contraindicated, therapy is for a minimum of 9 months for adults, children, and HIV-infected persons. Monitor those at risk for INH hepatotoxicity by serial laboratory assessment. For those exposed to INH-resistant strains or those who are intolerant, use RIF and PZA for 2 months with hepatotoxicity monitoring.[12]

TABLE 67-4 Treatment of Tuberculosis (Adults)*

Drug	Daily (maximum)	Three Times Weekly DOT (maximum)	Two Times Weekly DOT (maximum)	Potential Side Effects and Comments
Isoniazid	5 milligrams/kg PO* (300 milligrams)	15 milligrams/kg PO (900 milligrams)	15 milligrams/kg PO (900 milligrams)	Hepatitis, peripheral neuropathy, drug interactions.
Rifampin (RIF)	10 milligrams/kg PO* (600 milligrams)	10 milligrams/kg PO (600 milligrams)	10 milligrams/kg PO (600 milligrams)	Hepatitis, thrombocytopenia, GI disturbances, drug interactions.
Rifapentine	Not given daily	Not given 3 times weekly	600 milligrams PO twice weekly in adults; not approved in children <12 y old	Hepatitis, thrombocytopenia, exacerbation of porphyria. Recommended by Centers for Disease Control and Prevention for continuation therapy only for human immunodeficiency virus–negative patients.
Rifabutin	5 milligrams/kg PO (300 milligrams)	5 milligrams/kg PO (300 milligrams)	5 milligrams/kg PO (300 milligrams)	Similar to RIF; used for patients who cannot tolerate RIF.
Ethambutol	15–20 milligrams/kg PO (1.6 grams)	25–30 milligrams/kg PO (2.5 grams)	50 milligrams/kg PO (2.5 grams)	Retrobulbar neuritis, peripheral neuropathy.
Pyrazinamide	15–30 milligrams/kg PO (2 grams)	50 milligrams/kg PO (3 grams)	50 milligrams/kg PO (2 grams)	Hepatitis, arthralgia, hyperuricemia.

Abbreviation: DOT = directly observed therapy.

*See http://www.cdc.gov/tb for more accurate weight-based protocols and dosages for children.

TABLE 67-5 Engineering Controls to Reduce the Transmission of Tuberculosis

High airflow (at least 6 room air changes per hour) with external exhaust
High-efficiency particulate filters on ventilation system
Ultraviolet germicidal irradiation
Negative-pressure isolation rooms
Personal respiratory protection: high-efficiency particulate filter masks or respirators

DISPOSITION AND FOLLOW-UP

OUTPATIENT CARE

Most patients with tuberculosis can be treated initially as outpatients. If planning discharge or transfer for other nonmedical care, start or maintain therapy while awaiting smear and culture results on all with suspicious findings of active tuberculosis, notably cavitary lesions or known previous infection with new weakness or fevers.

Contact primary care physicians or public health services and arrange for long-term care before patient discharge. Discharge instructions include home isolation procedures and follow-up at the appropriate clinic to receive medication and ongoing care. **Antituberculosis medications should not be instituted in the ED unless there is joint agreement with the consultant and follow-up providers.**

HOSPITAL ADMISSION

Hospital admission should be done for the following cases: ill-appearing, hypoxemic, or dyspneic patients; if the diagnosis is uncertain; if noncompliance is likely or if the social situation makes it difficult to complete evaluation and start care; or patients with active drug-resistant tuberculosis. Hospitalized patients with suspected tuberculosis require respiratory isolation in a negative-pressure room (**Table 67-5**). An alternative to admission for therapy compliance alone is a court-ordered drug observation program (if available), where scheduled outpatient contacts to ensure medication use occur for the course of therapy.[2]

SPECIAL POPULATIONS

PATIENTS WITH TUBERCULOSIS AND HUMAN IMMUNODEFICIENCY VIRUS

HIV infection is the strongest known risk factor for tuberculosis, and the incidence of tuberculosis in HIV-positive patients is much higher than in the general population. Patients with a new diagnosis of tuberculosis are almost 20 times more likely to have HIV, and HIV patients are 20 to 30 times more likely to develop tuberculosis. Tuberculosis (pulmonary and extrapulmonary) often can be the initial clinical manifestation of immunodeficiency and is a defining event in the acquired immunodeficiency syndrome. Once active tuberculosis has developed, the risk of rapid progression and drug resistance is much higher in the HIV patient. Successful treatment with antiretroviral therapy lowers the rate of tuberculosis and reduces the incidence of extrapulmonary involvement.[17] **For these reasons, physicians considering a diagnosis of tuberculosis should obtain HIV testing to provide early diagnosis and therapy.**

Treatment of tuberculosis in HIV-positive patients is generally effective and not markedly different from others with the infection. However, due to the number of medications taken by patients with HIV, potential drug interactions are common, and compliance may become an issue. There is no consensus statement on the timing of antiretroviral therapy when treating both diseases. Recent studies support early antiretroviral therapy in combination with antituberculous medications, especially in those who are severely immunocompromised.[1,18]

Immune reconstitution inflammatory syndrome or paradoxical reaction (see Treatment of Active Tuberculosis) is a condition in which HIV patients clinically worsen as the immune system recovers after the initiation of antiretroviral therapy or antituberculous medications. The ideal timing of antiretroviral therapy in those with active tuberculosis is uncertain.[1,18] See chapter 154, Human Immunodeficiency Virus Infection.

MULTIDRUG-RESISTANT TUBERCULOSIS

Multidrug-resistant tuberculosis is defined as tuberculosis with isolates that demonstrate resistance to at least INH and RIF. *M. tuberculosis* becomes resistant by spontaneous genetic mutation, often as a result of inadequate drug therapy or noncompliance with initial treatment. While resistance is usually not confirmed until culture and sensitivity data are available, certain historical and clinical features raise the level of suspicion for multidrug-resistant tuberculosis. These include a history of tuberculosis treatment in the past, exposure to multidrug-resistant tuberculosis, known INH resistance in the community above 4%, and persistent symptoms or persistently positive sputum cultures despite 4 months of standard treatment.[19]

Extensive drug-resistant tuberculosis is a more intense worldwide threat to public health and tuberculosis control. Extensive drug-resistant tuberculosis is defined as disease resistant to INH and RIF, plus resistance to any fluoroquinolone, and resistance to at least one injectable second-line medication. It is associated with poor outcomes and higher mortality.

Treatment of multidrug-resistant tuberculosis depends on sensitivity patterns from culture. Some countries may use standardized regimens based on known local resistance patterns. Usually a combination therapy with four to six medications, including the more toxic and less potent second-line medications, is administered for up to 2 years. Success rates rarely exceed 75%.[20] In refractory cases, resectional surgery may be necessary in addition to ongoing medical therapy.[19]

The "Global Plan to Stop Tuberculosis" calls for new medications to fight against the problem of multidrug-resistant tuberculosis. In addition to testing and better current therapy compliance, new medications show promise, especially **delamanid**.[20]

CHILDREN

Tuberculosis in children occurs in the same risk groups as in the adult population (see Table 67-1). The clinical course and disease manifestations in children have several unique aspects. Although children are at greater risk for developing rapidly progressive and disseminated disease, their presenting signs and symptoms can be subtle. Primary tuberculosis in children is often asymptomatic and only identified through screening programs or contact tracing.[21] Children may be asymptomatic even with abnormal radiographs. Or, children may present with fever, cough, wheezing, poor feeding, and fatigue. The classic symptoms of fever, night sweats, and weight loss may be seen in older children; however, in those younger than 5 years, presentation may be that of miliary tuberculosis (see below), meningitis, or a pneumonia that does not respond to therapy. The most common extrapulmonary presentation is **cervical lymphadenitis,** but other regions may be involved including the meninges, pericardium, abdomen, bone, joints, kidneys, skin, and eyes.

The yield of sputum smears and cultures is lower in children because of difficulty in obtaining adequate samples in addition to the lower incidence of cavitary disease.[22,23] Traditionally, obtaining three early morning consecutive gastric lavage or gastric aspirate samples has been standard procedure. However, this is invasive, unpleasant, and often requires an overnight admission and trained staff. Sputum induction using bronchodilators, followed by nebulized saline and expectoration of mucus, can improve sampling.[23]

The diagnosis of tuberculosis in children is confirmed by culture in only 30% to 40% of cases.[13] The newer tests, IGRA and NAAT, are not recommended for children less than 5 years old. The immune response differs in this age group, making the tests less reliable.[11] Often, treatment is initiated based on a skin test or on clinical grounds (symptoms, a history of exposure, or abnormal radiographs), and the diagnosis is presumed based on response to treatment.[22] Multidrug therapy is currently recommended for all children considered to have active disease, whereas monotherapy is used for latent infections.

MILIARY TUBERCULOSIS

Miliary tuberculosis is a historic term used in reference to the gross appearance of the lung during disseminated tuberculosis. In such cases, the lung is often covered with multiple small lesions resembling millet seeds. Classic miliary tuberculosis shows diffuse nodules on radiographs (1 to 3 mm) in a patient with positive laboratory testing or by demonstration of mycobacteria in multiple organs. The classic radiographic findings may not appear on films until the disease has progressed over time. A miliary pattern on radiographs can be found in conditions other than tuberculosis including histoplasmosis, malignancy, siderosis, and sarcoidosis.[24]

Today, miliary tuberculosis refers to wide hematogenous spread during the primary or reactivation disease, and it is associated with higher mortality. Children, the elderly, and immunocompromised patients are all at increased risk of developing miliary disease.

Miliary disease during primary tuberculosis is generally more rapid and severe, often presenting with multiorgan failure, shock, and acute respiratory distress syndrome. Conversely, miliary reactivation often manifests with a chronic, nonspecific clinical course affecting any number of organ systems. Fever, anorexia, night sweats, cough, weight loss, splenomegaly, lymphadenopathy, and signs of multisystem illness should cause one to suspect miliary disease. Cutaneous involvement, seen more often in HIV patients, manifests as papules or vesiculopapules (*tuberculosis cutis miliaris disseminata* or *tuberculosis cutis acuta generalisata*). Choroidal tubercles found on ocular exam are pathognomonic for miliary tuberculosis.

TUBERCULOUS MENINGITIS

Tuberculous meningitis is often seen in children, although those with HIV or others who are immunocompromised may also be afflicted. The challenge is the subtle and subacute presentation over days to weeks, with gradual fever, headache, and cognition or sensorium changes that often are not accompanied by neck stiffness or irritation, in contrast with those seen in other forms of bacterial meningitis. Focal neurologic deficits or cranial nerve palsies may also be evident. Suspecting the infection and requesting tuberculosis cultures and smear are key to making a diagnosis, because other diagnostics are not helpful.[25] Long-term neurologic dysfunction is common, with ventriculoperitoneal shunting needed in 25% of patients for hydrocephalus. Tuberculous meningitis often seeds after a miliary infection. Treatment parallels other forms of tuberculosis.

PRACTICE GUIDELINES

The American Thoracic Society, Infectious Disease Society (http://www.idsociety.org), and Centers for Disease Control and Prevention (http://www.cdc.gov) have issued recent joint guidelines for the management of tuberculosis.

CHAPTER 68

Pneumothorax

Bret A. Nicks
David Manthey

INTRODUCTION AND EPIDEMIOLOGY

Pneumothorax occurs when free air enters the potential space between the visceral and parietal pleura. **Primary pneumothoraces** occur without clinically apparent lung disease, either spontaneously or from penetration of the intrapleural space by trauma. **Secondary pneumothoraces** occur in patients with underlying lung disease.

TABLE 68-1 Causes of Secondary Pneumothorax

Airway disease
Chronic obstructive pulmonary disease
Asthma
Cystic fibrosis (8%–20% will develop one in lifetime)
Interstitial lung disease
Sarcoidosis
Pulmonary fibrosis
Tuberous sclerosis
Infection
Human immunodeficiency virus infection, *Pneumocystis* pneumonia
Tuberculosis
Bacterial pneumonia, necrotizing
Lung abscess
Connective tissue disease
Marfan's syndrome
Ehlers-Danlos syndrome
Scleroderma
Rheumatoid arthritis
Cancer
Primary lung or metastatic disease
Catamenial pneumothorax

The incidence of **primary spontaneous pneumothorax** is 10 to 18 cases for men and 2 to 5 cases for women per 100,000 population.[1] Associated factors include cigarette smoking, male gender, mitral valve prolapse, Marfan's syndrome, and changes in ambient pressure. Familial patterns also suggest an inherited association.[2] Physical activity or exertion can precipitate but is not a common pneumothorax-triggering factor. **Traumatic pneumothoraces** are subdivided into iatrogenic and noniatrogenic. Noniatrogenic pneumothoraces will be further discussed in the chapter 261, "Pulmonary Trauma."

Causes of **secondary spontaneous pneumothorax** are listed in **Table 68-1**. Chronic obstructive pulmonary disease remains the most common cause.[3] Pneumothorax occurs in 5% of patients with acquired immunodeficiency syndrome, is associated with subpleural necrosis by *Pneumocystis* infection, and carries a high mortality. Because of necrosis of lung tissue and continued air leak, simple aspiration fails in this group of patients. Hemopneumothorax occurs in 2% to 7% of patients with secondary pneumothorax and, if associated with a large amount of blood in the pleural cavity, can be life threatening.[4-7] Treating the underlying disease may help decrease the risk of future pneumothorax.

PATHOPHYSIOLOGY

Under normal conditions, the parietal and visceral pleura are in close apposition. The pleural space is negatively pressured at –5 mm Hg with fluctuations of 6 to 8 mm Hg between inspiration and expiration. The inherent tendency of the chest wall is to expand and for the lungs to collapse from elastic recoil. With the loss of the normal negative pressure in the pleural space that "adheres" the visceral pleura (lungs) to the parietal pleura (ribs), the affected lung collapses. A primary spontaneous pneumothorax occurs when a subpleural bleb ruptures, disrupting pleural integrity. Rupture in primary spontaneous pneumothoraces usually involves the lung apex.[6-8] In secondary spontaneous pneumothoraces, disruption of the visceral pleura occurs secondary to underlying pulmonary disease processes.

Once there is a break in the visceral pleura, air travels down a pressure gradient into the intrapleural space, until pressure equilibrium occurs with partial or total lung collapse. Altered ventilation–perfusion relationships and decreased vital capacity contribute to dyspnea and hypoxemia. If air continues to enter the pleural space, intrapleural pressure becomes positive. **Tension pneumothorax** develops as inhaled air accumulates in the pleural space but cannot exit due to a check-valve system.

As intrathoracic pressure (>15 to 20 mm Hg) increases, the great vessels and heart are compressed and shifted contralaterally, severely restricting venous return, diastolic filling, and cardiac output causing ventilation-perfusion mismatch, and resulting in hypoxia and shock.[8] Tension pneumothorax can develop in the presence of a chest tube if gas egress is obstructed, including from the adjacent lung.

CLINICAL FEATURES

Classic symptoms of primary spontaneous pneumothorax are sudden onset of dyspnea and ipsilateral, pleuritic chest pain. The pleuritic component of the pneumothorax may resolve within the first 24 hours. Profound dyspnea is rare, unless the patient has poor reserve due to underlying parenchymal disease or develops a tension pneumothorax. Sinus tachycardia is the most common physical finding. Because many pneumothoraces are small, other classic findings like ipsilateral decreased breath sounds, hyperresonance to percussion, and decreased or absent tactile fremitus are absent. In *traumatic pneumothorax*, the positive predictive value of ipsilateral decreased breath sounds is 86% to 97% for the diagnosis.[9] Cough and exertional complaints are not common signs or symptoms.[2] Except for trauma, physical exam alone is not sensitive enough to exclude the diagnosis.

The clinical hallmarks of **tension pneumothorax** are tracheal deviation away from the involved side, hyperresonance of the affected side, hypotension, and significant dyspnea.[8]

DIAGNOSIS

Pneumothorax is an important differential consideration in patients with chest pain, especially in those with underlying lung disease. Patients with pleurisy, pleural effusions, infiltrates, or shingles can present with pain similar to those with pneumothorax.

IMAGING

Chest X-Ray A standard erect posteroanterior chest radiograph is the usual initial test and demonstrates loss of lung markings in the periphery and a pleural line that runs parallel to the chest wall (**Figure 68-1**).

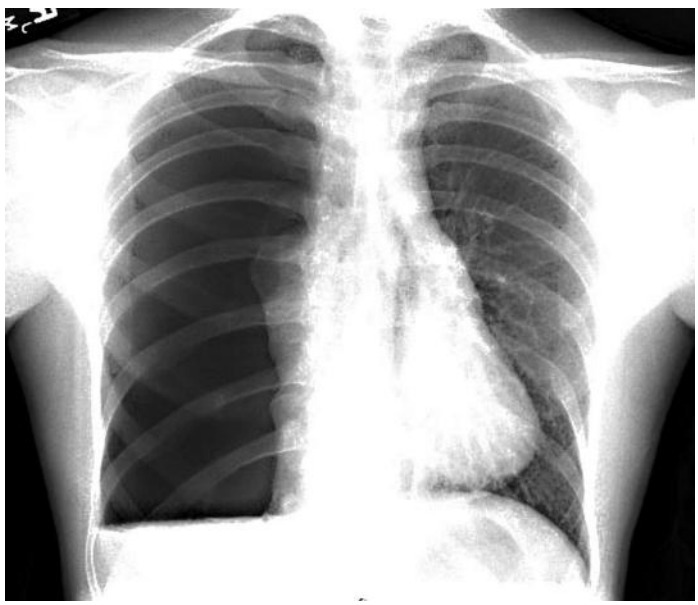

FIGURE 68-1. Spontaneous hemopneumothorax. Upright chest radiograph of a 19-year-old male college student with spontaneous hemopneumothorax. Note the large air-fluid level in the inferior portion of the right hemithorax in addition to the complete collapse of the entire right lung.

Ensure that the line does not extend outside of the chest cavity, suggesting a confluence of shadows or skin line. A lateral radiograph will identify a pneumothorax in an additional 14% of cases.[10] An expiratory radiograph does not identify many additional pneumothoraces. The sensitivity of anteroposterior chest radiography, when compared with CT, was 75.5% (95% confidence interval, 61.7% to 86.2%), with a specificity of 100% (95% confidence interval, 97.1% to 100%).[10-12] In critically ill patients, when they cannot be moved to an erect position, look for the **deep sulcus sign**, a deep lateral costophrenic angle, on the affected side.

Large bullae in patients with chronic obstructive pulmonary disease may look like a pneumothorax, although a pneumothorax pleural line will run parallel with the chest wall, whereas bullae will have a medially concave appearance. Pneumothoraces usually cross more than one lung segment, whereas bullae are limited to a single lobe. A chest CT can differentiate the two. A thoracostomy with the chest tube inserted into a bulla mistaken for a pneumothorax results in a large pneumothorax, associated bronchopulmonary fistula, and its complications.[12] Pleural adhesions cement the visceral and parietal pleura together, changing the appearance of the pneumothorax.

Pneumothorax size may be calculated by the Light index or Collins or Rhea methods, but most published formulae show only a modest correlation to actual pneumothorax size.[13-16] The American College of Chest Physicians supports a method of measurement from the apex of the lung to the cupula of the thoracic cavity on an upright posteroanterior film.[17] A measurement of less than 3 cm in this cephalad area is considered a small pneumothorax. Another method is to measure the interpleural distance at the level of the hilum; in this area, a distance of 2 cm correlates with a pneumothorax of approximately 50% by volume.[18] The British Thoracic Society defines a small pneumothorax as one with a <2-cm rim between the lung edge and chest wall and a large pneumothorax as one with a ≥2-cm rim.[18]

US US detects traumatic pneumothorax, with a reported sensitivity of 98.1% (95% confidence interval, 89.9% to 99.9%) and specificity of 99.2% (95% confidence interval, 95.6% to 99.9%).[13] The movement of the lung (ocean) against the stationary chest wall (shore) is often referred to as the "seashore." In a normal lung, there is commonly a sonographic reverberation distal to the pleura that looks like a **comet tail** and a **sliding sign** of the movement of the visceral pleura along the parietal pleura (**Figure 68-2**). In the presence of intrapleural air, pleural adhesions, effusions, and parenchymal disease, small pneumothoraces may be loculated, and therefore, the sliding sign and the comet tail reverberation are lost, limiting the specificity for pneumothorax.[14,15]

Chest CT Chest CT detects between 25% and 40% of pneumothoraces not visualized on a postprocedure chest radiograph.[12] CT can detect other pathology such as pulmonary blebs. If a chest radiograph does not demonstrate pneumothorax but there is clinical suspicion for the condition (e.g., in symptomatic high-risk patients, those with underlying lung disease or positive-pressure ventilation, or after lung biopsy), obtain a chest CT (**Figure 68-3**).

TREATMENT

The ED treatment goal is the elimination of intrapleural air. **Tension pneumothorax should be diagnosed clinically—before a radiograph—and *immediately* treated by needle decompression followed by tube thoracostomy.**

Treatment options are oxygen, observation, needle or catheter aspiration (either single or sequential aspirations), and tube thoracostomy (either small-size or standard chest tube) (see Tables 68-2 and 68-3). **Oxygen** administration (>28%) increases pleural air resorption three- to fourfold over the base 1.25% reabsorbed per day, by creating a nitrogen gas pressure gradient between the alveolus and trapped air.[19-21] Without supplemental oxygen, a 25% pneumothorax would take approximately 20 days to resolve. Recommended dosing ranges from 3 L/min nasal cannula to 10 L/min by mask and should be guided by the patient's status. Monitor for hypercapnia in patients with chronic obstructive pulmonary disease.

Observation is appropriate for small, stable pneumothoraces only. If this option is selected, observe the patient for at least 4 hours on

TABLE 68-2 Criteria for Stable Patient with Pneumothorax

Respiratory rate <24 breaths/min
No dyspnea at rest, speaks in full sentences
Pulse >60 and <120 beats/min
Normal blood pressure for patient
Room air oxygen saturation >90%
Absence of hemothorax

supplemental oxygen, and then repeat the chest radiograph. If symptoms and chest radiograph improve, the patient should return in 24 hours for repeat examination. First-time spontaneous pneumothorax of <20% lung volume in a stable, healthy adult may be treated initially with oxygen therapy and observation.[19-24]

Aspiration or tube thoracostomy is selected based on likelihood of recurrence and likelihood of spontaneous resolution. Pneumothoraces in patients with underlying pulmonary disease are likely to recur. Large pneumothoraces and those with an air leak are unlikely to resolve without drainage. Inability to return for care or to tolerate any pneumothorax increase (i.e., those with poor cardiopulmonary reserve) should prompt drainage.

When deciding to intervene procedurally on a pneumothorax, the stability of the patient, the degree of symptoms, the size and relative change in size over time, the cause of the pneumothorax, the degree of underlying lung disease, the likelihood of recurrence and resolution, and the need for positive-pressure ventilation are factors to consider. In situations when the patient is clinically stable (**Table 68-2**), various treatment approaches can be considered (**Tables 68-3 and 68-4**).[18-27]

The selection of catheter or chest tube size is based on the flow rate of air that the device can accommodate. Select large-bore tubes for anticipated big leaks, as from mechanical ventilation. Tension pneumothorax can develop if a large air leak develops, and small-bore tubes or catheters cannot handle the air flow. Every chest tube has a proximal hole, called the sentinel eye, which is visible radiographically and helps ensure that all drainage holes are inside the pleural cavity. Table 68-3 provides definitions for terms and various devices used to treat pneumothorax.[26-30]

NEEDLE DECOMPRESSION

To decompress, wear protective clothing or at least a mask to prevent material from squirting onto the operator. Use a 14-gauge needle for adults and an 18-gauge needle for children. Select a needle at least 2 inches (5 cm) long to penetrate the pleural cavity. Two locations are recommended: into the second or third intercostal space just above the rib (to avoid the intercostal artery) at the midclavicular line, or in the fourth or fifth intercostal space just above the rib and at the anterior axillary line (**Figure 68-4**). One small postmortem study analyzing both approaches reported only a 59% success rate in entering the pleural cavity.[31] If the needle is inserted medial to the midclavicular line, mediastinal vessels can

TABLE 68-3 Aspiration and Thoracostomy Devices*

Single aspiration	Insertion of a needle or catheter, aspiration of air using an attached syringe, and immediate removal of the device
Needle aspiration	18-gauge needle (provided in kits as an 8-French catheter over an 18-gauge needle)
Small-size catheter	≤14 French
Small-size chest tube	10–14 French
Pigtail catheter	14 French, placement using Seldinger technique
Moderate-size chest tube	16–22 French
Large-size chest tube	24–36 French

*The term "catheter" is used for a thin flexible tube; the term "chest tube" is used for a more rigid, larger tube. French sizes represent tube or catheter diameter (1 French = $^1/_3$-mm diameter), and the larger the French number, the larger the device.

TABLE 68-4 Treatment of Pneumothorax

Condition	Treatment Options
Small primary pneumothorax (<20% or 3 cm apex-cupula and asymptomatic)	Observation for >3 h on oxygen, repeat chest x-ray, discharge if no symptoms, and return for check if symptoms recur or in 24 h Or Small-size catheter aspiration with immediate catheter removal, then observe for >3 h, discharge if no symptoms, and return for check if symptoms recur or in 24 h Or Small-size catheter aspiration or small-size chest tube insertion, Heimlich valve, or water seal and admission
Small secondary pneumothorax	Small-size catheter or small-size chest tube insertion, Heimlich valve, or water seal and admission
Large pneumothorax, either primary or secondary, or bilateral pneumothoraces	Moderate-size chest tube and admission; large-size chest tube if fluid or hemothorax present; water seal and admission
Tension pneumothorax	Immediate needle decompression followed by moderate or large-size chest tube insertion, water seal drainage, and admission; immediate chest tube placement ideal

be injured. A finger cot cut at its distal end can then be placed over the needle to fabricate a one-way valve. The Heimlich valve is still occasionally used for ambulatory treatment of pneumothorax, and serious complications with its use are rare.[32]

NEEDLE OR CATHETER ASPIRATION

Needle or catheter aspiration is as effective as thoracostomy for treating the first episode of small primary or secondary spontaneous pneumothorax,[25] with success ranging from 37% to 75%, or higher in those with primary spontaneous pneumothorax.[26] Techniques include simple one-time aspiration with a large-gauge needle or a small-bore catheter, repeated aspirations through a small-size catheter, or chest tube attached to a one-way valve or water seal drainage. The catheter technique has the advantages of both aspiration and chest tube placement.[27]

Small-Size Catheters The catheter technique involves placing a small catheter either into the second anterior intercostal space in the midclavicular line or laterally at the fourth or fifth intercostal space in the anterior axillary line after local anesthesia and sterile preparation. Attach a three-way stopcock, and use a 60-mL syringe to aspirate the pleural space until resistance is met, often triggering a cough. Close the stopcock, secure the tube, and obtain a follow-up chest radiograph to ensure lung reexpansion. Aspiration of more than 4 L suggests continued air leak and failure of simple aspiration. Failure of the lung to fully expand warrants another aspiration attempt or formal tube thoracostomy and admission.

Pigtail Catheters Using Seldinger Technique Advantages of this technique are a smaller incision, less tissue dissection, and smaller scar.

Insert the needle into the pleural space, making sure placement is in the "triangle of safety" (**Figure 68-5**).[29,32] Aspirate fluid or air to verify location in the pleural space, and advance a guidewire through the needle. Place a dilator over the guidewire until the pleural space is entered. Remove the dilator and place the chest tube over the wire into the pleural space. Remove the stylet, secure the tube, and attach to suction.

Tube Thoracostomy Chest tube thoracostomy is used to treat a large pneumothorax, recurrent or bilateral pneumothorax, or coexistent hemothorax, or if there are abnormal vital signs or dyspnea. A chest tube is used in small spontaneous secondary pneumothoraces where large air leak is anticipated or noted. Standard chest tube thoracostomy with underwater seal drainage is the most commonly used approach, with a low complication rate and a success rate of 95%.[24,25] Most guidelines suggest a small 10- to 14-French chest tube for nontrauma, reserving larger 14- to 22-French chest tubes if a large air leak is probable, such as from mechanical ventilation or with underlying pulmonary disease.

The technique of tube thoracostomy is described in the chapter 261, "Pulmonary Trauma."

There is no clear difference between simple aspiration and intercostal tube drainage in overall short- and long-term outcomes,[24] and simple aspiration is as safe and effective as tube thoracostomy for small-volume air leak primary spontaneous pneumothorax.[25]

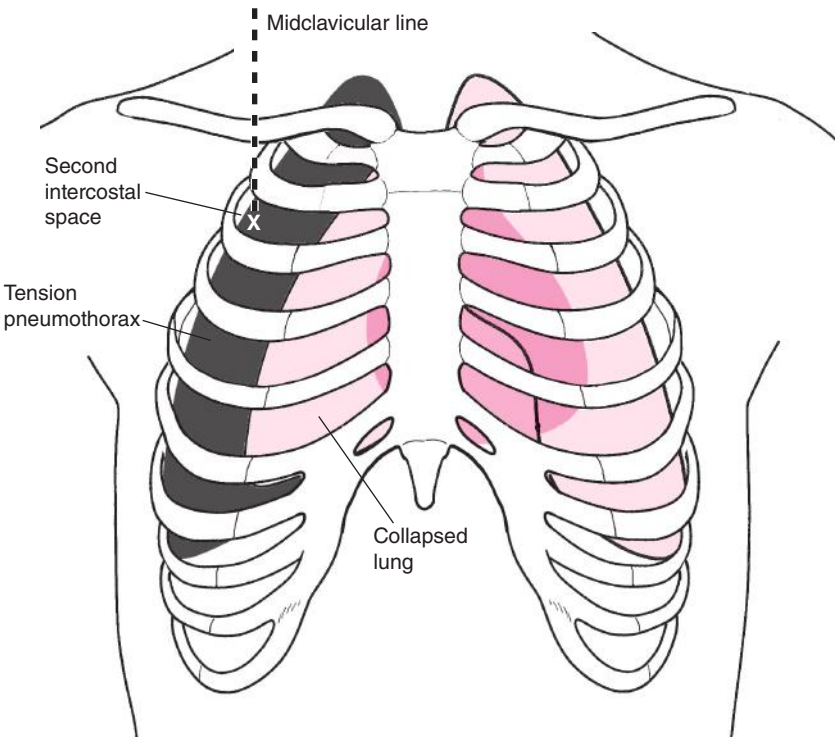

FIGURE 68-4. Needle placement for decompression of a right-sided tension pneumothorax. A site for a needle thoracostomy is the second intercostal space in the midclavicular line. FIGURE 68-5. Safe location of chest tube, within a triangle bordered by the fifth intercostal space, pectoralis major, and latissimus dorsi.

TREATMENT COMPLICATIONS

Complications of the pneumothorax itself can include those due to hypoxia, hypercapnia, and hypotension. Reexpansion lung injury is uncommon and seen more often when there is collapse of the lung for greater than 72 hours, a large pneumothorax, rapid reexpansion, or negative pleural pressure suction of greater than 20 cm.[3,8] Most patients need no treatment for re-expansion injury aside from observation or oxygen, with virtually no adverse outcomes.[30]

Intervention complications include intercostal vessel hemorrhage, lung parenchymal injury, empyema, and tube malfunction (development of an air leak or tension pneumothorax). Pleurodesis for recurrence prevention is used in those with first spontaneous pneumothorax with a persistent air leak, second ipsilateral spontaneous pneumothorax, first contralateral pneumothorax, bilateral spontaneous pneumothoraces, first episode of a secondary pneumothorax, or recurrent high-risk activities (flying or diving).[3,8]

SPECIAL CONSIDERATIONS

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothorax is a subset of traumatic pneumothorax and occurs more often than spontaneous pneumothorax. Transthoracic needle procedures (needle biopsy and thoracentesis) account for approximately half of iatrogenic pneumothoraces, and subclavian vein catheterization accounts for one fourth. Given that one central venous line is placed every minute in the United States and that pneumothorax occurs after 0.5% to 3.0% of subclavian line attempts, iatrogenic pneumothorax is common, underdetected, and underreported.[28] Factors associated with the increasing frequency of iatrogenic pneumothorax include the patient population, underlying disease, body habitus, and experience of the operator. US guidance for central venous catheter insertion for thoracentesis reduces the pneumothorax complication rate.

Although it is routine to obtain a chest radiograph after central line placement or transthoracic needle procedures, chest radiograph may not identify a pneumothorax if supine or if there is inadequate time for the pneumothorax to develop, with up to one third detected later.[28]

Treatment for iatrogenic pneumothorax is generally the same as that for spontaneous pneumothorax. Patients with a small pneumothorax after a needle puncture and those not requiring positive-pressure ventilation can be observed or initially treated with simple catheter aspiration (with or without a Heimlich valve), which is adequate for 60% to 80% of patients.[28] Long-term recurrence is not a concern with iatrogenic pneumothorax.

AIR TRANSPORT WITH PNEUMOTHORAX

Increased elevation causes an increase in gas volume (Boyle's law), increasing the risk for tension pneumothorax in air transport patients with pneumothorax, particularly when transported in fixed-wing vehicles (airplane) given the altitudes reached.[21] High-altitude flying is not recommended for at least 7 to 14 days after pneumothorax resolution.

DIVING

Similarly, due to Boyle's law, development of a pneumothorax at depth may lead to a tension pneumothorax with ascent. Current guidelines suggest that a history of spontaneous pneumothorax is a contraindication to underwater diving unless treated by surgical pleurectomy and normal lung function exists.[21]

DISPOSITION

Patients with a primary spontaneous pneumothorax who have been treated with observation or with catheter aspiration can be discharged if the pneumothorax does not increase in size over 3 to 6 hours and symptoms resolve or do not worsen. The remaining patients are observed longer or admitted, with that decision based on the size, therapy, and clinical condition.

CHAPTER 69

Acute Asthma

Rita K. Cydulka

INTRODUCTION AND EPIDEMIOLOGY

Asthma is a chronic inflammatory disorder characterized by increased responsiveness of the airways to multiple stimuli. In susceptible individuals, the inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes usually are associated with widespread and varying airflow obstruction.

Although most acute attacks are reversible and improve spontaneously or within minutes to hours with treatment with symptom-free intervals in between, many asthmatic patients develop chronic airflow limitation. This impacts the diagnosis of, management of, and attempts to prevent acute exacerbations.

Asthma affects approximately 8% of the U.S. population, is the most common chronic disease of childhood (9% prevalence), affects 7% of the elderly, and has a similar prevalence in developed nations around the world.[1-3] Approximately one half of cases of asthma develop before the age of 10 years old, and another one third develop before the age of 40 years old.

PATHOPHYSIOLOGY

Asthma is characterized by an abnormal accumulation of eosinophils, lymphocytes, mast cells, macrophages, dendritic cells, and myofibroblasts in airways. The pathophysiologic hallmark of asthma is a reduction in

TABLE 69-1 Physiologic Consequences of Airflow Obstruction

Increased airway resistance

airway diameter caused by smooth muscle contraction, vascular congestion, bronchial wall edema, and thick secretions. These changes are reflected in pulmonary function changes, increased work of breathing, and abnormal distribution of pulmonary blood flow (**Table 69-1**). Large and small airways contain plugs composed of mucus, serum proteins, inflammatory cells, and cellular debris. On a microscopic level, airways are infiltrated with eosinophils and mononuclear cells. Evidence of microvascular leakage, epithelial disruption, and vasodilation is frequently noted. The airway smooth muscle is hypertrophied and characterized by new vessel formation, an increased number of epithelial goblet cells, and deposition of interstitial collagen beneath the epithelium. Inflammation affects all bronchial pulmonary structures.

Asthma is a continuum from acute bronchospasm to airway inflammation to permanent airway remodeling. The structural changes associated with airway remodeling, such as sub–basement membrane thickening, subepithelial fibrosis, airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and mucous gland hyperplasia and hypersecretion are associated with nonreversible loss of lung function.[4] Acute allergic bronchoconstriction results from immunoglobulin E–dependent release of mediators from mast cells. These mediators include histamine, leukotrienes, tryptase, and prostaglandins that directly contract airway smooth muscle.[4] Bronchospasm induced by aspirin and other nonsteroidal anti-inflammatory drugs also involves mediator release from airway cells.[4]

Inflammation plays a key role in the pathophysiology of asthma regardless of disease severity. Inhaled antigens activate immunoglobulin E, mast cells, and T helper cells in the airway and induce the production of inflammatory mediators and cytokines. In turn, this initiates a cascade of reactions involving lymphocytes, mast cells, eosinophils, dendritic cells, macrophages, resident airway cells, and epithelial cells that perpetuate the inflammatory response, with further release of chemokines, cytokines, cysteinyl leukotrienes, and nitric oxide. The inflammatory process is multicellular, redundant, and self-amplifying.

Numerous host and environmental factors, such as number and type of infections in childhood, frequent antibiotic use, Western lifestyle, and repeated exposures to allergens, may contribute to the development of allergic asthma. Viral respiratory infections are among the most common of the stimuli that invoke acute asthma exacerbation.[5] Increased airway responsiveness secondary to infection may last anywhere from 2 to 8 weeks.[5] Exercise is another common precipitant of acute asthma. Environmental conditions, such as atmospheric pollutants and antigens noted in heavy industrial or densely populated urban areas, or increased indoor antigens, such as mold, house dust mites, cockroaches, and animal dander, are associated with higher incidence and severity of asthma. Occupational exposures, such as metal salt, wood and vegetable dust, pharmaceuticals, industrial chemicals, plastics, biological enzymes, vapors, gases, and aerosols, also may stimulate an asthma attack. Agents such as aspirin, β-blockers (including topical β-blockers), nonsteroidal anti-inflammatory drugs, sulfating agents, tartrazine dyes, and food additives and preservatives may trigger acute asthma. Exposure to cold air alone can induce acute bronchospasm. Endocrine factors, such as changing levels of estradiol and progesterone during the normal menstrual cycle and pregnancy, contribute to the level of airway reactivity.[6] Emotional stress also can produce an asthma attack.

CLINICAL FEATURES

The symptoms of asthma include dyspnea, wheezing, and cough. Many, but not all, patients will relay the history of asthma upon presentation. Early in the attack, patients will complain of a sensation of chest constriction and cough. As the exacerbation progresses, wheezing becomes apparent, expiration becomes prolonged, and accessory muscle use may ensue. A thorough history can be helpful in guiding care for asthma exacerbations[7-10] (**Table 69-2**). Acute asthma exacerbations are categorized based on clinical features[7-10] (**Table 69-3**).

Physical examination findings are variable. Patients presenting with a severe asthma attack may be in respiratory distress, with rapid breathing and loud wheezing, whereas patients with mild exacerbation may present with only cough and end-expiratory wheezing. At times, wheezing may be audible without a stethoscope. Other conditions may present with wheezing and mimic asthma (**Table 69-4**). The use of accessory muscles of inspiration indicates diaphragmatic fatigue. The appearance of paradoxical respiration, which is chest deflation and abdominal protrusion during inspiration followed by chest expansion and abdominal deflation during expiration, is a sign of impending ventilatory failure. Alteration in the mental status (e.g., lethargy, exhaustion, agitation, or confusion) also heralds respiratory arrest.

Directed physical examination reveals hyperresonance to percussion, decreased intensity of breath sounds, and prolongation of the expiratory phase, usually with wheezing. Although wheezing results from the movement of air through narrowed airways, the intensity of the wheeze may not correlate with the severity of airflow obstruction. The "silent chest" reflects very severe airflow obstruction, with air movement insufficient to promote an audible wheeze. A **pulsus paradoxus** (change in blood pressure during inspiration) >20 mm Hg is also indicative of severe asthma, although it is not specific for asthma. Although tachycardia and tachypnea are usually seen with acute asthma, a normal heart rate, a normal respiratory rate, and the absence of a pulsus paradoxus do not indicate complete relief of airway obstruction.

TABLE 69-2 Key History Points for Acute Asthma Exacerbation[7-10]

Symptoms	Pattern	Disease History	Risk Factors for Death from Asthma
Cough	Perennial and/or seasonal	Age at onset	Past history of severe exacerbation
Wheezing	Continual or episodic	Present management and medications	≥2 hospitalizations for asthma in the past year
Shortness of breath	Onset	Medication regimen adherence	>3 ED visits for asthma in the past year
Chest tightness	Duration	History of corticosteroid use (chronic and/or intermittent)	>2 canisters per month of inhaled short-acting β_2-agonist
Sputum production	Frequency	Intensive care admissions	Difficulty perceiving airflow obstruction or its severity
Fever	Aggravating factors	History of intubation	Low socioeconomic status or inner-city resident
	Usual pattern of exacerbation and outcome	Best spirometry measures	Illicit drug use
			Psychiatric disease or medical comorbidities

TABLE 69-3 Classifying Severity of Asthma Exacerbations in Patients >12 Years Old and Adults*

	Symptoms and Signs	Initial PEF (or FEV_1)	Clinical Course
Mild	Dyspnea only with activity	PEF ≥70% predicted or personal best	Prompt relief with inhaled SABA.
Moderate	Dyspnea interferes with or limits usual activity	PEF 40%–69% predicted or personal best	Relief from frequent inhaled SABA. Symptoms for 1–2 d after oral corticosteroids begun.
Severe	Dyspnea at rest; interferes with conversation	PEF <40% predicted or personal best	Partial relief from frequent inhaled SABA. Symptoms for ≥3 d after oral corticosteroids begun.
Subset: life-threatening	Too dyspneic to speak; perspiring	PEF <25% predicted or personal best	Minimal or no relief from frequent inhaled SABA; IV steroids; adjunctive therapy; needs ED or intensive care unit.

*The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation. Many of these parameters have not been systemically studied, so they serve only as general guides.

Abbreviations: FEV_1 = forced expiratory volume in 1 second; PEF = peak expiratory flow; SABA = short-acting β_2 agonist.

Source: www.nhlbi.nih.gov/files/docs/guidelines/asthsumm.pdf (National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services: NIH Publication Number 08-5846, October 2007, Fig. 20). Accessed November 18, 2014.

DIAGNOSIS AND PATIENT MONITORING

Bedside spirometry provides a rapid, objective assessment of patients and guides therapy. The forced expiratory volume in 1 second (FEV_1) and the peak expiratory flow rate (PEFR) rate directly measure the degree of large airway obstruction. Sequential measurements help assess severity and determine response to therapy. A flow-volume loop can help distinguish asthma from vocal cord dysfunction; the latter is often treated as asthma, sometimes with repeated visits. Vocal cord dysfunction responds to the moisture, *not* the drug, in a nebulized treatment, and "fails" metered-dose inhaler outpatient therapy because moisture is not a part of that delivery system. If not documented, obtain a full spirometry assessment only in patients with frequent outpatient failures.

Signs on physical examination and the subjective symptoms do not necessarily correlate well with the severity of airflow obstruction, making objective measures valuable. Patient cooperation is essential for these tests to be reliable, limiting the value of spirometry in severe exacerbations or in noncooperative patients.[7-10]

Pulse oximetry assesses oxygen saturation during treatment. Arterial blood gas measurement is not needed in most patients with mild to moderate asthma exacerbation, and it should be reserved for suspected hypoventilation with carbon dioxide retention and respiratory acidosis. With acute attacks, ventilation is stimulated, resulting in a decrease in partial pressure of arterial carbon dioxide ($Paco_2$). Therefore, a normal or slightly elevated $Paco_2$ (e.g., >42 mm Hg) indicates extreme airway obstruction and fatigue and may herald the onset of acute ventilatory failure. Patients with impending respiratory failure almost always have clinical evidence of severe attacks or spirometry demonstrating a PEFR or FEV_1 <25% predicted.[11] The use of capnography in acute asthma management is unclear. One small study reported good concordance between expired carbon dioxide levels measured by capnography and arterial carbon dioxide concentration,[12] but another reported differences of up to 10 mm Hg or more between the two measurements.[13]

Radiography is indicated only if there is clinical suspicion of pneumothorax, pneumomediastinum, pneumonia, or other cause for symptoms (e.g., acute heart failure) or complication of asthma. For admitted asthma patients, less than one third of patients have an abnormal chest radiograph.[14]

A CBC is not routinely needed and likely will show modest leukocytosis secondary to administration of β-agonist therapy or corticosteroids. For those few patients taking theophylline, measure the serum level. Routine ECG is also unnecessary but may reveal right ventricular strain, abnormal P waves, or nonspecific ST- and T-wave abnormalities, which resolve with treatment. Older patients, especially those with coexisting heart disease, should have cardiac monitoring during treatment.

TABLE 69-4 Important Asthma Mimickers

Acute heart failure ("cardiac asthma")
Upper airway obstruction
Multiple pulmonary emboli
Aspiration of foreign body or gastric acid
Tumors/disorders causing endobronchial obstruction
Interstitial lung disease
Vocal cord dysfunction

STANDARD TREATMENT

The goal is rapid reversal of airflow obstruction by repetitive or continuous administration of inhaled β_2-agonists, ensuring adequate oxygenation, and relieving inflammation.[7-10] **Figure 69-1** shows the National Asthma Education and Prevention Program Expert Panel ED treatment algorithm.[10] The following categories of medications are used in the treatment of acute asthma: β-adrenergic agonists, anticholinergics, and glucocorticoids. Treatments for impending or actual respiratory arrest are discussed below in "Status Asthmaticus."

ADRENERGIC AGENTS

β-Adrenergic agonists with rapid onset are the preferred initial rescue medication for acute bronchospasm (**Table 69-5**). Stimulation of β_1-receptors increases rate and force of cardiac contraction and decreases small intestine motility and tone, whereas β_2-adrenergic stimulation promotes bronchodilation, vasodilation, uterine relaxation, and skeletal muscle tremor.

β-Adrenergic drugs cause bronchodilation by stimulation of the enzyme adenyl cyclase, which converts intracellular adenosine triphosphate into cyclic adenosine monophosphate. This action enhances the binding of intracellular calcium to cell membranes, reducing the myoplasmic calcium concentration, and results in relaxation of bronchial smooth muscle. β-Adrenergic drugs also inhibit mediator release and promote mucociliary clearance.

The most common side effect of β-adrenergic drugs is skeletal muscle tremor. Patients also may experience nervousness, anxiety, insomnia, headache, hyperglycemia, palpitations, tachycardia, and hypertension. Clinical toxicity is rare and less common than undertreatment complications. Provoking dysrhythmias or myocardial ischemia is rare, especially in those without a prior history of coronary artery disease. The older catecholamine bronchodilators, such as epinephrine, are not β_2 specific and have a short duration of action.

Albuterol is a 50:50 racemic mixture (equal amounts of left and right isomers); it is now available in the hydrofluoroalkane formulation, which has increased the cost and the effectiveness. The *R* isomer has great binding affinity for the β_2-receptor and is responsible for bronchodilation. The *S* isomer has no bronchodilatory effect but has a long half-life (12 hours); this isomer may be responsible for late paradoxical bronchospasm in some patients. Levalbuterol (Xopenex®) is the pure *R* isomer form of the drug, intended to improve effectiveness and limit side effects such as tachycardia and rhythm change. Both racemic albuterol and levalbuterol can be given as intermittent or continuous nebulizations. Levalbuterol costs 5 to 25 times more than albuterol, and it has no clear advantage over albuterol regarding symptom change, admission, or tachycardia.[15-17]

Nonprescription racemic epinephrine (Asthmanefrin®) replaced Primatene® as an over-the-counter medication, and the cost is less than for prescription β_2-adrenergics. Asthmanefrin® contains 11.25 milligrams of racemic epinephrine/0.5 mL. In one study, subjects recruited through

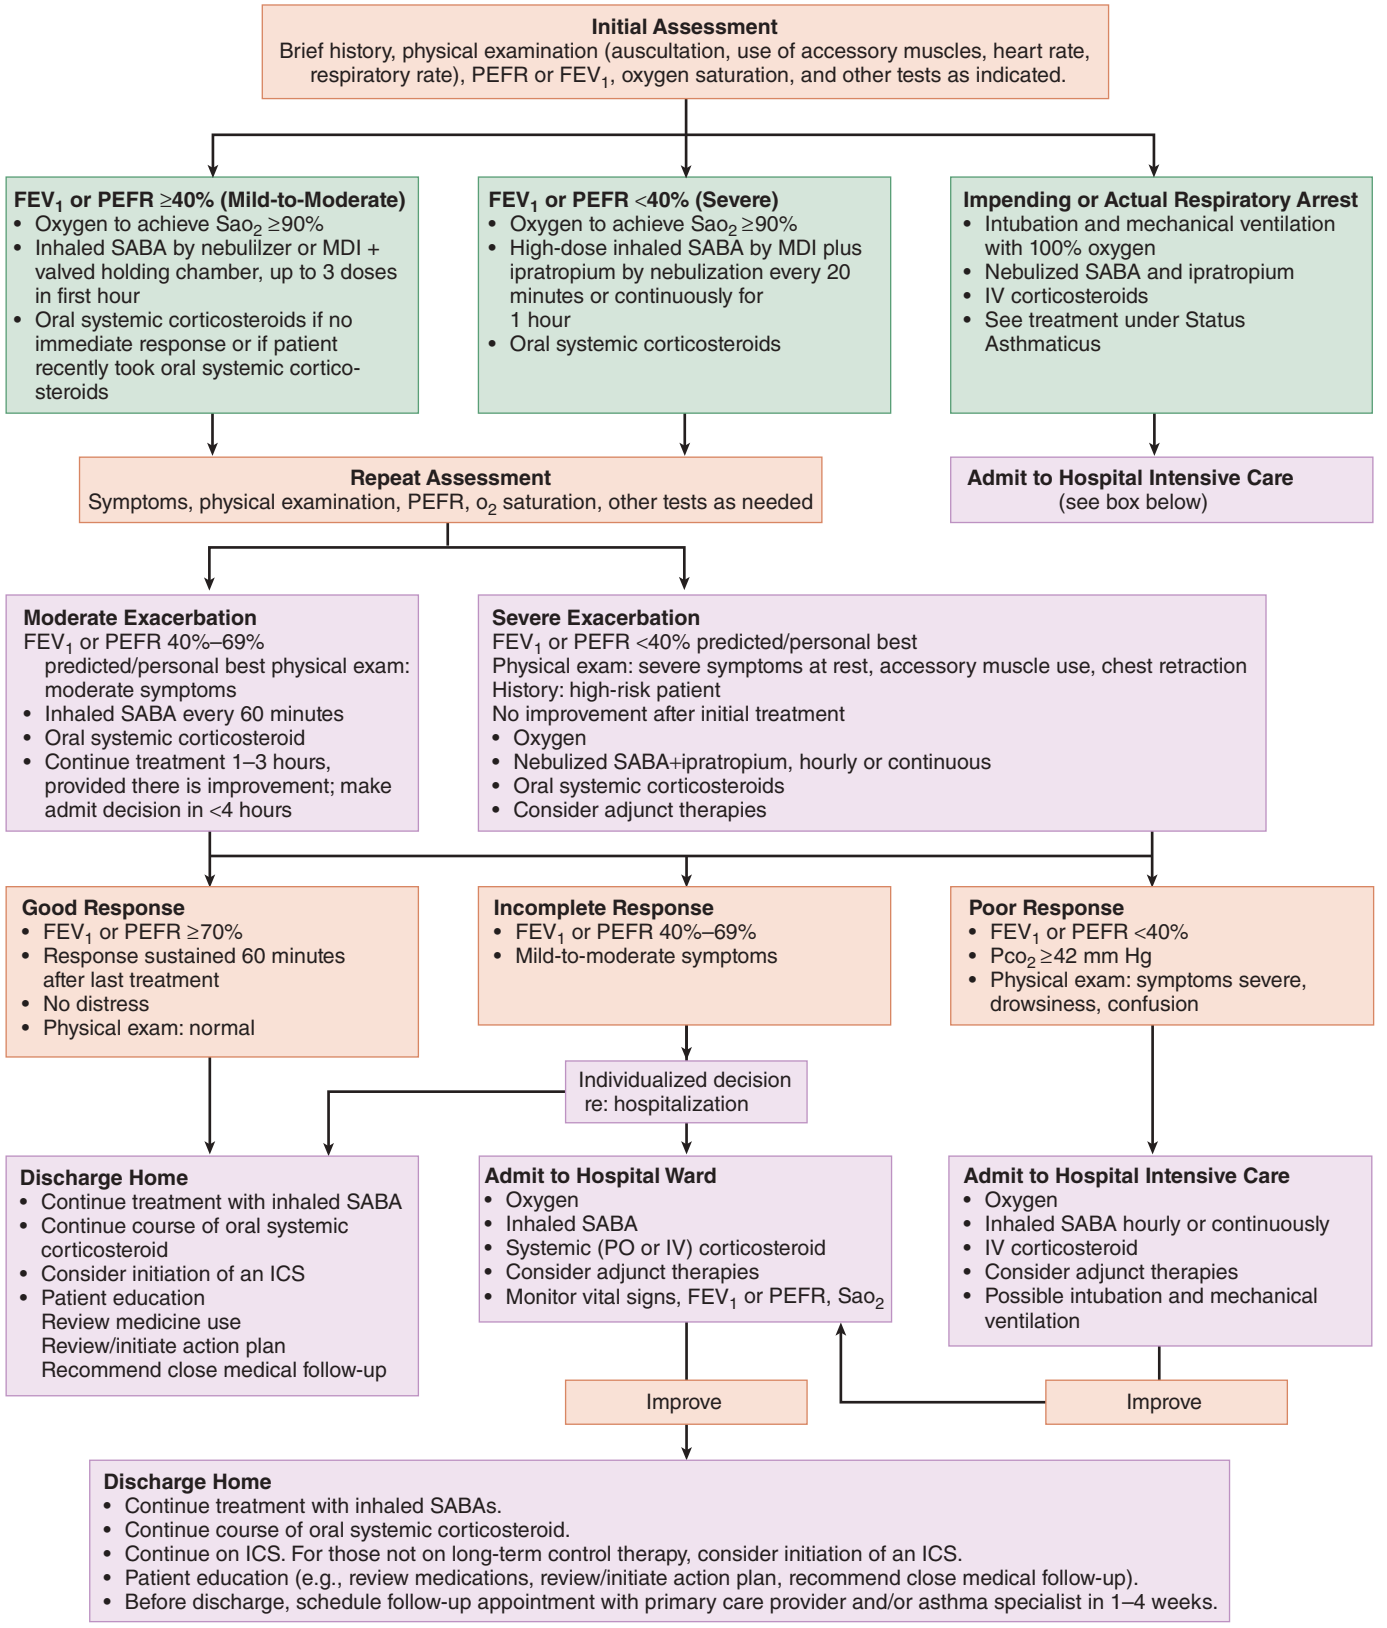

FIGURE 69-1. Management of asthma exacerbations: ED and hospital-based care. FEV_1 = forced expiratory volume in 1 second; ICS = inhaled corticosteroid; MDI = metered-dose inhaler; PEFR = peak expiratory flow rate; SABA = short-acting β_2-agonist; Sao_2 = oxygen saturation by pulse oximetry. TABLE 69-5 β-Adrenergic, Anticholinergic, and Steroid Dosages of Drugs for Asthma

Medication	Dose	Comments
Inhaled β_2-Agonists		
Albuterol		
Nebulizer solution (0.63 milligram/3 mL, 1.25 milligrams/3 mL, 2.5 milligrams/3 mL, 5.0 milligrams/mL)	2.5–5 milligrams every 20 min for three doses, then 2.5–10 milligrams every 1–4 h, as needed, or 10–15 milligrams/h as continuous nebulization.	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to minimum of 3 mL at gas flow of 6–8 L/min. Use large-volume nebulizers for continuous administration. May mix with ipratropium nebulizer solution.
MDI (90 micrograms/puff)	4–8 puffs every 20 min up to 4 h, then every 1–4 h as needed.	In mild-to-moderate exacerbations, MDI plus valved holding chamber is as effective as nebulized therapy with appropriate administration technique and coaching by trained personnel.
Bitolterol		
Nebulizer solution (2 milligrams/mL)	See albuterol dose.	Has not been studied in severe asthma exacerbations. Do not mix with other drugs.
MDI (370 micrograms/puff)	See albuterol MDI dose.	Has not been studied in severe asthma exacerbations.
Levalbuterol (R-albuterol)		
Nebulizer solution (0.63 milligram/3 mL, 1.25 milligrams/3 mL)	1.25–2.5 milligrams every 20 min for three doses, then 1.25–5 milligrams every 1–4 h, as needed.	Levalbuterol administered in one half the milligram dose of albuterol provides comparable efficacy and safety. Has not been evaluated by continuous nebulization.
MDI (45 micrograms/puff)	See albuterol MDI dose.	
Pirbuterol		
MDI (200 micrograms/puff)	See albuterol MDI dose.	Has not been studied in severe asthma exacerbations.
Systemic (Injected) β_2-Agonists		
Epinephrine		
1:1000 (1 milligram/mL)	0.3–0.5 milligram every 20 min for three doses SC.	No proven advantage of systemic therapy over aerosol.
Terbutaline		
(1 milligram/mL)	0.25 milligram every 20 min for three doses SC.	No proven advantage of systemic therapy over aerosol.
Anticholinergics/Combinations		
Ipratropium bromide		
Nebulizer solution (0.25 milligram/mL)	0.5 milligram every 20 min for three doses, then as needed.	May mix in same nebulizer with albuterol. Should not be used as first-line therapy; should be added to SABA therapy for severe exacerbations. The addition of ipratropium has not been shown to provide further benefit once the patient is hospitalized.
MDI (18 micrograms/puff)	Eight puffs every 20 min, as needed, up to 3 h.	Should use with valved holding chamber and face mask for children <4 y. Studies have examined ipratropium bromide MDI for up to 3 h.
Ipratropium with albuterol		
Nebulizer solution (each 3-mL vial contains 0.5 milligram of ipratropium bromide and 2.5 milligrams of albuterol.)	3 mL every 20 min for three doses, then as needed.	May be used for up to 3 h in the initial management of severe exacerbations. The addition of ipratropium has not been shown to provide further benefit once the patient is hospitalized.
MDI (each puff contains 18 micrograms of ipratropium bromide and 90 micrograms of albuterol.)	Eight puffs every 20 min as needed up to 3 h.	Should use with valved holding chamber and face mask for children <4 y.
Systemic Corticosteroids		Applies to all three corticosteroids for oral medications.
Prednisone	For inpatients: oral "burst," use 40–80 milligrams/d in one or two divided doses until PEFR reaches 70% of predicted or personal best.	For outpatients: oral "burst," use 40–60 milligrams in single or two divided doses for 5–10 d.
Methylprednisolone	IV: 1 milligram/kg every 4–6 h.	For outpatients: a single IM dose of 150 milligrams depot methylprednisolone may be used.[19]
Prednisolone	1–2 milligrams/kg/d for 5–10 d; may be divided twice daily.	More frequently used over prednisone in children due to increased palatably of available liquid formulations.

Notes: There is no known advantage for higher doses of corticosteroids in severe asthma exacerbations, nor is there any advantage for IV administration over oral therapy provided GI transit time or absorption is not impaired.

The course of systemic corticosteroids for an asthma exacerbation requiring an ED visit or hospitalization may last from 3 to 10 days. For corticosteroid courses of <1 week, there is no need to taper the dose. For slightly longer courses (e.g., up to 10 days), there probably is no need to taper, especially if patients are concurrently taking inhaled corticosteroids.

Inhaled corticosteroids can be started at any point in the treatment of an asthma exacerbation.

Abbreviations: MDI = metered-dose inhaler; PEFR = peak expiratory flow rate.

Source: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf (National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services: National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Publication No. 08-4051. Bethesda, MD, National Institutes of Health, 2007.) Accessed November 18, 2014.

local pharmacies reported no worse asthma outcomes than individuals treated with prescription β-agonists.[18] No other data exist to guide use of Asthmanefrin® versus prescribed agents.

Aerosol therapy with β_2-adrenergic drugs produces excellent bronchodilation and is favored over oral or parenteral routes. The aerosol route achieves topical administration of a relatively small dose of drug, thereby producing local effects with minimum systemic absorption and fewer side effects. Aerosol delivery occurs with a metered-dose inhaler coupled to a spacing device or with a compressor-driven nebulizer.[20] A spacing device attached to the inhaler improves drug deposition; when optimally used, *metered-dose inhaler therapy delivers the most drug to target airways,* better than nebulized therapy. Even with optimum technique, a maximum of 15% of the drug dose is retained in the lungs, regardless of the aerosol method used.

Aerosol treatments may be administered every 15 to 20 minutes or on a continuous basis.[21] Subcutaneous epinephrine and terbutaline are options for patients unable to coordinate aerosolized or metered-dose inhaler treatments, seen often in severe airflow-limited states. IV β-agonist infusions offer no advantage over aerosolized or metered-dose inhaler–delivered agents and carry increased risk.[22]

Salmeterol xinafoate and formoterol are β_2-adrenoreceptor agonists that bind with greater affinity to the β_2-receptor site than albuterol. **They are indicated for twice-daily maintenance therapy. Neither drug should be used for acute asthma exacerbations**. Bronchodilator effects last at least 12 hours, and tachyphylaxis has not been reported with long-term use. The number of asthma-related deaths among patients receiving salmeterol, especially in African Americans, has increased for unknown reasons, although this may be due to failure to recognize the need for or use rescue short-acting agents and to seek care appropriately. Long-acting β_2-adrenoreceptor agonists are an effective treatment for long-term control of asthma, especially in conjunction with inhaled corticosteroids. Short-acting β_2-adrenoreceptor agonists are used for infrequent or breakthrough symptoms that occur despite the use of long-acting β_2-adrenoreceptor agonists.[7-10,21]

CORTICOSTEROIDS

Corticosteroids are a cornerstone of asthma treatment. Steroids produce beneficial effects by restoring β-adrenergic responsiveness and reducing inflammation. The peak anti-inflammatory effect occurs at least 4 to 8 hours after IV or PO administration, but early use is wise to enhance care quickly; corticosteroids given within 1 hour of arrival in the ED reduce the need for hospitalization.[23] Although there is disagreement over the optimal dose in acute asthma, an initial dose of **PO prednisone** of 40 to 60 milligrams or **IV methylprednisolone** of 1 milligram/kg is sufficient, and higher-dose corticosteroid therapy offers no advantage.[24] Admitted patients should receive additional daily corticosteroids until subjective and objective improvements are achieved. Patients who are being discharged home with an FEV_1 or PEF of <70% predicted after aggressive ED treatment should be prescribed a 5- to 10-day nontapering course of prednisone (40 to 60 milligrams/d in a single daily dose or its equivalent) or a 2-day course of oral dexamethasone (16 milligrams/d in a single daily dose).[7-10,19,25,26] A single dose of **depot methylprednisolone**, 150 milligrams IM, is another option if compliance is a concern.[27]

Current recommendations favor inhaled corticosteroids for all patients with mild persistent asthma or more severe asthma.[7-10] This means discharging patients with mild persistent or more severe asthma on maintenance inhaled corticosteroids in addition to any systemic bursts.[28-31] Inhaled corticosteroid options are beclomethasone, 80 to 240 micrograms/d; budesonide, 180 to 600 micrograms/d; flunisolide, 500 to 1000 micrograms/d; fluticasone, 88 to 264 micrograms/d; mometasone, 200 micrograms/d; and triamcinolone acetonide, 300 to 750 micrograms/d.

ANTICHOLINERGICS

The effects of anticholinergics used in combination with β-adrenergic agents are additive. Anticholinergics affect large, central airways, whereas β-adrenergic drugs dilate smaller airways. Anticholinergic drugs competitively antagonize acetylcholine at the postganglionic junction between the parasympathetic nerve terminal and effector cell. This process blocks the bronchoconstriction induced by vagal cholinergic-mediated innervation to the larger central airways. In addition, anticholinergics reduce concentrations of cyclic guanosine monophosphate in airway smooth muscle, further promoting bronchodilation.

The anticholinergic commonly used is inhaled ipratropium bromide. Ipratropium is available as a nebulized solution and a metered-dose inhaler or in combination with albuterol[7-10] (Table 69-5). Use an aerosolized ipratropium bromide solution, 0.5 milligrams, in patients with moderate to severe exacerbation.[7-10] **Adding multiple doses of ipratropium bromide to a short-acting selective β-agonist may improve bronchodilation and decrease the need for hospitalization among severely obstructed asthmatics,[32] although this benefit is not universal.**[33] Potential side effects with anticholinergics include dry mouth, thirst, and difficulty swallowing. Less commonly, tachycardia, restlessness, irritability, confusion, difficulty in micturition, ileus, blurring of vision, or an increase in intraocular pressure can occur. Long-acting anticholinergic agents have no role in acute care.

STATUS ASTHMATICUS (ACUTE SEVERE ASTHMA)

Status asthmaticus is an acute severe asthma attack that does not improve with usual doses of inhaled bronchodilators and steroids. Signs and symptoms include hypoxemia, tachypnea, tachycardia, accessory muscle use, and wheezing. Wheezing may be absent when airflow is severely reduced. Rapid treatment is the key to preventing cardiopulmonary arrest. In addition to usual and ongoing bronchodilators coupled with early steroids, other treatment adjuncts exist.

MAGNESIUM

IV magnesium sulfate is indicated in the management of acute, very severe asthma (FEV_1 <25% predicted).[34] The magnesium dose is 1 to 2 grams IV over 30 minutes. Nebulized magnesium is effective and may also improve pulmonary function in severe asthma when it follows aggressive β-agonist and steroid therapy.[34-36] Dosing regimens vary; one regimen is 95 milligrams of nebulized magnesium sulfate in four divided doses 20 minutes apart, and another is 384 milligrams of nebulized magnesium sulfate in sterile water.[37] When using magnesium in any form, monitor blood pressure and deep tendon reflexes during administration[37] because hypotension or neuromuscular blockade may occur, although this is exceptionally rare in the doses recommended.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (see chapter 28, "Noninvasive Airway Management") improves airflow and respirations compared with usual care, and despite little research, it is commonly used in clinical practice for acute life-threatening asthma.[38,39] Noninvasive positive-pressure ventilation decreases the need for intubation, results in clinical improvement, and decreases the need for hospitalization.[39] Do not institute noninvasive positive-pressure ventilation if intubation is indicated or in patients with suspected pneumothorax.

KETAMINE

Ketamine inhibits reuptake of noradrenaline and thus increases circulating catecholamines, aiding some with severe asthma. An IV bolus dose of 0.2 milligram/kg followed by an infusion of 0.5 milligram/kg/h is sometimes used;[40] higher doses are validated.[41] If intubation is needed, ketamine is a good agent to aid during the procedure and after mechanical ventilation starts. Controlled trials substantiating ketamine's efficacy in treating severe acute asthma are lacking.

EPINEPHRINE

Although epinephrine is standard treatment for anaphylactic asthma, it is overlooked as an adjunct to treat status asthmaticus. Epinephrine can be given SC or IM, 0.5 milligram in adults (standard adult EpiPen® dose), in refractory situations.[41]

MECHANICAL VENTILATION

If the patient manifests progressive hypercarbia or acidosis or becomes exhausted or confused, intubation and mechanical ventilation (see chapter 29, "Intubation and Mechanical Ventilation") are necessary to prevent respiratory arrest. **Mechanical ventilation does not relieve the airflow obstruction—it merely eliminates the work of breathing and enables the patient to rest while the airflow obstruction is resolved.**

The potential complications of mechanical ventilation in asthmatic patients include extremely high peak airway pressures with subsequent barotrauma and hemodynamic impairment. Mucous plugging is frequent, leading to increased airway resistance, atelectasis, and pulmonary infection. Due to the severity of airflow obstruction during the early phases of treatment, the tidal volume may be larger than the returned volume, leading to air trapping and increased residual volume (intrinsic positive end-expiratory pressure). Using rapid inspiratory flow rates at a reduced respiratory frequency (12 to 14 breaths/min) and allowing adequate time for the expiratory phase can mitigate these effects. Also, it is reasonable to target adequate arterial oxygen saturation (≥90%) without concern for "normalizing" the hypercarbic acidosis. This approach is called *controlled mechanical hypoventilation* or *permissive hypoventilation*.

Ventilation of asthmatic patients requires sedation. Neuromuscular blocking agents may be required, but extended use may cause postextubation muscle weakness.[42] See chapter 111, Intubation and Ventilation in Infants and Children for further discussion.

AGENTS OF UNCERTAIN OR NO BENEFIT IN STATUS ASTHMATICUS

Heliox A mixture of 80% helium and 20% oxygen (heliox) can lower airway resistance and act as an adjunct in the treatment of severe asthma exacerbations.[43] Heliox does not reliably avert tracheal intubation, change intensive care and hospital admission rates and duration, or decrease mortality in severe asthma.[43]

Methylxanthines Aminophylline is no longer a first- or second-line treatment for acute asthma.[44] The most common side effects of methylxanthines are nervousness, nausea, vomiting, anorexia, and headache. At plasma levels >30 milligrams/mL, there is a risk of seizures and cardiac arrhythmias.

Other Agents **Mast cell modifiers**, such as cromolyn and nedocromil, exert their anti-inflammatory action by blockage of chlorine channels, modulating mast cell mediator release and eosinophil recruitment. These agents also inhibit early and late responses to allergen challenge and exercise. Neither is indicated for treatment of acute bronchospasm.

Leukotrienes are potent proinflammatory mediators that contract airway smooth muscle, increase microvascular permeability, stimulate mucus secretion, decrease mucociliary clearance, and recruit eosinophils into the airway. Several leukotriene modifiers, namely montelukast, zafirlukast, and zileuton, are available as oral tablets for the treatment of asthma. Leukotriene modifiers improve lung function, diminish symptoms, and diminish the need for short-acting β_2-agonists. They may be used as an alternative to low-dose inhaled corticosteroid therapy in mild persistent asthmatics and as steroid-sparing agents with inhaled corticosteroids in moderate persistent asthmatics.[7-10] Despite one trial with adjuvant IV montelukast for acute asthma,[45] **there is no indication for the use of any of the leukotriene modifiers in the ED.**

DISPOSITION AND FOLLOW-UP

Disposition decisions should take into account a combination of subjective parameters, such as resolution of wheezing and improvement in air exchange, as assessed by auscultation and patient opinion; objective measures, such as normalization of FEV_1 or PEFR; and historical factors, such as compliance, history of ED use, and hospitalization. Some degree of residual airflow obstruction, airway lability, and inflammation persists after treatment and discharge from the ED.

Advise discharged patients to use a short-acting β-agonist on a scheduled basis for several days and to complete any oral corticosteroids regimens. Add inhaled corticosteroids in patients with a history of persistent asthma who are not already using this regimen.[28-30]

A good response to treatment resolves symptoms and results in a PEFR or FEV_1 of >70% predicted; these patients can be safely discharged home. **Patients with a poor response to treatment have persistent symptoms and FEV_1 or PEFR of <40% predicted; these patients are usually best observed or admitted.** An incomplete response to treatment, the middle ground, is defined as some persistence of symptoms and a PEF or FEV_1 between 40% and 69% predicted. Most asthmatics treated in the ED fall into this category and may be discharged home safely, although some benefit from prolonged observation or admission[7-10] (Table 69-2).

Patients who fail to improve adequately over a period of several hours because they are in the late phase of their exacerbation and those with significant risk factors for death from asthma are best placed in an observation unit or hospital bed. Many patients can be successfully treated in an ED observation unit with evidence-based care protocols.[46] Intubated patients require intensive care unit admission.

Arrange follow-up care to ensure resolution and to review the long-term medication plan for the chronic management of asthma. High previous relapse rates suggest the need for follow-up within 1 to 4 weeks of the ED visit.[7-10] Deliver an appropriate written discharge plan of action that addresses routine care and care of worsening symptoms (**Table 69-6**).

TABLE 69-6 Checklist for ED Discharge

Intervention	Dose/Timing	Education/Advice	MD/RN Initials
Inhaled medications (e.g., MDI with valved holding chamber; nebulizer)	Select agent, dose, and frequency (e.g., albuterol).	Teach purpose.	
Short-acting β_2-agonist	2–6 puffs every 4 h for ___ days.	Teach and check technique.	
Corticosteroids	Low to medium dose for patients with chronic persistent asthma.	For MDIs, emphasize the importance of using a spacing device or holding chamber.	
Oral medications	Select agent, dose, and frequency (e.g., prednisone 40 milligrams once a day for 10 d).	Teach purpose. Teach side effects.	
Peak flow meter	For selected patients: measure a.m. and p.m. peak expiratory flow, and record best of three tries each time.	Teach purpose. Teach technique. Distribute peak flow diary.	
Follow-up visit	If possible, make appointment for follow-up care with primary clinician or asthma specialist or advise patient to make appointment.	Advise patient (or caregiver) of date, time, and location of appointment, ideally within 7 d of hospital discharge.	
Action plan	Before or at discharge.	Instruct patient (or caregiver) on simple plan for actions to be taken when symptoms, signs, and peak expiratory flow values suggest recurrent airflow obstruction.	

Abbreviation: MDI = metered dose inhaler.

Source: National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services.

Educate patients on asthma triggers, and review all discharge medications and the correct use of the inhaler and a peak flow meter (for daily tracking).

CHAPTER 70

Chronic Obstructive Pulmonary Disease

Rita K. Cydulka
Craig G. Bates

INTRODUCTION AND EPIDEMIOLOGY

Chronic obstructive pulmonary disease (COPD) is characterized by persistent airflow limitation that is generally progressive and associated with an abnormal inflammatory response to noxious particles or gases.[1-6] COPD has two main forms: *chronic bronchitis*, defined in clinical terms, and *emphysema*, defined in terms of anatomic pathology. This traditional categorization is often indistinct, limiting the clinical utility of the definitions.[2-6] **Chronic bronchitis** is the presence of chronic productive cough for 3 months in each of 2 successive years, where other causes of chronic cough have been excluded.[2-6] **Emphysema** results from destruction of bronchioles and alveoli. The World Health Organization's **Global Initiative for Chronic Obstructive Lung Disease** definition of COPD encompasses chronic bronchitis, emphysema, bronchiectasis, and asthma, and acknowledges that most patients have a combination of the different diseases.

COPD accounted for 715,000 U.S. hospitalizations in 2010,[7] with $49.9 billion estimated as the cost for care.[7] The prevalence of COPD in women has doubled in the past few decades, and women now account for >50% of COPD-related deaths; the prevalence has remained stable in men.[8] The prevalence of COPD is highest in those countries that have the greatest cigarette use.

CHRONICALLY COMPENSATED CHRONIC OBSTRUCTIVE PULMONARY DISEASE

PATHOPHYSIOLOGY

Although tobacco smoke is the major risk factor for developing COPD, only 15% of smokers will develop COPD. Occupational dust, chemical exposure, and air pollution are other risk factors for COPD. α_1-Antitrypsin deficiency accounts for <1% of COPD patients.

Irritants, notably tobacco smoke and air pollutants, trigger an increase in inflammatory cells in the airways, lung interstitium, and alveoli. Proteases eventually break down lung parenchyma and stimulate mucus secretion. Mucus-secreting cells replace cells that normally secrete surfactant and protease inhibitors. These changes result in a loss of elastic recoil, narrowing, and collapse of the smaller airways. Mucous stasis and bacterial colonization develop in the bronchi. The earliest objective changes in the evolution of COPD are clinically imperceptible; these early changes are small increases in peripheral airway resistance or lung compliance. Because dyspnea and hypersecretion often progress insidiously, it may take decades before COPD becomes clinically evident. The Global Initiative for Chronic Obstructive Lung Disease guidelines are helpful for the early diagnosis and treatment of COPD (**Table 70-1**),[6] although there is only a weak correlation between forced expiratory volume in 1 second (FEV_1), symptoms, and health-related quality of life.[6]

The central element of chronic lower airway obstruction is impedance to expiratory airflow due to increased resistance or decreased caliber of the small bronchi and bronchioles. Airflow obstruction results from a combination of airway secretions, mucosal edema, bronchospasm, and bronchoconstriction. Exaggerated airway resistance reduces total minute ventilation and increases respiratory work.

In emphysema, alveolar and capillary surfaces are distorted or destroyed, resulting in alveolar hypoventilation and ventilation–perfusion mismatch. The result is hypoxemia and hypercarbia. Sleep may blunt the ventilatory response to hypercarbia. The right ventricle hypertrophies and dilates, resulting in pulmonary hypertension and right ventricular failure. Right ventricular pressure overload is associated with atrial and ventricular arrhythmias. (See chapters 57, "Systemic Hypertension and chapter 58, "Pulmonary Hypertension.")

TABLE 70-1 Classification of COPD Severity[2-6]

Stage	In Patients with FEV_1/FVC <0.7:
Mild COPD	FEV_1 ≥80% predicted
Moderate COPD	FEV_1 between 50% and 79% predicted
Severe COPD	FEV_1 between 30% and 49% predicted
Very severe COPD	FEV_1 <30% predicted

Abbreviations: COPD = chronic obstructive pulmonary disease; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity.

CLINICAL FEATURES

The hallmark symptoms are chronic and progressive dyspnea, cough, and sputum production; these may vary from day to day.[2-6] Minor hemoptysis is frequent, especially in chronic bronchitis and bronchiectasis, although it may herald lung carcinoma. Physical findings may include tachypnea, accessory respiratory muscle use, or pursed-lip exhalation. Lower airway obstruction causes expiratory wheezing, especially during maximum forced exhalation, and prolongation of the expiratory time. Patients with chronic bronchitis exhibit coarse crackles as uncleared secretions move about the central airways. In patients with emphysematous disease, there is expansion of the thorax, impeded diaphragmatic motion, and global diminution of breath sounds. Poor dietary intake and excessive caloric expenditure for the work of breathing cause weight loss, notably in emphysema. In the early stages, arterial blood gas measurements reveal mild to moderate hypoxemia without hypercapnia.

As COPD advances, especially when the FEV_1 falls below 1 L, hypoxemia becomes more severe and hypercapnia develops. Arterial oxygenation worsens during acute exacerbations, exercise, and sleep. Clinical signs of severe COPD include facial vascular engorgement from secondary polycythemia, and tremor, somnolence, and confusion from hypercarbia. Right heart failure may occur and be seen as edema or ascites, and the signs are often disguised or underestimated by the seemingly more overwhelming signs of respiratory disease. If concomitant left heart failure exists, the cardiac auscultatory findings may be overshadowed by the pulmonary inflation abnormalities of COPD.

DIAGNOSIS

The diagnosis of chronic, compensated COPD is confirmed by spirometry: a postbronchodilator FEV_1 of <80% predicted, and a ratio of FEV_1 to forced vital capacity of <0.7.[6] Once the disease progresses, the percentage of predicted FEV_1 is a better measure of disease severity.[2-6]

Chronic bronchitis is not radiographically apparent unless bronchiectasis is present. In emphysema, radiographs show hyperaeration, seen as increased anteroposterior chest diameter, flattened diaphragms, increased parenchymal lucency, and attenuation of pulmonary arterial vascular shadows (**Figure 70-1**).

Distinguishing acute heart failure from COPD is difficult. A B-type natriuretic peptide level <100 picograms/mL supports a diagnosis of COPD; levels >500 picograms/mL have a sensitivity of 80% and positive predictive value of 47% for acute heart failure (see chapter 62, "Respiratory Distress").[9] The ECG detects dysrhythmias or ischemia but does not accurately assess the severity of pulmonary hypertension or right ventricular dysfunction.

FIGURE 70-1. Posteroanterior chest radiograph in a patient with chronic obstructive pulmonary disease.

TREATMENT

Treatment for chronic compensated COPD includes oxygen, pharmacotherapy, measures to decrease mucus secretion, smoking cessation, and pulmonary rehabilitation.

Oxygen Long-term oxygen therapy reduces COPD mortality. The goal of long-term oxygen therapy is to increase the baseline partial pressure of arterial oxygen (Pao_2) to ≥60 mm Hg or the arterial oxygen saturation (Sao_2) to ≥90% at rest. Criteria for long-term oxygen therapy are a Pao_2 ≤55 mm Hg, a Sao_2 ≤88%, or a Pao_2 between 56 and 59 mm Hg when pulmonary hypertension, cor pulmonale (sustained right ventricular failure), or polycythemia is present.[6]

Pharmacotherapy Pharmacotherapy does not alter disease progression but provides symptomatic relief, controls exacerbations, improves quality of life, and improves exercise performance.[10] Inhaled long-acting β_2-agonists are preferred over short-acting formulations, coupled with anticholinergics. Combining bronchodilators with different mechanisms and duration of action may increase bronchodilation without increasing side effects.[11] Combination inhalers of short-acting β_2-agonists with anticholinergic agents include fenoterol/ipratropium and salbutamol/ipratropium. Long-acting inhaled β_2-agonists, such as salmeterol, formoterol, olodaterol, and indacaterol, are used on a regular basis, adding short-acting inhaled β_2-agonists, usually albuterol, as needed. Anticholinergic agents cause bronchodilation by blocking the effect of acetylcholine on muscarinic-3 receptors. Long-acting anticholinergic agents, such as tiotropium, aclidinium, and glycopyrronium, are preferred over short-acting agents, such as ipratropium bromide or oxitropium bromide.[12,13] Bronchodilators often only chronically improve FEV_1 by 10% .

Experts do not recommend long-term systemic corticosteroid therapy for all COPD patients,[14] because only about 20% to 30% improve. Short-term steroid use (days) aids in treating exacerbations. Regular treatment with inhaled corticosteroids is indicated for patients with a documented spirometric response to inhaled corticosteroids, those with an FEV_1 of <50%, or those with predicted and recurrent exacerbations requiring antibiotic treatment or systemic corticosteroids.[6] Long-term treatment with inhaled corticosteroids added to long-acting bronchodilators is recommended for patients at high risk of exacerbation. Combination inhalers with long-acting β_2-agonists plus corticosteroids include formoterol/budesonide, formoterol/mometasone, salmeterol/fluticasone, and vilanterol/fluticasone.[6]

Theophylline is relegated to an adjunct COPD therapy.[15] Theophylline inhibits phosphodiesterase and has an anti-inflammatory effect. It is not commonly used, but can be used in some patients not well controlled with inhaled corticosteroids or long-acting β_2-agonists. Although retrospective studies suggest that statins decrease the rate and severity of exacerbations, rate of hospitalization, and mortality, a large prospective trial failed to demonstrate benefit of daily simvastatin over placebo.[16] Daily azithromycin may decrease acute exacerbations in older patients and those with milder Global Initiative for Chronic Obstructive Lung Disease staging.[17]

Secretion Mobilization Respiratory secretions are kept mobilized by generous oral fluid intake and room humidification. Limit the use of antihistamines, antitussives, mucolytics, and decongestants. Expectorants are not of clear benefit.

Smoking Cessation and Pulmonary Rehabilitation Smoking cessation is the only intervention that can reduce both the rate of decline in lung function[6] and mortality from respiratory causes.[2-6] The ED is a site to attempt smoking cessation interventions.[18] A combination of nicotine replacement therapy or medications and behavioral interventions can assist patients with smoking cessation, especially with referral to a program.[19]

Pulmonary rehabilitation can improve exercise capacity and quality of life and is recommended in patients with moderate to severe COPD. Pneumococcal vaccination and influenza vaccination are key to dampen acute infections.[6]

ACUTE EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Acute exacerbations of COPD are characterized by worsening of respiratory symptoms beyond normal day-to-day variations[20] and are usually triggered by an infection or respiratory irritant. More than 75% of patients with acute exacerbations have evidence of viral or bacterial infection, with up to half specifically due to bacteria.[21,22] Other important triggers for exacerbations are hypoxia, cold weather,[23] β-blockers, narcotics, or sedative-hypnotic agents. The final common pathway for an exacerbation is the release of inflammatory mediators that result in bronchoconstriction, pulmonary vasoconstriction, and mucus hypersecretion. The work of breathing increases due to higher airway resistance and lung hyperinflation. The oxygen demand of respiratory muscles increases, generating additional carbon dioxide and causing hypercapnia, resulting in further physiologic stress.[23] Acute exacerbations of COPD are primarily due to ventilation–perfusion mismatch rather than the expiratory airflow limitation seen with asthma exacerbations.[24] Supplemental oxygen increases blood oxygen concentrations and can help reverse pulmonary vasoconstriction.

CLINICAL FEATURES

The most life-threatening feature of an acute exacerbation is hypoxemia (arterial saturation <90%). Signs of hypoxemia include tachypnea, tachycardia, systemic hypertension, cyanosis, and a change in mental status. With increased work of breathing, carbon dioxide production increases; alveolar hypoventilation creates arterial carbon dioxide retention and respiratory acidosis.

The patient tries to overcome severe dyspnea and orthopnea by sitting in an up-and-forward position, using pursed-lip exhalation, and engaging accessory muscles to breathe. Pulsus paradoxus (a drop of >10 mm Hg in systolic blood pressure during respiratory cycles) may be noted during palpation of the pulse or during blood pressure recording. **Complications, such as pneumonia, pneumothorax, pulmonary embolism, or an acute abdomen, may exacerbate COPD. Other acute triggers include asthma, congestive heart failure, pneumonia, pulmonary embolism, tuberculosis, and metabolic disturbances.**

DIAGNOSIS

With the history, seek causes for exacerbation and triggers plus sputum changes; then assess oxygenation and acid-base status, and perform a physical examination.

Pulse oximetry may identify hypoxemia, and capnography may identify hypercarbia. Arterial blood gas analysis is the best tool in acute evaluation for assessing oxygenation, ventilation, and acid-base disturbances. Arterial blood gases clarify the severity of exacerbation and the probable clinical course. Respiratory failure is characterized by an arterial Pao_2 of <60 mm Hg or an arterial Sao_2 <90% in room air. Respiratory acidosis is present if the partial pressure of carbon dioxide (Pco_2) is >44 mm Hg. If the pH is <7.35, there is an acute and uncompensated component of respiratory or metabolic acidosis present.

In acute respiratory acidosis, the serum bicarbonate rises by 1 mEq/L for each 10-mm Hg increase in Pco_2, and the pH will change by 0.008 × (40 – Pco_2). In chronic respiratory acidosis, the bicarbonate rises by 3.5 mEq/L for each 10-mm Hg increase in Pco_2, and the pH will change by 0.03 × (40 – Pco_2) (Formulas 1 and 2). Changes outside of these ranges suggest an accompanying metabolic disorder (see chapters 15, "Acid-Base Disorders" and 62, "Respiratory Distress").

Frequently, patients with an acute COPD exacerbation are too dyspneic to perform bedside pulmonary function tests, and measurements are often inaccurate.[2-6] Similarly, physical examination and physician estimates of pulmonary function are inaccurate.[25]

Assessment of sputum includes questions about changes in volume and color, especially an increase in purulence. An increase in sputum volume and change in sputum color suggest a bacterial infection and the need for antibiotic therapy.[24,26] Sputum cultures usually contain mixed flora and do not help guide ED antibiotic selection.[2-6]

Ancillary Studies Radiographic abnormalities are common in COPD exacerbation and may identify the underlying cause of the exacerbation, such as pneumonia, or may identify an alternative diagnosis such as acute heart failure.[27]

The ECG can identify ischemia, acute myocardial infarction, cor pulmonale, and dysrhythmias. Measure levels in patients who take theophylline. Other tests, such as CBC, electrolytes, B-type natriuretic peptide, D-dimers, and CT angiography of the chest, are chosen based on clinical findings.

TREATMENT

The goals of treatment are to correct tissue oxygenation, alleviate reversible bronchospasm, and treat the underlying cause (**Table 70-2**). Factors that influence therapy in the ED include a patient's mental status changes; the degree of reversible bronchospasm; recent medication usage and assessment for drug toxicity; prior history of exacerbation courses, hospitalization, and intubation; presence of contraindications to any drug or drug class; and specific causes or complications from the exacerbation. Patients who do not respond as expected to standard therapy should prompt a reevaluation for other potentially life-threatening issues. See **Table 70-3** for an overview of the differential diagnosis of COPD exacerbations.

TABLE 70-2 ED Management of COPD Exacerbations[2-6]

Assess severity of symptoms
Administer controlled oxygen
Continuous cardiovascular status monitoring
Perform arterial blood gas measurement after 20–30 min if arterial oxygen saturation remains <90% or if concerned about symptomatic hypercapnia
Administer bronchodilators
β_2-Agonists and/or anticholinergic agents by nebulization or metered-dose inhaler with spacer
Add oral or IV corticosteroids
Consider antibiotics if increased sputum volume, change in sputum color, fever, or suspicion of infectious etiology of exacerbation
Consider adding IV methylxanthine if above treatments do not improve symptoms
Consider noninvasive mechanical ventilation
Evaluation may include chest radiograph, CBC with differential, basic metabolic panel, ECG
Address associated comorbidities

TABLE 70-3 Critical Differential Diagnosis of Chronic Obstructive Pulmonary Disease (COPD) Exacerbations[2-6]

Diagnosis	Clinical Features	Caveats
Asthma	Earlier onset Varying symptoms Family history Reversible airflow	Can coexist with COPD. Many patients diagnosed with asthma actually have COPD or mixed asthma-COPD
CHF	Presence of orthopnea (LR, 2.0) and dyspnea with exertion (LR, 1.3) slightly favors CHF Jugular venous distention, hepatojugular reflux, bibasilar rales Chest x-ray may show cardiomegaly or interstitial edema BNP <100 picograms/mL not likely to be CHF; BNP >500 picograms/mL more likely to be CHF	Can coexist with COPD. Shares some historical elements also found in COPD. Multiple conditions can falsely elevate or decrease the BNP level.
PE	Risk factors include older age, recent surgery or trauma, prior venous thromboembolic disease, hereditary thrombophilia, malignancy, smoking, and use of medications containing estrogen Patients with intermediate to high pretest probability may require further testing, such as CT angiography; D-dimer may be useful in ruling out PE in low-risk patients	20%–25% of patients with a severe COPD exacerbation with an unclear trigger have a PE. Triad of PE (pleuritic chest pain, dyspnea, tachycardia, and hypoxemia) unusual.
ACS	Obtain ECG or troponin in those with chest pain or dyspnea and risk factors for ACS	Dyspnea may be the primary complaint in patients with ACS.
Pneumothorax	Obtain chest x-ray, US, or CT	COPD is a risk factor for spontaneous pneumothorax.
Pneumonia	Obtain chest x-ray	Frequently coexists with a COPD exacerbation.

Abbreviations: ACS = acute coronary syndrome; BNP = B-type natriuretic peptide; CHF = congestive heart failure; LR, likelihood ratio; PE = pulmonary embolism.

Oxygen **Administer oxygen to raise the Pao_2 above 60 mm Hg or the Sao_2 above 90%.** Use any of the following devices: standard dual-prong nasal cannula, simple facemask, Venturi mask, or nonrebreathing mask with reservoir and one-way valve. Because oxygen administration may produce hypercapnia, arterial blood gases and/or continuous end-tidal carbon dioxide and oxygen saturation monitoring with venous blood gases will allow optimal assessment of the Pco_2 and acid-base status. It may take 20 to 30 minutes from administration of supplemental oxygen for improvement to occur. If adequate oxygenation is not achieved or respiratory acidosis develops, assisted ventilation may be required.

β_2-Adrenergic Agonists Short-acting β_2-agonists and anticholinergic agents are first-line therapies in the management of acute, severe COPD.[2-6] Both lead to improved clinical outcomes and shorter ED lengths of stay, especially when used together.[2-6] Aerosolized forms, using nebulizer or metered-dose inhalers, deliver drug to the target area optimally and minimize systemic toxicity. β_2-Agonists are best given every 30 to 60 minutes if tolerated.[2-6] Nebulized aerosols every 20 minutes may result in more rapid improvement of FEV_1, but more frequent side effects,[28] including tremor, anxiety, and palpitations. Continuous cardiac monitoring is helpful, especially for patients with heart disease.

Anticholinergics Some guidelines favor β_2-agonists as a first-line therapy, whereas others favor anticholinergic agents. Ipratropium bromide given as a single dose by metered-dose inhaler with a spacer or as

an inhalant solution by nebulization (0.5 milligram or 2.5 mL of the 0.02% inhalant solution) is the usual agent of choice, although aerosolized glycopyrrolate (2 milligrams in 10 mL of saline) is also effective. Side effects are minimal and appear to be limited to dry mouth and an occasional metallic taste.

Evidence regarding the efficacy of the combination of a β_2-adrenergic agent and an anticholinergic agent compared with a single agent alone is conflicting, although many physicians favor using this combination initially and some favor using it if the response to maximal doses of a single bronchodilator is poor. Long-acting inhaled anticholinergics, such as tiotropium, aclidinium, and glycopyrronium, are not used for the acute management of COPD.[2-6]

Corticosteroids The use of a short course (5 to 7 days) of systemic steroids improves lung function and hypoxemia and shortens recovery time in acute COPD exacerbations.[29] Use of corticosteroids in the ED does not affect the rate of hospitalization but does decrease the rate of return visits. The lack of effect on hospitalization rates is likely due to the approximately 6-hour delay before onset of action. There appears to be no clear benefit from a dose >40 to 60 milligrams of oral prednisone daily.[29] Hyperglycemia is the most common adverse effect.

Antibiotics Prescribe antibiotics if there is evidence of infection, such as change in volume of sputum and increased purulence of sputum.[26] **Choose agents directed at the most common pathogens associated with COPD exacerbation: *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.** There is no specific agent shown to be superior.[24,26] Initial antibiotics include macrolides (azithromycin), tetracyclines (doxycycline), or amoxicillin with or without clavulanic acid. There is little evidence regarding the duration of treatment, which ranges from 3 to 14 days.

Methylxanthines Methylxanthines, such as theophylline (oral) and aminophylline (parenteral), inhibit phosphodiesterases and may enhance respiration in two ways: by improving the mechanics of breathing (at the smooth muscle and diaphragm) and through an anti-inflammatory effect that happens at lower doses than used previously for bronchodilation and potentiating exogenous steroid effects. Data are conflicting on the value in acute COPD care, and these agents may induce nausea and vomiting.[30,31] The therapeutic index is narrow, so drug levels must be monitored. Methylxanthines (aminophylline 3 to 5 milligrams/kg IV over 20 minutes) are third-line options after inhaled therapies and steroids and when first-line therapies fail.

Noninvasive Ventilation Indications and relative contraindications of noninvasive ventilation are listed in **Table 70-4** Noninvasive ventilation can be delivered by nasal mask, full facemask, or mouthpiece. Patients with respiratory failure who receive noninvasive ventilation have better outcomes in terms of intubation rates, short-term mortality rates, symptomatic improvement, and length of hospitalization.[32] Disadvantages of noninvasive positive-pressure ventilation include slower correction of gas exchange abnormalities, risk of aspiration, inability to control airway secretions directly, and possible complications of gastric distention and skin necrosis. **Contraindications to noninvasive ventilation include an uncooperative or obtunded patient, inability of the patient to clear airway secretions, hemodynamic instability, respiratory arrest, recent facial or gastroesophageal surgery, burns, poor mask fit, or extreme obesity**. Noninvasive ventilation methods are discussed in detail elsewhere (see chapter 28, Noninvasive Airway Management).

All patients receiving noninvasive positive-pressure ventilation require continuous cardiorespiratory monitoring and frequent reassessment for setting changes and for tolerance of therapy.

Assisted Ventilation **Mechanical ventilation is indicated if there is evidence of respiratory muscle fatigue, worsening respiratory acidosis, deteriorating mental status, or refractory hypoxemia (Table 70-5).** The goals of assisted ventilation are to rest ventilatory muscles and to restore adequate gas exchange. After endotracheal intubation, the methods most commonly used are assist control ventilation, pressure support ventilation, or pressure support ventilation in combination with intermittent mandatory ventilation. Adverse events associated with invasive ventilation include pneumonia, barotrauma, and inability to wean the COPD patient from the ventilator.

Current evidence does not support the use of a mixture of helium and oxygen or magnesium in the treatment of an acute COPD exacerbation.

TABLE 70-4 Indications and Relative Contraindications for Noninvasive Ventilation[2-6]

Selection criteria	Acidosis (pH <7.36)/hypercapnia ($Paco_2$ >50 mm Hg)/oxygenation deficit (Pao_2 <60 mm Hg or Sao_2 <90%)
	Severe dyspnea with clinical signs like respiratory muscle fatigue or increased work of breathing
Exclusion criteria (any)	Respiratory arrest
	Cardiovascular instability (hypotension, arrhythmias, myocardial infarction)
	Change in mental status; uncooperative patient
	High aspiration risk
	Viscous or copious secretions
	Recent facial or gastroesophageal surgery
	Craniofacial trauma
	Fixed nasopharyngeal abnormalities
	Burns
	Extreme obesity

Abbreviations: $Paco_2$ = partial pressure of arterial carbon dioxide; Pao_2 = partial pressure of arterial oxygen; Sao_2 = arterial oxygen saturation.

TABLE 70-5 Indications for Intubation with Mechanical Ventilation[2-6]

Unable to tolerate noninvasive ventilation (NIV) or NIV failure
Respiratory or cardiac arrest
Respiratory failure
Decreased consciousness or increased agitation
Massive aspiration
Persistent inability to remove respiratory secretions
Hypotension
Persistent hypoxemia despite optimal respiratory treatment
Hemodynamic instability

DISPOSITION AND FOLLOW-UP

Patients who fail to improve, those who deteriorate despite medical therapy, those with significant comorbidity, or those without an intact social support system are admitted. Objective criteria regarding hospital admission, observation unit stay, and ED discharge are lacking. The Global Initiative for Chronic Obstructive Lung Disease guidelines help guide the ED disposition decision-making process (**Tables 70-6** and **70-7**). Select patients without respiratory failure may avoid hospitalization with nurse-administered home care ("hospital at home care").[33] After ED discharge, 25% to 43% of patients with COPD exacerbation show ongoing or relapse of symptoms.[34-36]

The following are associated with a higher risk for relapse within 2 weeks after an ED visit: five or more ED or clinic visits in the past year,

TABLE 70-6 Indications for Hospital Admission[2-6]

Marked increase in intensity of symptoms, such as sudden development of resting dyspnea or inability to walk from room to room
Failure of exacerbation to respond to initial medical management
Significant comorbidities
Newly occurring dysrhythmias, heart failure
Frequent exacerbations and/or frequent relapse after ED treatment
Older age
Insufficient home support

TABLE 70-7 Indications for Intensive Care Admission[2-6]

Severe dyspnea that responds inadequately to initial emergency therapy
Respiratory or ventilatory failure (current or impending) despite supplemental oxygen and noninvasive positive-pressure ventilation
Decreasing level of consciousness or increasing confusion or agitation
Hemodynamic instability
Presence of comorbidities leading to end-organ failure

the amount of activity limitation (based on a 4-point scale), the initial respiratory rate (for each 5 breaths/min over 16 breaths/min), and use of oral corticosteroids before arrival in the ED.[34-36]

If discharging from the ED or observation unit, arrange the following: (1) a supply of home oxygen, if needed; (2) adequate and appropriate bronchodilator treatment (usually a metered-dose inhaler with a spacer *and* teaching; nebulized therapies are reserved for those who cannot use the metered-dose inhaler); (3) short course of oral corticosteroids[2-6]; and (4) a follow-up appointment with the primary care physician or pulmonologist, preferably within a week. Reassess inhaler technique, reinforce importance of completion of steroid therapy and antibiotics, if prescribed, and review management plan.

Gastrointestinal Disorders

CHAPTER 71

Acute Abdominal Pain

Mary Claire O'Brien

INTRODUCTION AND EPIDEMIOLOGY

More adult patients visit the ED for "stomach and abdominal pain, cramps, or spasms" than for any other chief complaint. Demographics (age, gender, ethnicity, family history, sexual orientation, cultural practices, geography) influence both the incidence and the clinical expression of abdominal disease. History, physical examination, and laboratory studies can be helpful, but imaging is often required to make a specific diagnosis. Clinical suspicion for serious disease is especially important for patients in high-risk groups.

PATHOPHYSIOLOGY

Abdominal pain is divided into three neuroanatomic categories: visceral, parietal, and referred.

VISCERAL PAIN

Obstruction, ischemia, or inflammation can cause stretching of unmyelinated fibers that innervate the walls or capsules of organs, resulting in visceral pain. Visceral pain is often described as "crampy, dull, or achy," and it can be either steady or intermittent (colicky). Because the visceral afferent nerves follow a segmental distribution, visceral pain is localized by the sensory cortex to an approximate spinal cord level determined by the embryologic origin of the organ involved (**Table 71-1**).

Because intraperitoneal organs are bilaterally innervated, stimuli are sent to both sides of the spinal cord, causing intraperitoneal visceral pain to be felt in the midline, independent of its right- or left-sided anatomic origin. For example, stimuli from visceral fibers in the wall of the appendix enter the spinal cord at about T10. When obstruction causes appendiceal distention in early appendicitis, pain is initially perceived in the midline periumbilical area, corresponding roughly to the location of the T10 cutaneous dermatome.

PARIETAL PAIN

Parietal (somatic) abdominal pain is caused by irritation of myelinated fibers that innervate the parietal peritoneum, usually the portion covering the anterior abdominal wall. Because parietal afferent signals are sent from a specific area of peritoneum, parietal pain—in contrast to visceral pain—can be localized to the dermatome superficial to the site of the painful stimulus. As the underlying disease process evolves, the symptoms of visceral pain give way to the signs of parietal pain, causing tenderness and guarding. As localized peritonitis develops further, rigidity and rebound appear. Patients with peritonitis generally prefer to remain immobile.

REFERRED PAIN

Referred pain is felt at a location distant from the diseased organ. Referred pain patterns are also based on developmental embryology. For example, the ureter and the testes were once anatomically contiguous and therefore share the same segmental innervations. Thus acute ureteral obstruction is often associated with ipsilateral testicular pain. Referred pain is usually perceived on the same side as the involved organ, because it is not mediated by fibers that provide bilateral innervation to the cord. Referred pain is felt in the midline only if the pathologic process is also located in the midline.

CLINICAL FEATURES

CLINICAL RISK

To determine the urgency and method of the diagnostic approach, we recommend the use of a pragmatic scheme based on patient acuity and the identification of risk factors.

- Patient Acuity: Is this patient critically ill? If so, simultaneously resuscitate and evaluate.
- Risk Factors: Are there special conditions or risk factors that affect clinical risk or mask the disease process?

Patient Acuity: Is This Patient Critically Ill? Critically ill patients need immediate stabilization. Markers of high acuity include extremes of age, severe pain of rapid onset, abnormal vital signs, dehydration, and evidence of visceral involvement (e.g., pallor, diaphoresis, vomiting). The intensity of abdominal pain may bear no relationship to the severity of illness. Serious illness may be present even if vital signs are normal, particularly in high-risk groups such as the elderly and the immunocompromised. Shock that develops rapidly after the onset of acute abdominal pain is usually the consequence of intra-abdominal hemorrhage. Systolic pressure does not drop until blood loss reaches 30% to 40% of normal blood volume. Tachycardia is a useful parameter for the assessment of volume depletion, but its absence does not exclude blood/fluid loss. If pulse and blood pressure are in the normal range but there is reason to suspect intravascular volume depletion, obtain orthostatic vital signs. An increase in pulse rate of 30 beats/min after standing for 1 minute (or near-syncope that develops with a lesser increase) represents the loss of a liter of blood or its equivalent (a 20% blood loss for an average adult; roughly 3 L of normal saline).[1] The presence of orthostatic tachycardia is useful, but its absence does not exclude severe bleeding. Orthostatic hypotension is a later finding, representing the failure of sympathetic reflex tachycardia to maintain cardiac output. The threshold of 20 points of pulse change may not be applicable to patients on medications such as β-blockers, diabetic patients (who may have autonomic neuropathy), and the elderly (due to the effects of aging on the cardiac conduction system). "Orthostatics" should not be performed in patients who are already hypotensive. Tachypnea may indicate a cardiopulmonary process, metabolic acidosis, anxiety, or pain. Temperature is neither sensitive nor specific for disease process or patient condition. The presence or absence of fever cannot be used to distinguish surgical from medical disease.

Resuscitation of the critically ill patient with abdominal pain includes a cardiac monitor, oxygen (2 to 4 L/min via nasal cannula or mask), large-bore IV access, and an isotonic fluid bolus adjusted for age, weight, and cardiovascular status. For critically ill patients, blood samples should be drawn at the time of IV insertion, including, at a minimum, electrolytes, BUN and creatinine, CBC with platelets, clotting studies, and a type and antigen screen of blood. Order cross-matched blood if hemorrhage is suspected or if urgent transfusion is anticipated. In the presence of circulatory collapse, visualization of an enlarged aorta is

TABLE 71-1 Visceral Pain Features

Embryologic Origin	Involved Organs	Location of Visceral Pain
Foregut	Stomach, first/second parts of duodenum, liver, gallbladder, pancreas	Epigastric area
Midgut	Third/fourth parts of duodenum, jejunum, ileum, cecum, appendix, ascending colon, first two thirds of transverse colon	Periumbilical area
Hindgut	Last one third of transverse colon, descending colon, sigmoid, rectum, intraperitoneal GU organs	Suprapubic area

taken as de facto evidence of leakage or rupture, requiring immediate surgery. Bedside ED US can visualize and measure the abdominal aorta.[2,3] **Perform bedside US to identify abdominal aortic aneurysm and perform FAST if intra-abdominal hemorrhage is suspected.**[2,3]

Risk Factors: Are There Special Conditions or Risk Factors That Affect Clinical Risk or Mask the Disease Process? Identify pertinent past medical illness (diabetes, heart disease, hypertension, liver disease, renal disease, human immunodeficiency virus status, sexually transmitted diseases), previous abdominal surgeries, pregnancies and menstrual history (deliveries, abortions, ectopics), medications (steroids, immune suppressants, acetylsalicylic acid/nonsteroidal anti-inflammatory drugs, antibiotics, laxatives, narcotics, fertility agents, intrauterine devices, chemotherapeutic agents), allergies, and any recent trauma. Ask about previous episodes of similar abdominal pain, diagnostics, and treatments. Review previous medical records. Obtain a social history that includes habits (tobacco, alcohol, other drug use), occupation, possible toxic exposures, and living circumstances (homeless, dwelling heated, running water, living alone, other family members ill with similar symptoms).

A number of conditions camouflage critical illness in patients with acute abdominal pain. High-risk groups include patients with cognitive impairment secondary to dementia, intoxication, psychosis, mental retardation, or autism; patients who cannot communicate effectively because of aphasia or language barriers; patients in whom physical or laboratory findings may be minimal (the elderly) or obscured (patients with spinal cord injury); asplenic patients; neutropenic patients; transplant patients; patients whose immune systems are impaired by illness (human immunodeficiency virus; chronic renal disease; diabetes, cirrhosis, hemoglobinopathy; malnutrition, chronic malignancy, autoimmune disease, mycobacterial infection); and patients taking immune-suppressive or immune-modulating medications, such as steroids, calcineurin inhibitors, tumor necrosis factor inhibitors, antimetabolic agents, monoclonal and polyclonal antibodies, and chemotherapeutic agents.

In general, patients with mild to moderate immune dysfunction have delayed or atypical presentations of common diseases. Patients with severe immune dysfunction are more likely to present with opportunistic infections. The CD4 count is the most important measure of immune competency in patients with acquired immunodeficiency syndrome. **Patients with CD4 counts over 200/mm^3 are much less likely to have opportunistic infections.**

PHYSICAL EXAMINATION

Obtain a clear description of the pain itself **(PPQRSTT: provocative/palliative factors, quality, radiation, associated symptoms, timing, and what the patient has taken for the pain).**

Before the complete physical examination, take a few moments to gain the patient's trust by explaining what needs to be done, exposing only what needs to be seen, and re-covering exposed parts of the body sequentially. Provide patient privacy. Note the patient's skin (color, temperature, turgor, perfusion status), and perform a targeted heart and lung examination.

Inspection Inspect the abdomen for signs of distention (ascites, ileus, obstruction, volvulus), obvious masses (hernia, tumor, aneurysm, distended bladder), surgical scars (adhesions), ecchymoses (trauma, bleeding diathesis), and stigmata of liver disease (spider angiomata, caput medusa).

Auscultation of Bowel Sounds Bowel sounds are nonspecific diagnostic signs. Decreased bowel sounds suggest ileus, mesenteric infarction, narcotic use, or peritonitis. Hyperactive bowel sounds may be noted in small bowel obstruction.

Percussion Liver size can be estimated by the presence of percussion dullness in the midclavicular line, except in cases of severe bowel distention. A fluid wave may suggest ascites, and tympany may suggest dilated loops of bowel.

Palpation The vast majority of clinical information is acquired through gentle palpation, using the middle three fingers, and saving the painful area for last. Voluntary guarding (contraction of the abdominal musculature in anticipation of or in response to palpation) can be diminished by asking patients to flex the knees. Those who remain guarded after this maneuver will often relax if the clinician's hand is placed over the patient's, and the patient is then asked to use his or her own hand to palpate the abdomen. Distracting the patient with conversation may divert attention from the examination. Optimally, the patient's tenderness will be confined to one of the four traditional abdominal quadrants (right upper, right lower, left upper, left lower), and pain location can be used to generate a differential diagnosis. Often, this is not the case, and one finds more diffuse tenderness involving one or more of the four abdominal quadrants. Peritoneal irritation is suggested by rigidity (involuntary guarding or reflex spasm of abdominal muscles), as is pain referred to the point of maximum tenderness when palpating an adjacent quadrant. Rebound tenderness, often regarded as the *sine qua non* for peritonitis, has several important limitations. In patients with peritonitis, the combination of rigidity, referred tenderness, and pain with coughing usually provides sufficient diagnostic confirmation that little additional information is gained by eliciting the unnecessary pain of rebound. More than one third of patients with surgically proven appendicitis do not have rebound tenderness.[4] False positives occur without peritonitis, perhaps due to a nonspecific startle response. One might reasonably question whether rebound has sufficient predictive value to justify the discomfort it causes patients.

Evaluate the abdominal aorta, particularly in patients >50 years of age with acute abdominal, flank, or low back pain. Palpation cannot reliably exclude abdominal aortic aneurysm, and the presence or absence of femoral pulses is generally not helpful in the clinical diagnosis of abdominal aortic aneurysm.

It is wise to perform a pelvic examination in the evaluation of lower abdominal pain in women of reproductive age who have not had a complete hysterectomy. The presence of peritoneal signs, cervical motion tenderness, and unilateral or bilateral abdominal and/or pelvic tenderness suggests pelvic infection, or ectopic gestation in pregnant women. In males, hernia, testicular, and prostate examinations are indicated because disorders of these structures can cause lower abdominal pain.

The rectal examination does not increase diagnostic accuracy beyond what has already been obtained by other components of the physical examination. The main value of the rectal examination is the detection of grossly bloody, maroon, or melanotic stool.

One common approach to the evaluation of acute abdominal pain is to use the location of the pain (diffuse, right upper quadrant, right lower quadrant, left upper quadrant, left lower quadrant) to guide the generation of a differential diagnosis (**Figure 71-1**).[5]

Alternatively, abdominal crises may be grouped according to presenting symptomatology: pain, vomiting, abdominal distention, muscular rigidity, and/or shock (**Table 71-2**).

Although the location of the patient's pain and the grouping of symptoms can both help to differentiate among known diseases, clinical suspicion and an understanding of the individual is paramount, because the causes of acute abdominal pain vary considerably with patient demographics. For example, older adults are more likely than younger adults to have biliary disease, diverticulitis, and bowel obstruction. Appendicitis occurs more commonly in younger adults. In the words of Sir William Osler, it is important to know "what sort of patient has the disease."

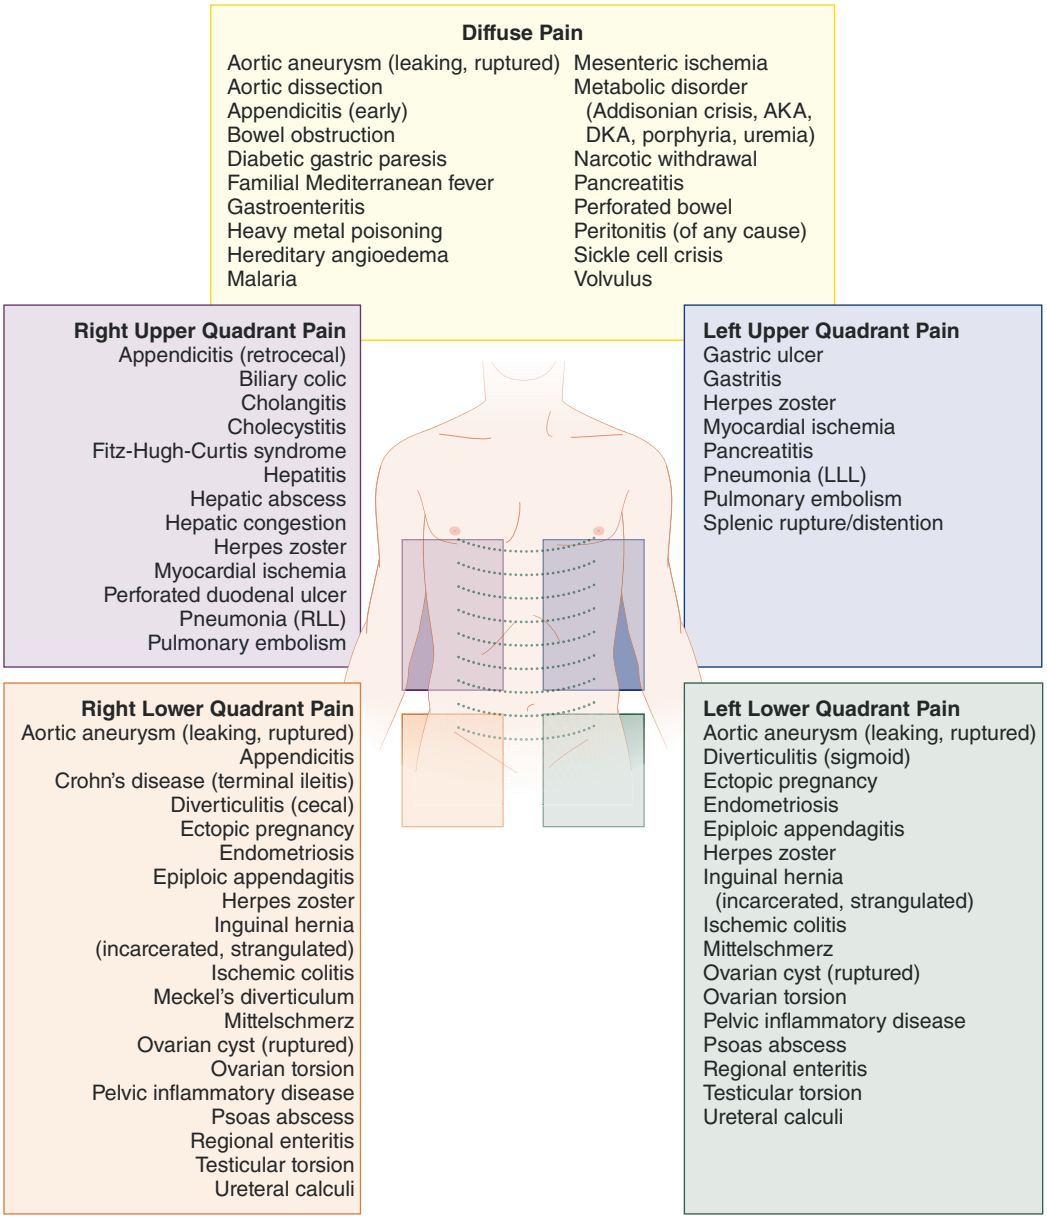

FIGURE 71-1. Differential diagnosis of acute abdominal pain by location. AKA = alcoholic ketoacidosis; DKA = diabetic ketoacidosis; LLL = left lower lobe; RLL = right lower lobe.

SYMPTOM TREATMENT AND FURTHER CLINICAL DIAGNOSIS

At this point, provide symptomatic relief. **Opioid analgesia relieves pain and will not obscure abdominal findings, delay diagnosis, or lead to increased morbidity/mortality.**[6,7] Do not withhold analgesia from patients with acute undifferentiated abdominal pain. The information on the safety of opioids cannot be extrapolated to nonsteroidal anti-inflammatory drugs such as parenteral ketorolac because nonsteroidal anti-inflammatory drugs are not pure analgesics and can mask early peritoneal inflammation.

Administer antiemetics as needed. A Cochrane review[8] reported that ondansetron and metoclopramide reduced postoperative nausea and vomiting.[8] Both drugs had equivalent effects. The dosage of IV ondansetron is 4 milligrams or 8 milligrams (0.45 milligram/kg total daily) to a maximum of 32 milligrams daily. Headache is a reported side effect. The dosage of IV metoclopramide is 10 milligrams, given slowly to minimize extrapyramidal side effects. Sometimes, 25 to 50 milligrams of IV diphenhydramine is administered as prophylaxis against dystonia. Patients with akathisia or dystonic reactions from metoclopramide cannot tolerate any other agents of the same class and should be given ondansetron. Such reactions are extremely rare from ondansetron. (See chapter 72, Nausea and Vomiting, for further discussion of antiemetics.)

Consider placement of nasogastric and urinary catheters. Nasogastric aspirate may confirm upper GI bleeding, and nasogastric suction may be used to decompress a bowel obstruction. A urinary catheter will relieve bladder obstruction, and hourly urine output helps to gauge renal perfusion.

LABORATORY TESTING

Laboratory testing does not take the place of a conscientious history and physical examination, and there is no evidence to support the usefulness of "routine abdominal labs." Information obtained by laboratory testing should help refine the differential diagnosis or alter the plan of treatment. **Table 71-3** lists laboratory studies that may be appropriate in

TABLE 71-2 Groupings of Known Abdominal Diseases by Symptoms

Pain/vomiting/ ± rigidity	Pain/vomiting/distention	Pain (± vomiting)
Acute pancreatitis	Bowel obstruction	Acute diverticulitis
Diabetic gastric paresis	Cecal volvulus	Adnexal torsion
Diabetic ketoacidosis		Mesenteric ischemia
Incarcerated hernia		Myocardial ischemia*
		Testicular torsion
Pain/shock	**Pain/shock/rigidity**	**Distention (± pain)**
Abdominal sepsis	Perforated appendix	Elderly with bowel obstruction/volvulus
Aortic dissection	Perforated diverticulum	
Hemorrhagic pancreatitis	Perforated ulcer	
Leaking/ruptured abdominal aortic aneurysm	Ruptured esophagus Splenic rupture	
Mesenteric ischemia (late)		
Myocardial ischemia*		
Ruptured ectopic pregnancy		

Note: These symptoms and etiologic groupings are a guideline and are not intended to be a rule.

*The symptoms of myocardial ischemia are variable.

TABLE 71-3 Suggested Laboratory Studies for Goal-Directed Clinical Testing in Acute Abdominal Pain

Laboratory Test	Clinical Suspicion
Amylase	Pancreatitis (if lipase is not available)
Lipase	Pancreatitis
β-Human chorionic gonadotrophin	Pregnancy Ectopic or molar pregnancy
Coagulation studies (prothrombin time/ partial thromboplastin time)	GI bleeding End-stage liver disease Coagulopathy
Electrolytes	Dehydration Endocrine or metabolic disorder
Glucose	Diabetic ketoacidosis Pancreatitis
Gonococcal/chlamydia testing	Cervicitis/urethritis Pelvic inflammatory disease
Hemoglobin	GI bleeding
Lactate	Mesenteric ischemia
Liver function tests	Cholecystitis Cholelithiasis Hepatitis
Platelets	GI bleeding
Renal function tests	Dehydration Renal insufficiency Acute renal failure
Urinalysis	Urinary tract infection Pyelonephritis Nephrolithiasis
ECG	Myocardial ischemia or infarction

(Reproduced with permission from Fitch M: Utility and limitations of laboratory studies, in Cline DM, Stead LG (eds): *Abdominal Emergencies*. New York. McGraw-Hill Medical; 2008, p. 19.)

the evaluation of acute abdominal pain based on the clinical suspicions. Obtain an electrocardiogram for patients with upper abdominal pain, especially in elderly patients.

Be aware of the limitations of laboratory studies. The CBC does not offer sufficiently powerful likelihood ratios to revise disease probability. In a review of adult patients with appendicitis, only 65% had a serum WBC ≥12,000 mm^3.[9] A higher degree of leukocytosis was not associated with perforation. One approach to the use of the WBC is to take note only of high threshold abnormalities (e.g., a very elevated WBC [>20,000/mm^3]) and to resist the temptation to draw any reassurance from a "normal" WBC. **A single WBC cannot exclude serious or surgical disease.** Among patients with acute mesenteric ischemia, up to 25% have a normal serum lactate on initial presentation,[10] and studies on the utility of serum lactate values are limited by (among other things) varying intervals from the onset of symptoms to ED presentation. In a large study of patients with acute pancreatitis, serum lipase was 90% sensitive and 93% specific when drawn at the time of ED presentation.[11] Nineteen patients had pancreatitis with normal initial lipase levels; 14 of these had elevated lipase levels when the test was repeated later on the day of admission.[11]

DIAGNOSTIC IMAGING

Diagnostic imaging does not take the place of a conscientious history and physical examination. Not all patients with abdominal pain require imaging. Moreover, if the clinical impression suggests that the need for surgery is obvious, it is not necessary to wait for diagnostic imaging before surgical consultation.

Plain Radiographs In some institutions, an "abdominal series" includes an upright abdomen; in others, an upright chest; in still others, only a single supine film is obtained. If plain radiographs are obtained, make sure the inguinal region is included to help identify incarcerated hernia. Radiographic evidence of small bowel obstruction may be seen 6 to 12 hours before symptoms develop. However, signs may be absent in up to half of patients with developing small bowel obstruction.[12,13] Although an upright chest film is better to detect free air than an abdominal film, the sensitivity for small amounts of free air is only about 30%.[12,13] The use of plain abdominal radiographs should be limited to screening for obstruction, sigmoid volvulus, perforation, or severe constipation.

Ultrasound In adults, an abdominal US examination can visualize the gallbladder, pancreas, kidneys and ureters, urinary bladder volume, and aortic dimensions. Abdominal US is not useful for diagnosis of small or large bowel disorders. The detection of free air or appendicitis by US is operator dependent and limited by patient obesity and bowel gas.[14]

US is the preferred modality for the evaluation of biliary tract disease. When acute cholecystitis or biliary dyskinesia is strongly suspected but the US is normal, cholescintigraphy is recommended. Use bedside US to identify the urinary bladder and to determine whether acute urinary retention is the cause of acute lower abdominal pain and distention.

Abdominal-Pelvic CT Scanning CT scanning is a sensitive and specific diagnostic tool for many causes of abdominal pain. Its clinical usefulness is balanced by delays in surgical management and increase in ED throughput if oral contrast is used, and by radiation dose.[15] The radiation dose of abdominal CT is about 10 msV, about 10 times that of plain abdominal radiographs.[12]

Options for CT scanning include noncontrast studies, or PO, PR, and/or IV contrast. Protocols vary depending on institutional, surgical, and radiology protocols; the prior probability of specific GI disorders in the patient population served; and individual radiologist preference. There are many contradictory studies on the best approach, especially for undifferentiated abdominal pain, for which the differential diagnosis is broad. Most studies have focused on the CT diagnosis of appendicitis.[16]

Noncontrast abdominopelvic CT has about 97% specificity for the diagnosis of acute appendicitis, with the possible exception of patients with a low BMI (<25). Noncontrast CT is the preferred imaging modality for the diagnosis of kidney and ureteral stones.

The use of oral contrast for the ED diagnosis of acute abdominal pain as a general protocol has been called into question.[16,17] Factors that affect

the usefulness of oral contrast include patient vomiting, type and volume of oral contrast administered, transit time to the distal colon (variable, may be several hours), gastric emptying time (delayed induction of anesthesia, several hours), inadequate bowel opacification, and prolonged ED throughput time.[16] However, PO contrast CT is the imaging modality of choice in many institutions for suspected GI abscess, perforation, or fistula.

Rectal contrast CT can identify distal large bowel obstruction if that is the focused question.

IV contrast CT provides superior visualization of bowel mucosa, visceral organs, and vascular structures. It can identify small and large bowel obstruction and the transition point. It is the initial test of choice for suspected abdominal aortic aneurysm rupture or mesenteric ischemia. The risks of IV contrast are nephrotoxicity and allergic reactions. **If the serum creatinine is >1.5 or the glomerular filtration rate is <60, the use of IV contrast is generally not recommended except in life-threatening situations.** Patients receiving IV contrast should be hydrated with 1 to 2 L of normal saline as long as there are no contraindications to vigorous hydration. IV contrast is contraindicated in patients with a history of allergy to IV contrast or to iodine. There is no literature to support an allergy to shellfish as a contraindication to the use of IV contrast.

Common diagnoses for acute abdominal pain are listed in **Table 71-4**.

TREATMENT

ANTIBIOTICS

Antibiotics are indicated for suspected abdominal sepsis and peritonitis. Endogenous gut flora cause abdominal infections in the GI or GU tract. In all intra-abdominal nongynecologic infections, coverage should minimally be targeted at anaerobes and facultative aerobic gram negatives. An exception to this generalization is the need to provide additional coverage for gram-positive aerobes (e.g., *Pneumococcus*) in spontaneous (primary) bacterial peritonitis. Antibiotic treatment is summarized in **Table 71-5**.

The treatment of pelvic inflammatory disease (PID) requires different antibiotic combinations than do GI and GU infections. (For a detailed discussion, see chapter 103, Pelvic Inflammatory Disease.)

DISPOSITION AND FOLLOW-UP

Surgical consultation is required once a surgical diagnosis is made. Otherwise, consider hospital admission or observation for high-risk patients with acute abdominal pain. Patients who are elderly, immunocompromised, unable to communicate, or cognitively impaired are at especially high risk. Patients who appear ill, have intractable pain or vomiting, are unable to comply with discharge or follow-up instructions, or who lack appropriate social support should also be considered for admission. **Patients with an unclear diagnosis at discharge, even if the CT scan is "negative" (or for whom response to treatment is a concern) should be asked to return to the ED or their primary care physician for re-evaluation within 12 hours.** Discharge instructions should address diet (e.g., clear liquids only, push fluids, no fatty foods, no acidic foods) and medications (e.g., antacids, analgesics, avoid narcotics). The patient and the patient's family should understand that the diagnosis is uncertain, and they should know which symptoms warrant a return to the ED (e.g., increased/different pain, fever, vomiting, syncope, bleeding).

SPECIAL POPULATIONS

WOMEN

Gynecologic and nongynecologic disease can cause acute lower abdominal or pelvic pain in women (**Table 71-6**).

Hemorrhage from an ectopic gestation is the leading cause of pregnancy-related maternal death in the first trimester, despite improved diagnostic and treatment modalities. **Obtain a qualitative or quantitative urine or serum pregnancy test in women of childbearing age with acute abdominal pain who have not had a hysterectomy.** If the qualitative human chorionic gonadotropin is positive, transvaginal sonography should be the next diagnostic test to answer the question: Is this pregnancy in the uterus? Either inside or outside the uterus, a gestational sac is typically visible if the patient's serum β human chorionic gonadotropin is >1500 mIU/mL (the operator-dependent "discriminatory zone"). Detailed discussion of ectopic pregnancy is provided in chapter 98, Ectopic Pregnancy and Emergencies in the First 20 Weeks of Pregnancy. **Suspect ectopic pregnancy in a woman of reproductive age with hemodynamic collapse.** The presence of right lower quadrant pain in a woman who has an appendix is a common diagnostic dilemma. In general, the results of pelvic examination, consideration of patient risk factors for gynecologic versus gastrointestinal disease, and the clinician's best estimate of pretest probability for gynecologic versus gastrointestinal disease are the best guides for further imaging. If pretest probability favors gynecologic disease, a transvaginal ultrasound would be the next step. If pretest probability favors gastrointestinal disease or appendicitis, abdominopelvic CT scanning would be the next step.

ELDERLY PATIENTS

Symptoms in the elderly may be mild, vague, or underreported, and presentations may be late and atypical. Among those >80 years old, mortality almost doubles if the diagnosis is incorrect at the time of admission.[18] Poor hearing, decreased vision, and impaired cognition may affect the ability to give an adequate history. Surgical complications are more common: perforated viscus, gangrenous gallbladder, necrotizing pancreatitis, strangulated hernia, and infarcted bowel. Fever is not a reliable marker for serious disease, and the elderly may be hypothermic in the presence of serious abdominal infection. Fewer than 20% of elderly patients with perforated appendicitis have a "classic" presentation.[19] A WBC has a low predictive value for surgical disease in the elderly. **Although certain variables have been associated with poor outcome (age >84 years old, bandemia, free air) and others with the need for surgery (hypotension, abnormal bowel sounds, massively dilated loops of bowel, extreme leukocytosis), the absence of these variables does not preclude significant disease.**

Cholecystitis is the most common surgical entity in elderly patients with abdominal pain, followed by small bowel obstruction, perforated viscus, appendicitis, and large bowel obstruction. Viral gastroenteritis is uncommon among the elderly, but diarrhea occurs in 31% to 40% of patients with mesenteric ischemia.[10,20]

Any acute abdominal pain is important in an elderly patient. No single test can distinguish among patients who should be admitted and patients who can be safely discharged. **A liberal imaging/admission/observation policy is strongly advocated when the diagnosis is in doubt or follow-up is uncertain.**

BARIATRIC SURGERY PATIENTS

The purpose of bariatric surgery is to limit the absorption of nutrients from ingested food by reducing the size of the stomach, with or without a degree of associated malabsorption (**Table 71-7**). Detailed discussion of bariatric surgery complications is provided in chapter 298, The Patient With Morbid Obesity.

Staple breakdown after gastroplasty and band slippage after laparoscopic adjustable gastric banding may present as sudden intolerance to food or gastroesophageal reflux. Obstruction and erosion may also occur at the site of a gastric band. Diarrhea is a frequent complaint with predominantly malabsorptive procedures, and long-term malabsorption may result in protein depletion and vitamin deficiencies (particularly fat-soluble vitamins: A, D, and K).

Several specific problems can occur after successful Roux-en-Y gastric bypass (**Table 71-8**).

Bowel obstruction may be caused by internal hernia, anastomotic stenosis, or adhesions. Symptoms may be nonspecific (nausea, bloating, abdominal pain). Bowel obstruction in the immediate postoperative period after Roux-en-Y gastric bypass is a surgical emergency, as distention of biliopancreatic limb and distal stomach can result in gastric rupture and peritonitis. Bilious emesis after Roux-en-Y gastric bypass is pathognomonic for common channel obstruction, which requires immediate surgical intervention.[21] Gallstone formation is increased during the

TABLE 71-4 Common Diagnoses for Acute Abdominal Pain in Adults

Diagnosis	Epidemiology	Typical Location	Typical Radiation	Typical Quality	Helpful	Cautions	Laboratory	Imaging	Complications
Appendicitis	Peak age: adolescence and young adulthood	Early: periumbilical; late: RLQ. If retrocecal or third trimester pregnancy may be RUQ	—	Initially dull, becomes severe	RLQ pain; pain migrated from periumbilical area; pain before vomiting 100% sens, 66% spec; rigidity	Anorexia: 84% sens; vomiting 50% sens; fever: 67% sens; elevated WBC: 70%–90% sens	No single test is highly sensitive or specific; C-reactive protein may be helpful	CT preferred in adults and nonpregnant women	Perforation, abscess
Biliary colic	F >> M before age 60 y old, Hispanic > white > black	RUQ > epigastric	Right subscapular area	Initially colicky, becomes continuous; colic typically resolves <6 h	Bloating and dyspepsia are not related to gallstones	—	Suspect common bile duct stone if elevated bilirubin	US: 86%–96% sens, 78%–98% spec	Cholecystitis
Bladder outlet obstruction	Benign prostatic hypertrophy	Suprapubic	—	—	—	—	—	Bedside US	—
Bowel obstruction	History previous abdominal surgery	Diffuse	—	Colicky	Vomiting, distention	—	—	Plain films: 77% sens; 93% CT sens	Incarceration, strangulation
Cholecystitis	Most common surgical cause of abdominal pain in elderly	RUQ > epigastric	Right subscapular area	Continuous	(+) Murphy sign increases likelihood of cholecystitis (odds ratio 2.3–2.8); jaundice suggests obstruction	Up to 90% afebrile; elevated WBC only 63% sens and 57% spec. Cholangitis: elevated WBC only 80% sens	No single test can exclude diagnosis; elevated bilirubin/aspartate aminotransferase/alkaline phosphatase each only 70% sens and 42% spec	US: 91% sens; hepatobiliary iminodiacetic acid scan: 97% sens, 90% spec	Common bile duct obstruction; ascending cholangitis; gangrene
Diverticulitis	M > F before age 40 y old; incidence increases with age	Sigmoid (85%): LLQ; cecal/Meckel: RLQ	—	—	50% report previous episode of similar pain	Temperature may be normal; 25% (+) fecal occult blood	WBC may be normal	CT: sens 93%–100%; spec 100%	Perforation; abscess; fistula; obstruction
Epiploic appendagitis	Middle age; M > F	LLQ	—	—	Fever unusual; n/v infrequent; diarrhea 25%	In general, pts are not systemically ill	—	CT	—
Mesenteric arterial occlusion	Atrial fibrillation	Any	—	Severe	Pain out of proportion to physical findings; nausea: 56%–93%; vomiting: 38%–80%; diarrhea: 31%–48%	Atrial fibrillation	Lactate: 75%–90% sens; not specific; elevated WBC: 90%	Selective CT angiography: 96% sens	Metabolic acidosis
Mesenteric venous thrombosis	Hypercoagulable states, liver disease	Most commonly: generalized or epigastric	—	—	—	—	—	Contrast-enhanced CT	—
Mesenteric ischemia (nonocclusive)	Critically ill pts; vasoactive drugs	—	—	—	—	—	—	Angiography	—
Myocardial ischemia	—	Upper midline	—	Steady, dull	Abnormal ECG	ECG may be normal	Troponin: 80% sens at 4 h from symptom onset	—	—
Pancreatitis	M > F. Risks: alcohol; biliary disease; drugs; endoscopic retrograde cholangiopancreatography	Epigastric	Back	Severe, constant	Nausea and vomiting common	May have low-grade fever	Lipase: 90% sens first 24 h	US may show edema; CT: 78% sens, 86% spec	Hemorrhage; pseudocyst; adult respiratory distress syndrome; sepsis

PID	Sexually transmitted diseases; prior PID; multiple partners	RLQ and/or LLQ	—	—	Vaginal discharge; dyspareunia; cervical motion tenderness	Fever not necessary for diagnosis	Elevated WBC not necessary for diagnosis	—	Tubo-ovarian abscess; perihepatitis; infertility; ectopic pregnancy; chronic pain
Peptic ulcer disease	Peak age: 50s; M > F; chronic aspirin or NSAIDs; smoking; alcohol; *Helicobacter pylori*	Epigastric	—	Severe, persistent	Vomiting, tachycardia	Nonulcer dyspepsia more likely if: age <40 y old, no weight loss, no night pain, no vomiting	—	—	Perforation; bleeding
Perforated viscus	—	Any	—	Severe	—	—	—	Upright chest x-ray: 80% sens for free air	—
Ovarian torsion	—	RLQ or LLQ	Back, flank, or groin	Sudden onset, severe, sharp; may have nausea/vomiting	Adnexal mass	—	—	Pelvic US with Doppler flow	Ovarian salvage decreases with delay in diagnosis
Renal/ureteral colic	Average age: 30–40 y old; white > black; family history of stones	Right or left flank	Ipsilateral groin/scrotum	Severe; colicky; nausea and vomiting common	85%–90% have hematuria; only 30% have gross hematuria	—	Urinalysis	CT	Obstruction; infection
Ruptured ectopic pregnancy	Previous ectopic; PID; infertility treatment; intrauterine device <1 y; tubal surgery	RUQ or LLQ	—	Sudden onset; severe pain	Pelvic mass	Pelvic exam may be normal	Pregnancy test	Transvaginal US	Shock
Ruptured/leaking abdominal aortic aneurysm	Older; male; atherosclerotic cardiovascular disease; smoker; (+) family history	Mid-abdomen or flank	Back, groin, or thigh	Severe; sudden onset; constant	Pulsatile mass detected: 22%–96% sens	Only 50% are hypotensive at presentation. Normal pulses do not exclude diagnosis	—	Bedside US 100% sens	Shock
Tubo-ovarian abscess	PID	Unilateral or bilateral pain	—	—	—	Fever may be absent	Leukocytosis may be absent	—	Rupture, peritonitis, shock

Abbreviations: > = more than; >> = much more than; < = less than; + = positive; F = female; LLQ = left lower quadrant; M = male; NSAIDs = nonsteroidal anti-inflammatory drugs; n/v = nausea and vomiting; PID = pelvic inflammatory disease; pts = patients; RLQ = right lower quadrant; RUQ = right upper quadrant; sens = sensitivity; spec = specificity.

TABLE 71-5 Antibiotic Regimens for Intra-abdominal Infections

Antibiotic	Comments
Aminoglycosides Gentamicin or tobramycin, 1.5 milligrams/kg IV every 8 h *or* Amikacin, 5 milligrams/kg IV every 8 h *and* Metronidazole, 1 gram IV followed by 500 milligrams IV every 6 h *or* Clindamycin, 900 milligrams IV every 8 h	Traditional therapy, if no reluctance for use of aminoglycoside; often selected for sicker, older, immunocompromised, or hypotensive patients; use ideal body weight for determining milligrams/kg/dose; adjust dosage for decreased glomerular filtration rate
Second-generation cephalosporins Cefoxitin, 2 grams IV every 6 h *or* Cefotetan, 2 grams IV every 12 h	Often selected for those less ill
Ampicillin-sulbactam, 3 grams IV every 6 h *or* Ticarcillin-clavulanate, 3.1 grams IV every 6 h	—
Piperacillin-tazobactam, 3.375 grams IV every 6 h *or* Imipenem-cilastatin, 1 gram IV every 8 h	Piperacillin-tazobactam often selected for suspected biliary sepsis
Aztreonam, 2 grams IV every 8 h maximum dose *and* Clindamycin or metronidazole (see above for dosages)	For patients with allergy to penicillins or cephalosporins
Ceftriaxone, 2 grams IV every 12 h maximum dose *or* Cefotaxime, 2 grams IV every 6 h	For spontaneous bacterial peritonitis, coverage for *Pneumococcus* as well as *Escherichia coli*

period of rapid weight loss after bariatric surgery. "Dumping syndrome" is caused by rapid postprandial gastric emptying, the release of gastric hormones, and splanchnic vasodilation. Patients with early dumping complain of nausea, vomiting, bloating, abdominal cramps, diarrhea, and sweating 30 to 60 minutes after a meal. Late dumping occurs 1 to 3 hours postprandially. It is a hyperinsulinemic and hypoglycemic state.

TABLE 71-7 Types of Bariatric Surgical Procedures

Restrictive	Primarily Malabsorptive; Mildly Restrictive	Primarily Restrictive; Mildly Malabsorptive
Vertical banded gastroplasty ("stomach stapling")	Biliopancreatic diversion	Roux-en-Y gastric bypass
Laparoscopic adjustable gastric banding	Duodenal switch	

TABLE 71-8 Complications after Roux-en-Y Gastric Bypass

Anastomotic leak
Bowel obstruction (includes internal hernia and volvulus of Roux limb)
Cholelithiasis
Dumping syndrome
Enteric leak
Marginal ulcer
Metabolic complications (B_{12}, iron, thiamine, vitamin and mineral deficiencies; hyperoxaluria)
Stenosis of gastrojejunostomy site

Dietary modification is the initial treatment for dumping syndrome; patients should be advised to avoid highly concentrated foods and to separate eating and drinking. Severe cases of dumping syndrome have been successfully treated with subcutaneous octreotide.[22] The diagnosis of enteric leak requires a high index of suspicion, because the clinical presentation varies widely.[23] With Roux-en-Y gastric bypass, leaks occur most commonly at the gastrojejunostomy anastomosis. Patients with enteric leak typically present with features suggestive of sepsis (tachycardia, fever, abdominal pain). CT may show extravasation of oral contrast material, a finding highly suggestive of leak in the early postoperative period. Primary repair is the treatment of choice. The mortality for undiagnosed enteric leak is extremely high.

EPIPLOIC APPENDAGITIS

Epiploic (omental) appendages are fatty pedicular structures, typically 3 cm in length, that are found on the serosal surface of the normal colon. Their function is not known. It is estimated that each person has 50 to 100 epiploic appendages, most commonly on the sigmoid colon and cecum.[24] Acute epiploic appendagitis is a self-limited inflammatory condition usually caused by the torsion of an epiploic appendage. Spontaneous venous thrombosis and hernia incarceration of epiploic appendages have been more rarely reported. The cardinal sign is pain, which can mimic acute diverticulitis or acute appendicitis. In general, patients do not appear systemically ill, and fever is unusual. Nausea and vomiting are infrequent, but diarrhea has been reported in up to 25% of cases.[24] On US, epiploic appendagitis appears as an oval noncompressible hyperechoic mass at the site of maximal abdominal tenderness, with no color Doppler blood flow.[25] Normal epiploic appendages are not visualized on abdominal CT images in the absence of significant intraperitoneal fluid (e.g., hemoperitoneum, ascites).[25] Epiploic appendagitis appears on CT as an oval fatty mass with a slightly hyperdense rim and surrounding mesenteric stranding suggestive of inflammation.[25] Central calcification may occur from fatty necrosis. On occasion, the pedicle stalk of an epiploic appendage may break off, forming a free intraperitoneal body. The treatment is supportive and nonoperative. Pain control should be provided. Antibiotics are not indicated. Most cases resolve spontaneously within 1 to 2 weeks.

THE POSTOPERATIVE PATIENT WITH ACUTE ABDOMINAL PAIN

ILEUS AND EARLY POSTOPERATIVE BOWEL OBSTRUCTION

Anesthesia and surgical manipulation of the bowel decrease the normal propulsive activity of the gut. In the absence of precipitating factors, no specific treatment is necessary, and normal bowel function returns 2 to 3 days postoperatively. Mild cramps and flatus signal the return of peristalsis. A delay in the return of normal GI function may be caused by electrolyte abnormalities, intra-abdominal inflammation or infection, pancreatitis, or medications (particularly opioids, anticholinergics, phenothiazines, and psychotropics). The clinical findings of adynamic postoperative ileus are nausea, vomiting, abdominal distention, cramps, and obstipation. Plain radiographs of the abdomen demonstrate diffusely

dilated loops of bowel, with air present in the distal colon and rectum. Adynamic ileus is treated supportively and by correction of precipitating factors.

The clinical differentiation of adynamic ileus and mechanical small bowel obstruction can be difficult. Patients with obstruction may report a temporary return of GI function postoperatively. The symptoms of obstruction are similar to those of adynamic ileus, but vary depending on the location and extent of the obstruction. Proximal obstruction is usually associated with early emesis and less abdominal distention, distal obstruction with later (sometimes bilious or feculent) emesis, and significant abdominal distention. High-pitched bowel sounds suggest mechanical obstruction. Plain abdominal radiographs show air-fluid levels (which suggest but are not pathognomonic for obstruction), thickened valvulae conniventes proximal to the obstruction, and little air in the bowel distal to the obstruction. The amount of dilated bowel is variable. Abdominal CT can reliably identify the transition point of normal to abnormal bowel, the degree of mechanical obstruction, and the presence of complications (perforation, abscess). In the absence of complications, partial small bowel obstruction is managed with observation. Surgery is generally required for high-grade obstruction or peritonitis. Mechanical small bowel obstruction is most often caused by adhesions.

ACUTE URINARY RETENTION

Acute urinary retention after ambulatory surgery should be an obvious diagnosis based on the patient's report of inability to urinate. Bedside bladder US confirms the diagnosis. Treatment is urinary bladder drainage.

CHAPTER 72

Nausea and Vomiting

Bophal Sarha Hang
Susan Bork
Jeff Ditkoff

INTRODUCTION AND EPIDEMIOLOGY

Nausea and vomiting accompany a variety of illnesses. Symptoms may be due to primary GI disorders such as bowel obstruction or gastroenteritis. However, symptoms may also represent pathology of the central nervous system (increased intracranial pressure, tumor), psychiatric conditions (bulimia nervosa, anxiety), endocrine or metabolic abnormalities (diabetic ketoacidosis, hyponatremia), or iatrogenic causes (medications, toxins). Also, nausea and vomiting may be the result of severe pain, myocardial infarction, sepsis, or other systemic illnesses. A comprehensive history and physical examination, as well as the use of various diagnostic modalities, are needed to determine the cause and its complications.

In the United States, the most common cause of acute nausea and vomiting is viral gastroenteritis. Other important considerations are side effects from medication and, in young women, pregnancy.[1]

PATHOPHYSIOLOGY

Multiple neurons in the medulla oblongata are activated in a sequential fashion to induce vomiting. The vomiting center is the chemoreceptor trigger zone, located in the area postrema of the fourth ventricle. Chemoreceptors in this area are outside the blood–brain barrier and are stimulated by circulating medications and toxins, including dopaminergic antagonists (levodopa, bromocriptine), nicotine, digoxin, and opiate analgesics. Another important peripheral pathway for emesis is mediated through vagal afferents. Vagal activation is triggered by direct gastric mucosal irritants (such as nonsteroidal inflammatory agents) or increased luminal distention (gastric outlet obstruction, gastroparesis). Vagus activation stimulates neurons in the area postrema and nucleus tractus solitarius. These areas are rich in serotonin receptors and are a major site of action of antiemetic drugs, such as granisetron and odansetron.[2] Similar receptors are found throughout the gastrointestinal tract, as well as the cortex and limbic system, vestibular system, heart, and genitalia. The anatomic locations and receptor-mediated triggering factors in emesis are shown in **Table 72-1**.

TABLE 72-1 Anatomic Locations of Receptor-Mediated Triggering Factors in Emesis

Anatomic Site	Chemoreceptors	Triggering Factor
Chemoreceptor trigger (area postrema)	Dopamine 5-HT_3 H_1 M_1 Vasopressin	Medications (dopamine agonists, digoxin, opiates, nicotine, chemotherapeutic drugs) Metabolic (uremia, diabetic ketoacidosis, hypercalcemia) Neuroendocrine (hyperemesis gravidum) Toxins
Peripheral vagal afferents	5-HT_3	Gastric irritants (salicylate, erythromycin, copper, ipecac) Bacterial toxins (*Staphylococcus* enterotoxin) Gastrointestinal distention (biliary colic, small bowel obstruction) Inflammation (peritonitis, cholecystitis) Chemotherapy Radiation
Vestibular system	H_1 M_1	Motion Labyrinth tumors or infections Benign position vertigo or Ménière's disease
Cerebral cortex and limbic system	Poorly characterized	Psychogenic (fear, anxiety) Noxious odors Visual stimuli

Abbreviations: 5-HT_3 = serotonin; H_1 = histamine; M_1 = muscarine.

Efferent pathways in the vagal, phrenic, and spinal nerves control the physiologic event of vomiting through coordinated muscle activity. Three stages of vomiting have been described: nausea, retching, and actual vomiting. Nausea is the unpleasant feeling that precedes vomiting. During nausea, there may be autonomic symptoms of hypersalivation, repetitive swallowing, and tachycardia. The exact physiologic pathway is not well understood but may be related to afferent abdominal vagal stimulation. During retching, there is gastric relaxation and repetitive simultaneous contraction of the diaphragm and abdominal muscles that allow for the development of a pressure gradient. Vomiting is the retrograde expulsion of gastric contents, and it is a response to changes in intra-abdominal and intrathoracic pressure generated by the contraction of the abdominal and respiratory muscles.[3]

CLINICAL FEATURES

The differential diagnosis of nausea and vomiting is exhaustive, as pathology of almost every organ system may lead to nausea and vomiting (**Table 72-2**). A thorough history and physical examination will help guide the diagnostic approach to the patient presenting with nausea and vomiting.

HISTORY

Identify the onset and duration of the symptoms. The evaluation for acute symptoms is quite different from the evaluation of a chronic problem.

TABLE 72-2 Differential Diagnosis of Nausea and Vomiting

Gastrointestinal	Neurologic	Infectious	Drugs/Toxins	Endocrine	Miscellaneous
Functional disorders	Head injury	Bacterial toxins	Digoxin	Pregnancy	Myocardial infarction
Psychogenic	Stroke	Pneumonia	Aspirin	Adrenal insufficiency	Acute glaucoma
Irritable bowel syndrome	Pseudotumor	Spontaneous bacterial peritonitis	NSAIDs	Diabetic ketoacidosis	Nephrolithiasis
Obstruction	Hydrocephalus	Urinary tract infection	Acetaminophen	Parathyroid disorders	Pain
Adhesions	Mass lesion	Viruses	Opiates	Thyroid disorders	Psychiatric disorders
Esophageal disorders	Meningitis	Adenovirus	Alcohol	Uremia	Anorexia nervosa
Achalasia	Migraines	Norwalk virus	Theophylline	Electrolyte disorders, especially hyponatremia	Bulimia
Intussusception	Labyrinthitis	Rotavirus	Chemotherapeutics		Conversion disorder
Tumor	Ménière's disease		Anticonvulsants		Depression
Pyloric stenosis	Motion sickness		Antibiotics		
Strangulated hernia			Antiarrhythmics		
Volvulus			Hormones		
Organic disorders			Illicit drugs		
Appendicitis			Radiation therapy		
Cholecystitis			Toxins		
Cholangitis			Arsenic		
Hepatitis			Organophosphates		
Irritable bowel disease			Carbon monoxide		
Mesenteric ischemia			Ricin		
Pancreatitis					
Peptic ulcer disease					
Peritonitis					

Abbreviation: NSAIDs = nonsteroidal anti-inflammatory drugs.

If the problem is chronic, asking the patient the results of any tests that have already been performed will help narrow the diagnostic possibilities. Chronic symptoms are defined as those symptoms present for >1 month.

Frequency of the episodes is helpful to gauge the severity of illness. Ask how many times vomiting occurred and the interval between episodes. Timing of the episodes, such as increased number of episodes in the morning, may suggest pregnancy or a central nervous system cause, whereas postprandial vomiting suggests gastroparesis or gastric outlet obstruction.

The content of the vomitus may be helpful to determine whether an obstruction is present and its location. Esophageal disorders produce vomitus with undigested food particles. Bile is often associated with a small bowel obstruction, whereas vomitus composed of food particles and devoid of bile often represents a gastric outlet obstruction. Large bowel obstruction often is composed of feculent material and has a foul odor.

Because of the number of organ systems that are the potential cause of pathology, it is important to ask the patient about associated symptoms. The presence or absence of abdominal pain is a focal starting point. If pain is present, elicit its location and quality. Pain preceding the nausea and vomiting is most particularly associated with an obstructive process.[2] Fever or, possibly, diarrhea suggests gastroenteritis. Ask about sick contacts or ingestion of food suspicious for a foodborne illness. A history of recent weight loss is associated with a malignancy or psychiatric component. Any central nervous system sign, such as headache, visual changes, vertigo, or neurologic deficits, may suggest a central cause for the nausea and vomiting. Obtain a thorough past medical history. Always ask about prior abdominal surgeries because the patient is at risk for bowel obstruction from adhesions. Review the patient's medication list to identify a medication with a common side effect of nausea and vomiting, such as nonsteroidal anti-inflammatory agents, cancer chemotherapeutic agents, various antibiotics, various antihypertensives and antiarrhythmics, and oral contraceptives. Other medications at toxic levels are known to cause nausea and vomiting. Examples include acetaminophen, salicylates, and digoxin.

PHYSICAL EXAMINATION

Assess vital signs for hypotension and tachycardia. Observe skin turgor, mucous membrane hydration, and capillary refill to assess for dehydration. In children, the most useful predictors of significant dehydration (>5% loss of body weight) are abnormal capillary refill, abnormal skin turgor, absent tears, and abnormal respiratory pattern.[4] The abdominal examination is particularly important to assess for an emergent problem, as well as to help narrow the differential diagnosis to a possible gastrointestinal cause.[5] Inspect, auscultate, and palpate the abdomen. (For further discussion of abdominal evaluation, see chapter 71, Acute Abdominal Pain.)

Investigate any other important examination findings particular to various organ systems, as findings may provide valuable information regarding the cause of the nausea and vomiting (**Table 72-3**).

DIAGNOSTIC TESTING

LABORATORY

After completing a proper history and physical examination, obtain serum and urine studies to help determine the cause of the symptoms and to evaluate for complications. Most often, a CBC as well as electrolyte testing is part of the basic evaluation. Obtain a pregnancy test in a woman in childbearing years who has not had a hysterectomy. Obtain liver function tests and a serum lipase in patients with upper abdominal pain or jaundice. Check thyroid function tests if thyrotoxicosis is suspected. Obtain specific drug levels for possible ingestions or suspected toxicity in patients taking acetaminophen, salicylates, digoxin, or theophylline. Also, obtain ethanol levels and narcotic drug screening tests in patients with suspected intoxication or withdrawal states.

TABLE 72-3 Differential Diagnosis Based on Physical Examination Findings

Physical Examination	Abnormal Signs or Symptoms	Some Diagnostic Considerations
General	Toxic appearing	Dehydration
	Generalized weakness	Chronic malnutrition
	Weight loss	Malignancy
Vital signs	Fever	Infection (gastroenteritis, appendicitis, cholecystitis)
	Tachycardia	Bowel perforation secondary peritonitis
	Hypotension	Severe volume depletion
	Hypertension	Intracranial hemorrhage or stroke
Head, eyes, ears, nose, throat	Nystagmus	Peripheral vs. central causes (benign positional vertigo, cerebellar infarct)
	Exophthalmos	Graves' disease
	Pin-point pupils	opiate abuse
	Fixed-dilated pupil, eye pain	Acute glaucoma
	Dry mucous membranes	Dehydration
		Bulimia
	Poor dental enamel, parotid gland enlargement	Bulimia
Abdomen	Distention, decreased bowel sounds, surgical scars	Small bowel obstruction, gastroparesis, gastric outlet obstruction, ileus
	Hernias or palpable masses	Incarcerated hernia, tumors
	Abdominal rigidity	Peritonitis
Neurologic	Mental status	Dehydration, intracranial lesion or pathology, brainstem tumor, elevated intracranial pressure
	Cranial nerve findings or neurologic deficits	
	Papilledema	
Extremities	Scarring on dorsal surface of the hands	Bulimia
Skin	Jaundice	Hepatobiliary disease (hepatitis, choledocholithiasis)
	Poor skin turgor	Dehydration
	Hyperpigmentation	Addison's disease
	Decreased elasticity	Scleroderma
	Skin track marks	Drug abuse/withdrawal

A urinalysis may be beneficial in several ways. The specific gravity may be used to help determine the degree of dehydration. The presence of ketones may suggest not only dehydration, but also diabetic ketoacidosis or hyperemesis gravidarum in a pregnant patient. The presence of bilirubinuria may suggest a biliary tract obstruction. Nitrites, leukocyte-esterase, bacteria, and white blood cells may indicate an upper or lower urinary tract infection. Also, red blood cells, in the proper clinical picture, may support a diagnosis of kidney stones. Lastly, an erythrocyte sedimentation rate may be evaluated to search for an inflammatory cause.

IMAGING

Flat and upright abdominal films are useful screening tests for bowel obstruction. Plain radiography is less sensitive than CT scanning, but the radiation dose is <1 mSv, about one tenth the radiation dose of an abdominal CT scan.[6,7] Abdominal CT with PO and IV contrast can diagnose a mechanical obstruction, identify the cause, and visualize visceral and vascular pathology. A noncontrast abdominopelvic CT or renal US are tests of choice if kidney stones are suspected. If the history or physical examination suggest a CNS cause, a CT of the head or MRI of the brain is ordered to evaluate for an intracranial mass or lesion. Other radiographic tests are available but are often ordered for a patient who requires admission to the hospital, or upon consultation with a gastroenterologist. These tests include esophagogastroduodenoscopy, upper GI radiography with barium contrast, small bowel follow-through, enteroclysis, gastric emptying scintigraphy, antroduodenal manometry, and cutaneous electrogastrography.

ANCILLARY TESTING

An abdominal US is helpful to evaluate a patient with associated right upper quadrant or epigastric pain to diagnose possible gallbladder, hepatic, or pancreatic pathology. Hepatobiliary iminodiacetic acid scans are sometimes performed in suspected cases of biliary dysfunction and/or cholecystitis. Suspected testicular torsion would also be diagnosed by US. Obtain an electrocardiogram for suspected myocardial infarction. Measure intraocular eye pressures if glaucoma is a part of the differential diagnosis.

TREATMENT

Stabilize the patient, paying attention to the ABCs: airway, breathing, and circulation. After stabilization, provide symptomatic relief (**Table 72-4**). Definitive management will often require disease-specific treatment. If no clear cause is noted at the outset, an H_1 histaminergic such as promethazine or a serotonin receptor antagonist such as ondansetron may be helpful for initial treatment, pending further workup.[8] However, promethazine is more sedating, with the potential side effect of vascular damage during IV administration. Recent studies have also compared the efficacy of selective serotonin receptor antagonist (tropisetron, ondansetron) versus other agents in treating nausea and vomiting for undifferentiated ED patients. Serotonin receptor blockers significantly lower the rates of vomiting when compared with metoclopramide.[9] Both ondansetron and prochlorperazine are equally effective.[10] Patients given either drug must be monitored for akathisia that may develop up to 48 hours after administration. Based on overall safety and efficacy, serotonin receptor antagonists such as ondansetron should be used as first-line therapy for undifferentiated nausea and vomiting in all age groups. For patients in the ED who have no response to ondansetron in 30 minutes, administration of another drug with activity at a different receptor site is more likely to be successful than repeat dosing of ondansetron.[11]

TABLE 72-4 Antiemetic Agents for the Treatment of Nausea and Vomiting

Medication Class	Route	Common Side Effects	Comments
Antihistamines		Drowsiness	Also show efficacy in prevention of motion sickness. Useful for migraines and vertigo.
Dimenhydrinate (Dramamine®)	PO		
Diphenhydramine (Benadryl®)*	IV, IM, PO		Used in migraines and vertigo, which are vestibular in origin.
Meclizine (Antivert®)	PO		
Benzodiazepines		Sedation	Adjunct for chemotherapy-induced nausea and vomiting.
Alprazolam (Xanax®)	PO		
Diazepam (Valium®)	PO, IV, PR		
Lorazepam (Ativan®)	PO, IV, IM		
Butyrophenones		Agitation, restlessness, sedation	Treatment of acute chemotherapy-induced symptoms.
Haloperidol (Haldol®)*	PO, IM		
Corticosteroids		Insomnia	Used as an adjunct in severe cases of chemotherapy-induced nausea and vomiting; reduces prostaglandin formation.
Dexamethasone	PO, IV, IM		
Serotonin antagonists		Constipation, dizziness	Well tolerated; uncommon side effects include headache, rare case report of anaphylaxis.
Ondansetron (Zofran®)*	PO, IV, SL		
Granisetron (Kytril®)*	PO, IV		
Dolasetron (Anzemet®)*	PO, IV		
Phenothiazines		Extrapyramidal symptoms,‡ sedation, orthostatic hypotension	Treatment in migraines, vertigo, and motion sickness; rare side effects include neuroleptic malignant syndrome, blood dyscrasias, and cholestatic jaundice.
Prochlorperazine (Compazine®)†	PO, IV, IM		
Promethazine (Phenergan®)†	PO, IV, IM, PR		
Benzamides		Extrapyramidal symptoms,‡ hyperprolactinemia	Used in treatment of gastroparesis and children with reflux.
Metoclopramide (Reglan®)	PO, IV, IM		
Trimethobenzamide (Tigan®)	PO		

*QT-interval prolongation reported.

†Nonspecific Q or T distortions reported.

‡Extrapyramidal symptoms: dystonia, tardive dyskinesia, oculogyric crisis, parkinsonism.

CHAPTER 73

Disorders Presenting Primarily With Diarrhea

Nicholas E. Kman
Howard A. Werman

GENERAL ASSESSMENT OF PATIENTS WITH DIARRHEA

INTRODUCTION AND EPIDEMIOLOGY

This chapter discusses the general assessment of patients with diarrhea and the special considerations of acute infectious and traveler's diarrhea, *Clostridium difficile* diarrhea and colitis, inflammatory bowel disease, ileitis and colitis, and ulcerative colitis.

Acute diarrhea is the sudden onset of an increase in the normal water content of stool. In general, humans lose approximately 10 mL/kg/day of fluids in stool. The increased water content of diarrhea results in an increased frequency of stools from 3 or more times daily to more than 20 bowel movements in a 24-hour period. Diarrhea is an increased frequency of defecation, usually greater than 3 bowel movements per day for a daily stool weight exceeding 200 grams.[1,2] Practically speaking, however, diarrhea is present when the patient is making more stools of lesser consistency more frequently.

PATHOPHYSIOLOGY

There are four basic mechanisms of diarrhea: increased intestinal secretion, decreased intestinal absorption, increased osmotic load, and abnormal intestinal motility. Normally, the jejunum receives between 6 and 8 L per day of fluid in the form of oral intake and gastric, pancreatic, and biliary secretions. Dietary intake actually constitutes a small portion of the jejunal load (1.5 L). A healthy small intestine absorbs nearly 75% of the fluid to which it is exposed. The 2 L of fluid not absorbed by the small intestine then enters the colon, where fluid is absorbed at an even higher rate. The absorptive power of the colon approaches 90% efficiency and far exceeds that of the small intestine. In fact, the colon can make up for a decrease in small intestinal absorption. Under normal conditions, very little fluid (<100 mL) is lost in the stool each day.[3]

In diarrheal states, normal intestinal physiology is disrupted. At a cellular level, intestinal absorption occurs through the villi, and secretion occurs through the crypts. Fluids are absorbed by two mechanisms: passively with the transport of sodium and actively with the absorption of glucose. Selected enterotoxins block the passive sodium resorption and specifically stimulate sodium excretion, resulting in a net loss of fluid. The glucose-dependent mechanism of water absorption, however, is unaffected by these toxins and can be exploited by including glucose in the rehydration treatments. The composition of oral rehydration therapies recommended by the World Health Organization is based largely on this physiology. In addition, diarrheal states, enterotoxins, inflammation, or ischemia disrupt the structure of the intestinal villi preferentially with less involvement in the crypts. As a result, diarrhea occurs because of diminished intestinal villi absorption *and* unopposed crypt secretion (the crypts are more resilient after injury).[4]

Another mechanism by which disease processes cause diarrhea is by the delivery of an osmotic load to the intestine. For example, administration of a laxative results in the collection of an osmotically active, nondigestible agent within the intestinal lumen. Other substances such as diet products and medications (e.g., colchicine) have similar effects.

Osmosis occurs, drawing fluid into the intestinal lumen, and results in diarrhea. Increased intestinal motility also causes diarrhea. This mechanism is responsible for diarrhea in patients with irritable bowel syndrome, neuropathies, or a shortened intestine secondary to surgery.

Diarrheal illness is primarily a viral infection (norovirus), but can also be caused by bacteria and parasites. Antibiotic and nosocomial diarrhea is most often caused by *C. difficile*. Many drugs affect gastrointestinal function. Erythromycin accelerates gastric emptying. Clavulanate stimulates small bowel motility. Other drugs that cause diarrhea are laxatives, sorbitol, lactose, nonsteroidal anti-inflammatory drugs, and cholinergics. Inflammatory bowel disease, ulcerative colitis, and Crohn's disease are characterized by diarrhea. **If patients have fecal evidence of inflammation and *Shigella*, *Salmonella*, *Campylobacter*, *C. difficile*, or *Entamoeba histolytica* have been excluded, suspect inflammatory bowel disease.** Less common causes of severe diarrhea include gastrointestinal bleeding, thyrotoxicosis, toxin exposure, and mesenteric ischemia, which are addressed elsewhere in the text.

CLINICAL FEATURES

History After confirming a diarrheal illness, focus on identifying the cause. Determine whether the diarrhea is acute (<3 weeks) or chronic (>3 weeks). The acute diarrheas are of greatest concern to the emergency physician as they are more apt to be a manifestation of an immediately life-threatening illness (infection, ischemia, intoxication, or inflammation).[2] In the United States, most infectious diarrheal illnesses are caused by noroviruses or rotaviruses and occur in the winter.[5]

Ask directed questions to characterize the diarrhea: Is the diarrhea bloody or melenic? Is it associated with possible food poisoning or the ingestion of certain foods, such as milk or sorbitol? Does it resolve or persist with fasting? If so, this can indicate an osmotic or secretory diarrhea, respectively. Are the stools of smaller volume, localizing to the large intestine, or of larger volume, indicating small intestine pathology? What symptoms accompany the diarrhea? Is there fever or abdominal pain, which may suggest diverticulitis, infectious gastroenteritis, or inflammatory bowel disease? Seizures accompanying diarrhea often point toward shigellosis but could also indicate theophylline toxicity or hyponatremia. Does the patient have heat intolerance and anxiety, suggesting thyrotoxicosis, or paresthesias and reverse temperature sensation, suggesting ciguatera poisoning?

Next, define the host by obtaining the medical and surgical history. The differential diagnosis for diarrhea is broadened if the patient is immunocompromised. Is the patient taking medication that may cause diarrhea? Has the patient recently traveled outside the United States or to a rural area? Rural hiking places the patient at risk for *Giardia,* particularly if water-purification procedures were not strictly followed, and travel to third-world countries increases the chances of parasitic infection and traveler's diarrhea. A patient's occupation may be a clue to a diagnosis of organophosphate poisoning.

Physical Examination Some examination findings helpful for diagnosis include thyroid enlargement, masses, oral ulcers, erythema nodosum, episcleritis, or an anal fissure, which would point toward inflammatory bowel disease. Reiter's syndrome, the triad of arthritis, conjunctivitis, and urethritis or cervicitis, should cause concern for *Salmonella, Shigella, Campylobacter,* or *Yersinia* infection.

Abdominal and rectal examinations are critical. Especially in the elderly, fecal impaction may result in diarrhea as liquid stool passes around the impaction. Pay attention to the presence or absence of surgical scars, tenderness, masses, or peritoneal signs. Check the stool for blood, because bloody diarrhea can be caused by inflammation, infection, or ischemia. An elderly patient with bloody diarrhea and abdominal pain out of proportion to the physical examination may have mesenteric ischemia—a true emergency.

DIAGNOSTIC STOOL EVALUATION

Diagnostic testing is rarely immediately helpful in the ED, but it can be helpful at patient follow-up. Since most diarrheal illnesses are self-limited, viral, or last less than 24 hours, most patients who present within 24 hours of onset need no microbiologic examination. **Patients who have severe abdominal pain, fever, and diarrhea that is voluminous, purulent, or bloody may have acute infectious diarrhea associated with the following pathogens: *Salmonella*, *Campylobacter*, *Shigella*, shiga toxin-producing *Escherichia coli*, *Yersinia*, *Vibrios*, or *C. difficile*.**[5] Patients fitting this subset will require microbiologic evaluation, as described next.

Wright's Stain When applied to a stool sample, Wright's stain allows detection of fecal leukocytes. A positive Wright's stain has a sensitivity of 52% to 82% and a specificity of 83% for the presence of bacterial pathogens by stool culture.[6] Historically, Wright's stain for fecal leukocytes has been used to differentiate invasive from noninvasive infectious diarrheas. In the past, this was an important distinction: physicians were reluctant to prescribe antibiotics for patients with infectious diarrhea because of the fear of prolonging the *Salmonella* carrier state. They therefore reserved antimicrobial treatment for the toxic patients who they felt *truly* had invasive diarrhea. Many physicians now treat patients with diarrheal illness with antibiotics regardless of whether or not the diarrhea is invasive or bacterial in origin.[7]

Bacterial Stool Culture Bacterial stool culture is expensive and labor intensive and plays a minor role in the ED evaluation of diarrhea. The diagnostic yield of stool cultures is probably <5%, unless there is careful patient selection.[1] Obtain stool cultures for bacteria in ill children; toxic, dehydrated, or febrile patients; patients with a diarrheal illness >3 days; patients with blood or pus in the stool; and the immunocompromised. For systemic illness, fever, or bloody stools, test for *Salmonella*, *Shigella*, *Campylobacter*, Shiga toxin-producing *E. coli*, or amoebic infection.[1,4,5] Many laboratories culture for only three common bacterial pathogens: *Salmonella, Shigella,* and *Campylobacter.* If other enteric pathogens are suspected, notify the laboratory so that appropriate testing may be performed.

Ova and Parasite Evaluation Suspect parasitic infection and evaluate stool for ova and parasites in travelers exposed to untreated water and those presenting with diarrhea for more than 7 days. Stool tests for ova and parasites lack sensitivity, because many parasites are fastidious, and shedding of the organisms is intermittent. Multiple samples may need to be collected for a positive result. Direct immunofluorescence staining improves the sensitivity for detecting *Giardia* and *Cryptosporidium.*[8]

***Clostridium difficile* Toxin Assay** *C. difficile* infection is the commonest cause of antibiotic-associated or nosocomial diarrhea. Diagnosis is by the *C. difficile* toxin assay. Unfortunately, this assay has a 10% false-negative rate, and the turnaround time on the test approaches 24 hours.[9]

Other Diagnostic Tests If diarrhea is not infectious in origin, data acquisition should be dictated by the differential diagnosis. Severely dehydrated patients need serum electrolyte and renal function measurements. Serum drug levels can assist the physician in making the diagnosis of theophylline, lithium, or heavy metal intoxication. In patients with a history of abdominal surgery, abdominal films may help rule out partial obstruction as a cause of diarrhea. A chest radiograph may help diagnose *Legionella* pneumonia in a patient with diarrhea and a cough. For patients in whom mesenteric ischemia is suspected, obtain a serum lactate, IV contrast CT scan, or mesenteric angiography.

Treatment Severely dehydrated patients need IV hydration. Oral rehydration with a glucose-based electrolyte solution can be initiated in patients without associated nausea or vomiting and without severe dehydration. Glucose-containing, caffeine-free beverages are the fluids of choice. The glucose transport mechanism is unaffected by enterotoxins, allowing for water absorption in the small intestine. For patients who can afford to buy it, Gatorade® is a good rehydration choice for patients with mild dehydration. The World Health Organization recommends a solution with a higher sodium concentration for more extensive dehydration. Mildly dehydrated patients should aim to drink 30 to 50 mL/kg over the first 4 hours. For moderate dehydration, patients should drink 100 mL/kg over the next 4 hours.[2]

Counsel patients to avoid caffeine, which stimulates gastric motility, and sorbitol-containing chewing gum or raw fruits, which can worsen osmotic diarrhea. Initially, avoid lactose until the colonic villi are able to recover and produce the necessary digestive enzymes. Encourage patients to attempt early solid food intake, but with the previously mentioned restrictions, because eating expedites the recovery from diarrheal illnesses.[10]

ACUTE INFECTIOUS AND TRAVELER'S DIARRHEA

INTRODUCTION AND EPIDEMIOLOGY

Viruses cause the vast majority of infectious diarrheas, followed by bacterial and parasitic organisms. **Norovirus causes 50% to 80% of all** infectious diarrhea in the United States, followed with much less frequency by non–Shiga toxin producing *E. coli*, *C. difficile*, invasive bacteria, Shiga toxin-producing *E. coli*, and protozoa.[1,5]

Approximately 40% of the 50 million Americans who travel annually to developing countries develop diarrhea in the first 2 weeks of travel.[11] **A history of foreign travel is associated with an 80% probability of bacterial diarrhea.**[5] The most important risk factor for traveler's diarrhea is the destination of travel, with the risk increasing with travel to areas of lower socioeconomic status. Countries in Asia, Africa, Latin America, and parts of the Middle East are considered high-risk destinations for traveler's diarrhea, with incidence rates ranging between 20% and 75%.[12] Other risk factors include the level of food contamination, the season of travel (rainy seasons are associated with a higher risk of traveler's diarrhea), use of a proton pump inhibitor, previous contraction of traveler's diarrhea (suggests genetic susceptibility), and the type of travel (adventure travel, camping, backpacking, and living with native inhabitants are associated with higher risk).[13] The major bacteria responsible are the toxin and non–toxin-producing strains of *E. coli*. These strains of *E. coli* make up most identifiable cases in Mexico and South America. The invasive bacteria, such as *Campylobacter jejuni*, *Shigella*, and *Salmonella,* are more commonly seen in travelers to southern Asia.[5,12]

CLINICAL FEATURES

The presence of severe abdominal pain, fever, or bloody stool requires microbiologic studies to rule out bacterial or amoebic infection.[11] Assess stool for polymorphonuclear white blood cells or fecal leukocytes by microscopy or by immunoassay for the neutrophil protein lactoferrin.[5] The presence of fecal leukocytes increases the likelihood of a bacterial pathogen. However, bloody stool without white blood cells is a common feature of Shiga toxin–producing *E. coli* or *E. coli* O157:H7 and colitis that is due to *E. histolytica*.[1,5]

Laboratory Testing Obtain stool culture for *Salmonella*, *Shigella*, *Campylobacter*, and *E. coli* O157:H7; assay for Shiga toxin; and obtain microscopy or antigen assay for *E. histolytica*.[5]

Exposure of a traveler or hiker to untreated water and illness that persists for more than 7 days should prompt evaluations for protozoal pathogens. Test stool for *E. histolytica* antigen, *Giardia intestinalis* antigen, and *Cryptosporidium parvum* antigen by enzyme immunoassay.[1,5] Rarely, helminthes such as *Ascaris, Enterobius,* and *Strongyloides* have been implicated.[14]

TREATMENT

Treatment of infectious diarrhea includes antibiotics, antimotility agents, restoration of fluid balance, and avoidance of agents that worsen diarrhea (**Table 73-1**). **Loperamide and antibiotics improve outcome.**[15,16]

For years, physicians avoided antibiotic use in the treatment of infectious diarrhea because of a fear of prolonging the *Salmonella* carrier state. This fear arose from an article published in 1969 in which the duration of *Salmonella* excretion was felt to be prolonged after antibiotic treatment.[17] Contemporary literature has put this to rest. Antibiotics shorten the duration of illness by about 24 hours.[7,17] Regardless of the causative agent, all patients—even those who had a negative Wright's stain, negative stool culture, and a low diarrheal illness score, suggesting less clinically significant disease and/or a viral cause—improve on ciprofloxacin.[18] Even though most cases of infectious diarrhea are self-limited, because of the inconveniencing and debilitating nature of the disease, **we recommend ciprofloxacin treatment for all patients believed to have an infectious diarrhea who do not have a contraindication to the drug** (e.g., children, allergy, pregnancy, or drug interaction). There are reports of growing fluoroquinolone resistance in bacterial pathogens.[19] Trimethoprim/sulfamethoxazole also shortens the duration of infectious diarrhea in adults but may be inferior to a course of ciprofloxacin because of resistant organisms.[18] Concerns remain about the impact of ciprofloxacin on the intestinal flora[20] and its side effect profile, and other non–gastrointestinal-absorbed agents such as rifaximin are an option.[21] (See **Table 73-2** for specific treatments.)

Loperamide shortens the duration of symptoms when combined with an antibiotic regimen. Loperamide, bismuth subsalicylate, and kaolin are the only agents that are labeled as antidiarrheals. **Do not use antimotility** agents in the subset of patients with bloody diarrhea or suspected inflammatory diarrhea because of the possibility of prolonged fever, toxic megacolon in *C. difficile* patients, and hemolytic uremic syndrome in children infected with Shiga-toxin producing *E. coli*.[1]

TABLE 73-1 Empiric Treatment of Traveler's Diarrhea in the Adult

Rehydration			
Fluids: chicken broth with fruit juices, Gatorade®, noncaffeinated sodas, packages of salts and glucose to be reconstituted with boiled or treated water, CeraLyte 90®, Pedialyte®			
Foods: complex carbohydrates (bananas, bread, rice, apple juice, and tortillas), potatoes, crackers, *Lactobacillus*-containing yogurt			
	Trade Name	**Dosage**	**Comments**
Antimotility Agents			
Bismuth subsalicylate	Pepto-Bismol®	30 mL or 2 tablets every 30 min for 8 doses; repeat on day 2	Salicylate toxicity may occur with excessive dosing; may cause bismuth encephalopathy in HIV-positive patients.
Loperamide	Imodium®	4 milligrams initially, then 2 milligrams after each unformed stool for no more than 2 days; maximum, 16 milligrams per day	Preferred first-line agent for antimotility, with minimal central opiate effects. Can be used with antibiotics.
Diphenoxylate and atropine	Lomotil®	4 milligrams four times a day for 2 days	Second-line agent with more central opiate effects (narcotic related to meperidine); may potentiate the action of barbiturates, tranquilizers, and alcohol.
Antibiotics			
Ciprofloxacin	Cipro®	500 milligrams single dose or 500 milligrams twice a day for 3 days	For moderately severe illness in adults; complete 3-day course if single dose fails; significant drug–drug interactions may occur.
Azithromycin	Zithromax®	1000 milligrams in a single dose	Safe for children and pregnant women
Trimethoprim/sulfamethoxazole (see sulfamethoxazole-trimethoprim)	Bactrim®	160 milligrams/800 milligrams for single dose, 160 milligrams/800 milligrams twice a day for 3 days	For moderately severe illness; resistance limits reliable effectiveness.
Rifaximin[13,22]	Xifaxan®, Salix®	200 milligrams PO three times daily for 3 days	For moderately severe illness; do not use for fever or bloody stools; class C in pregnancy.

Abbreviation: HIV = human immunodeficiency virus.

TABLE 73-2 Antimicrobial Recommendations for Infectious Pathogens in Adults

Organism	Primary Treatment	Alternative Treatment
Empiric treatment—but not for bloody diarrhea; not for Shiga toxin *E. coli* 0157:H7	Ciprofloxacin 500 milligrams PO twice a day for 5 days	Trimethoprim-sulfamethoxazole DS, 1 tab PO twice a day for 5 days
C. difficile	Metronidazole 500 milligrams PO 3 times a day for 14 days	Vancomycin, 125 milligrams PO four times a day for 14 days
E. coli 0157:H7	No antibiotics	No antibiotics
Listeria monocytogenes	No antibiotics	No antibiotics
Yersinia	No antibiotics; usually self-limited	Ciprofloxacin 500 milligrams PO twice a day for 3 days; or trimethoprim-sulfamethoxazole DS,1 tab PO twice a day for 3 days
Salmonella non-typhi	Ciprofloxacin 750 milligrams PO twice a day for 5 days	Azithromycin 500 milligrams PO once a day for 7 days
Shigella	Ciprofloxacin 750 milligrams PO twice a day for 3 days	Azithromycin 500 milligrams PO once a day for 3 days
V. cholerae	Doxycycline 500 milligrams PO for one dose *OR* Azithromycin 1 gram PO for one dose	Trimethoprim-sulfamethoxazole DS,1 tab PO twice a day for 3 days
E. histolytica	Metronidazole 750 milligrams PO three times a day for 10 days *AND* Paromomycin 10 milligrams/kg three times a day PO for 7 days	Metronidazole *AND* iodoquinol 650 milligrams PO three times a day for 20 days *OR* Tinidazole 2 grams PO once a day for three days *AND* paromomycin or iodoquinol
Cyclospora	Trimethoprim-sulfamethoxazole DS, 1 tab PO twice a day for 10 days	
Giardia	Tinidazole 2 grams PO for one dose	Nitazoxanide 500 milligrams PO twice a day for 3 days *OR* Metronidazole 750 milligrams PO three times a day for 10 days *OR* Paromomycin 10 milligrams/kg/day PO three times a day for 10 days

Note: Length of treatment often varies with different sources.

Probiotics are safe and beneficial when used alongside rehydration therapy.[23] Proton pump inhibitors are not effective.[15]

DISPOSITION

Admit the toxic patient and any patient who cannot comply with oral rehydration. Be conservative in admitting those at extremes of age. Most patients with diarrhea can be discharged home.

The best way to combat many infectious diarrheas is with prevention. Counsel families about frequent hand washing to minimize spread of disease. Counseling families about the proper selection and preparation of food and beverages consumed while traveling is a cornerstone of prevention.[12] Encourage the use of boiled, bottled, and carbonated water for drinking, brushing teeth, and preparing food and infant formula. Water can be made safe by boiling, treating it chemically, or filtering.[12] A quick phrase for prevention is, "Peel it, boil it, cook it, or forget it!"

In addition, vaccines against the most common etiologic agent, rotavirus, are now available.[24]

Provide work excuses for patients employed in the food, day-care, and healthcare industries.

CLOSTRIDIUM DIFFICILE–ASSOCIATED DIARRHEA AND COLITIS

INTRODUCTION AND EPIDEMIOLOGY

C. difficile is a spore-forming obligate anaerobic bacillus that causes infection ranging from mild diarrhea to severe pseudomembranous colitis. ***C. difficile* infection is the most common cause of bacterial diarrhea in hospitalized patients in Europe and North America.** The incidence and severity of disease has increased at an alarming rate of 25% per year since 2000.[25] A more virulent strain of *C. difficile* called North American pulsed-field type 1 or B1/NAP1/027 affects hospitalized patients, but can also occur in community-dwelling healthy adults.[26] This strain causes more severe disease that more often progresses to toxic megacolon.

The organism secretes two toxins, A and B, that cause a secretory diarrhea. At the most severe end of the spectrum, three different syndromes have been described: neonatal pseudomembranous enterocolitis, postoperative pseudomembranous enterocolitis, and antibiotic-associated pseudomembranous colitis. In pseudomembranous colitis, membrane-like yellowish exudative plaques overlie and replace necrotic intestinal mucosa. Recent antibiotic use, gastrointestinal surgery or manipulation, severe underlying medical illness, chemotherapy, and advancing age are risk factors for pseudomembranous colitis. Transmission of the organism is by direct human contact as well as contact with inanimate objects (commodes, telephones, rectal thermometers).

PATHOPHYSIOLOGY

Hospitalized patients are colonized with *C. difficile* in 10% to 25% of cases, so the development of diarrhea in recently discharged patients is suggestive of *C. difficile* infection. There is a linear relationship between the length of hospital stay, colonization with *C. difficile,* and the development of *C. difficile* diarrhea. Broad-spectrum antibiotics—most notably clindamycin, second- and third-generation cephalosporins, ampicillin/amoxicillin, and fluoroquinolones—reduce fecal anaerobes, which are needed for carbohydrate metabolism and bile acid breakdown. Accumulation of gut carbohydrates can cause osmotic diarrhea, and the accumulation of bile acids, which are colonic secretory agents, also results in diarrhea. Toxin-producing *C. difficile* then flourishes within the colon. Almost any antibiotic (including metronidazole and vancomycin) can lead to pseudomembranous colitis, and chemotherapeutic agents, proton pump inhibitors, and antiviral agents have also been implicated. Bowel ischemia, inflammatory bowel disease, recent bowel surgery, uremia, malnutrition, shock, advanced age, peripartum status, and Hirschsprung's disease also contribute to the development of *C. difficile* infection and pseudomembranous colitis.[26]

Most disease-producing strains of *C. difficile* produce two toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin, that interact in a complex way to produce pseudomembranous colitis and its associated symptoms.

CLINICAL FEATURES

The disease typically begins 7 to 10 days after the institution of antibiotic therapy, although symptoms may occur up to 60 days after the antibiotic is discontinued. Pseudomembranous colitis results in a spectrum of clinical manifestations that vary from frequent, mucoid, watery stools to a toxic picture that includes profuse diarrhea (20 to 30 stools per day), crampy abdominal pain, fever, leukocytosis, and dehydration. Stool examination may demonstrate fecal leukocytes, which are not generally found in more benign forms of antibiotic-induced diarrhea.[27] In 1% to 3% of patients, toxic megacolon or colonic perforation may occur in patients with pseudomembranous colitis.[28]

DIAGNOSIS

The diagnosis is suggested by a history of diarrhea that develops during administration of antibiotics or within 2 weeks of their discontinuation.

Stool Assays The diagnosis is confirmed by the demonstration of *C. difficile* in the stool and by the detection of the toxin in stool filtrates. The organism is best identified by stool culture using a selective growth medium. This technique has a sensitivity approaching 100%, but lacks specificity because the presence of *C. difficile* does not necessarily implicate it in the cause of the disease.

Instead, *C. difficile* toxins are detected directly using a number of techniques including tissue-culture assay, enzyme-linked immunosorbent assays, latex agglutination, dot-immunobinding assays, and polymerase chain reaction. Tests vary in their sensitivity, specificity, and time to completion. Although tissue-culture assays are considered the gold standard, most laboratories use the enzyme-linked immunosorbent assay technique to detect the clostridial toxins; it has a sensitivity of 63% to 94% and a specificity of 75% to 100%.[28] Five to 20% of patients require more than one stool specimen to detect toxin.

Colonoscopy Colonoscopy reveals characteristic yellowish plaques within the intestinal lumen. Lesions may be seen throughout the entire alimentary tract, although they are typically limited to the right colon. Colonoscopy is not routinely needed to establish a diagnosis , but may be used in patients who require a rapid diagnosis and those who cannot produce a stool specimen due to ileus.

TREATMENT

Mild *C. difficile* infection in an otherwise healthy patient is treated by discontinuing the offending antibiotic.[25] This is effective in only about 20% of cases, however. Severely ill persons must be hospitalized. For specific antibiotic regimens, see **Table 73-3**.[29,30] Fidaxomicin (macrolide antibiotic) 200 milligrams PO twice a day for 10 days is also available for treatment.[31]

Rarely, emergency colectomy may be required for patients with severe *C. difficile* infection. Indications for emergency colectomy based on 30-day mortality include leukocytosis greater than 20,000 mm^3, lactate >5 mmoL/L, age >75 years, immunosuppression, shock, toxic megacolon, colonic perforation, or multiorgan system failure.

Relapses occur in 20% to 30% of patients.[29] Patients with prolonged antibiotic use, prolonged hospitalization, advanced age, diverticulosis, or multiple comorbidities are at increased risk for relapse.[26] The addition of monoclonal antibodies against the toxin to antibiotics reduces infection recurrence.[32] Probiotic treatment is not a useful adjunct for *C. difficile* infection.[33] The use of antidiarrheal agents is controversial.[34] Steroids are rarely needed.

Ensure contact isolation, use of personal protective equipment, and good hand washing with soap and water when caring for patients with suspected *C. difficile*–associated disease. Alcohol-based rubs are not effective in eliminating the spores of *C. difficile.*

TABLE 73-3 Treatment of *Clostridium difficile* Infection Based on Severity of Illness

Disease Severity	Treatment
Mild: WBC <15,000 mm^3	Metronidazole 500 milligrams PO three times a day for 14 days
Moderate: WBC >15,000 mm^3, patient able to tolerate PO	Vancomycin 125 milligrams PO four times a day for 14 days
First relapse	Metronidazole 500 milligrams PO three times a day for 14 days
Second relapse	Vancomycin 125 milligrams PO four times a day for 14 days; then taper dose over 4 weeks
Severe disease with toxic megacolon	Metronidazole 500 milligrams IV every 6 hours *and* vancomycin 500 milligrams PO every 6 hours (PO preferred to IV)

Note: Assume the offending antibiotic is discontinued.

DISPOSITION

Hospitalize patients with severe diarrhea, clinical toxicity, or symptoms that persist despite appropriate outpatient management. Consult the surgeon for suspected toxic megacolon or intestinal perforation for consideration of colectomy. For those patients who are discharged, discontinue antibiotics and encourage good oral hydration. Follow the antibiotic recommendations in **Table 73-3.**

INFLAMMATORY BOWEL DISEASE/ILEITIS/ COLITIS CROHN'S DISEASE

INTRODUCTION AND EPIDEMIOLOGY

Crohn's disease is a chronic granulomatous inflammatory disease of the gastrointestinal tract of unknown origin. **Crohn's disease can involve any part of the gastrointestinal tract from the mouth to the anus.** The ileum is involved in the majority of cases. In 20%, the disease is confined to the colon, making differentiation from ulcerative colitis difficult. The terms *regional enteritis, terminal ileitis, granulomatous ileocolitis,* and *Crohn's disease* are all used to describe the same disease process.

The peak incidence of Crohn's disease occurs between 15 and 22 years of age, with a secondary peak from 55 to 60 years. It is more common in women. The incidence is increasing, especially in children.[35] The disease is four times more common among Jews than non-Jews and is more common in whites than blacks, Asians, or Native Americans. A family history of inflammatory bowel disease is present in 10% to 15% of patients, particularly with early onset of disease. Ulcerative colitis as well as Crohn's disease may be present in other family members, and siblings of patients with Crohn's disease have a higher incidence of the disease. Smoking, oral contraceptive use, and the use of nonsteroidal anti-inflammatory agents worsen the course of the disease.

PATHOPHYSIOLOGY

The most important pathologic feature of Crohn's disease is the involvement of all the layers of the bowel and extension into mesenteric lymph nodes. The disease is discontinuous, with normal areas of bowel ("skip areas") located between one or more involved areas. Longitudinal, deep mucosal ulcerations are characteristic. If ulcerations penetrate the bowel wall, fissures, fistulas, and abscesses result. Late in the disease, a cobblestone appearance of the mucosa results from the criss-crossing of ulcers with intervening normal mucosa.

CLINICAL FEATURES

The clinical course of Crohn's disease varies and in the individual patient is unpredictable. Abdominal pain, anorexia, diarrhea, and weight loss are present in most cases. Chronic abdominal pain, fever,

and diarrhea may be present for several years before definitive diagnosis is established. Perianal fissures or fistulas, hematochezia, abscesses, or rectal prolapse can develop, particularly with colonic involvement.[36,37] Patients may also present with complications of the disease, such as obstruction with vomiting, crampy abdominal pain, and obstipation, or an intra-abdominal abscess with fever, abdominal pain, and a palpable mass.

In 10% to 20% of patients, the extraintestinal manifestations of arthritis, uveitis, or liver disease may be presenting symptoms. Crohn's disease should also be considered in the differential diagnosis of patients with fever of unknown etiology.

The clinical course and manifestations of the disease appear to be related to its anatomic distribution: in 30% the disease involves only the small bowel, in 20% only the colon is involved, and in 50% both the small bowel and colon are involved. A small percentage of patients present with disease involving the mouth, esophagus, and stomach. Crohn's disease of the stomach may demonstrate symptoms of peptic ulcer disease.

Extraintestinal manifestations are seen in up to 40% of patients with Crohn's disease (**Table 73-4**),[38] and the incidence and types of extraintestinal complications are similar in patients with Crohn's disease and ulcerative colitis.

TABLE 73-4 Common Extraintestinal Manifestations of Inflammatory Bowel Disease

Manifestation	Description
Arthritic	
Peripheral arthritis	Migratory monoarticular or polyarticular pain in peripheral joints (hip, knee, ankle, wrist) with effusion
Ankylosing spondylitis	Pain and stiffness of spine, hips, neck, and rib cage with limitation in truncal motion, loss of lumbar lordosis; decreased chest expansion and forward cervical flexion in advanced disease
Sacroiliitis	Low back pain with morning stiffness, relieved by exercise; progressive joint sclerosis
Ocular	
Episcleritis	Eye burning or itching without visual changes or pain; scleral and conjunctival hyperemia
Uveitis	Acute blurring of vision, photophobia and pain; perilimbic scleral injection
Dermatologic	
Erythema nodosum	Painful, red, raised nodules on extensor surfaces of arms or legs
Pyoderma gangrenosum	Ulcerative lesions with a necrotic center and violaceous skin typically found in pretibial region or trunk
Hepatobiliary	
Cholelithiasis	Varies from asymptomatic stones to right upper quadrant pain, fever, vomiting
Fatty liver	Mild right upper quadrant pain; hepatomegaly
Pericholangitis	Mild elevation in serum alkaline phosphatase, asymptomatic
Chronic active hepatitis	Autoimmune elevation of liver aminotransferase enzymes, may progress to cirrhosis
Primary sclerosing cholangitis	Pruritus progressing to jaundice, fatigue, and lethargy; laboratory findings vary from mild elevations of alkaline phosphatase to cirrhosis, portal hypertension, and liver failure; male predominance
Cholangiocarcinoma	Extrahepatic biliary mass, evidence of biliary obstruction, jaundice, right upper quadrant pain, fever, malaise
Pancreatitis	Varies from painless elevation of serum amylase to clinically apparent central abdominal pain radiating to back; may be associated with drugs such as azathioprine, 6-mercaptopurine, sulfasalazine, mesalamine, olsalazine, metronidazole
Vascular	
Thromboembolic disease	Symptoms of deep venous thrombosis and pulmonary emboli; portal vein, mesenteric vein, and hepatic venous thrombosis reported
Other	
Malnutrition	Fatigue, malaise, muscular wasting, cachexia
Chronic anemia	Fatigue, malaise, pallor, dyspnea; may be microcytic (blood loss), macrocytic (B_{12} deficiency), or autoimmune hemolytic
Nephrolithiasis	Flank pain, nausea, vomiting, hematuria; stones result from increased dietary oxalate absorption (calcium oxalate stones) and dehydration (urate stones)

DIAGNOSIS

In most patients, the definitive diagnosis of Crohn's disease is established months or years after symptom onset. A provisional diagnosis of appendicitis or pelvic inflammatory disease may change to Crohn's disease after imaging or at the time of surgery. A detailed history asking about previous bowel symptoms that preceded the onset of acute right lower quadrant pain provides clues to the correct diagnosis.

ED evaluation focuses on determining the severity of the attack; identifying significant complications such as obstruction, intra-abdominal abscess, life-threatening hemorrhage, or toxic megacolon; and eliminating other possible causes of the patient's complaints.

Laboratory Testing Laboratory evaluation should include a CBC, serum electrolytes, BUN, creatinine, and a type and cross-match where appropriate. C-reactive protein levels can monitor disease activity.[39] Fecal markers of inflammation (calprotectin and lactoferrin) are other markers of disease activity.[40]

Imaging Plain radiographs of the abdomen may demonstrate obstruction, perforation, or toxic megacolon. Abdominal CT scanning with PO and IV contrast identifies bowel wall thickening, segmental narrowing, destruction of the normal mucosal pattern, mesenteric edema, fistulas, and abscesses, which suggest the diagnosis of Crohn's disease. Extraintestinal complications such as gallstones, renal calculi, sacroiliitis, and osteomyelitis can also be seen on CT scan. Diagnosis is confirmed by colonoscopy.

Differential Diagnosis The differential diagnosis of Crohn's disease includes lymphoma, ileocecal amebiasis, sarcoidosis, deep chronic mycotic infections involving the gastrointestinal tract, gastrointestinal tuberculosis, Kaposi's sarcoma, *Campylobacter* enteritis, and *Yersinia* ileocolitis. Fortunately, most of these are uncommon conditions and can be differentiated by appropriate laboratory tests. *Yersinia* ileocolitis and *Campylobacter* enteritis may cause chronic abdominal pain and diarrhea similar to Crohn's disease, but can be diagnosed by appropriate stool cultures. It is not uncommon that a bout of acute bacterial diarrhea may uncover a diagnosis of inflammatory bowel disease.[41] Acute ileitis should not be confused with Crohn's disease. Young patients with acute ileitis usually recover without sequelae and should not undergo surgery. When Crohn's disease is confined to the colon, ischemic bowel disease (particularly in the elderly) and pseudomembranous colitis as well as ulcerative colitis must be included in the differential diagnosis.

TREATMENT

The aim of therapy for this incurable disease includes relief of symptoms, induction of remission, maintenance of remission, prevention of complications, optimizing timing of surgery, and maintenance of nutrition.[42,43]

Initial treatment (**Table 73-5**) consists of adequate fluid resuscitation and restoration of electrolyte balance. Place a nasogastric tube for obstruction, peritonitis, or toxic megacolon. Administer broad-spectrum antibiotics for fulminant colitis or peritonitis. Patients with severe disease should receive IV steroids such as hydrocortisone 300 milligrams per day or an equivalent dose of methylprednisolone (48 milligrams per day) or prednisolone (60 milligrams per day).

Salicylates Sulfasalazine 3 to 5 grams per day is for mild to moderate Crohn's disease. Sulfapyridine is a byproduct of the colonic breakdown of sulfasalazine. Many of the toxic side effects of sulfasalazine (vomiting,

TABLE 73-5 Treatment of Fulminant Colitis

Oral antibiotics
Ampicillin, trimethoprim-sulfamethoxazole, ciprofloxacin, cephalexin, or rifaximin
and
Metronidazole or clindamycin

anorexia, nausea, headache, diarrhea, epigastric distress, etc.) are attributable to sulfapyridine.

The active moiety in sulfasalazine is mesalamine. Many of the newer 5′-acetyl salicylic acid drugs feature a derivative of mesalamine without the sulfapyridine component. Pentasa®, Asacol®, Claversal®, Salofalk®, and Lialda® are mesalamine derivatives. Olsalazine (Dipentum®) and balsalazide (Colazide®) are 5-aminosalicylic molecules. The mesalamine formulations are most effective in patients with colonic disease and particularly in those with mild disease.

Corticosteroids Oral glucocorticoids such as prednisone (40 to 60 milligrams per day) have traditionally been reserved for more severely affected patients but are now used as induction therapy. An ileal-released form of budesonide (9 milligrams per day) may be beneficial in patients with ileal and right colon disease. Glucocorticoids are not preferred for maintaining remission because of their complications and concerns about effectiveness.

Immunosuppressives Immunosuppressive drugs such as 6-mercaptopurine, azathioprine, and thioguanine are useful in maintenance, as steroid-sparing agents, in healing fistulas, and in patients in whom there are serious contraindications to surgery.[44] Both agents have been associated with leukopenia, fever, hepatitis, and pancreatitis, necessitating the need for close follow-up, particularly during the initial phase of therapy. The response to immunosuppressives should not be expected before 3 to 6 months following the initiation of therapy. Parenteral methotrexate (15 to 25 milligrams per week) is considered third line and has been used following steroid and thiopurine metabolite failure.

Antibiotics Antibiotics are first-line agents for perianal disease and help induce remission. Ciprofloxacin (1.0 to 1.5 milligrams/kg per day) induces remission with rates (55%) similar to those in patients treated with mesalamine (4 grams per day).[45] Metronidazole (10 to 20 milligrams/kg per day) is also effective for perianal complications and fistulous disease. Combination therapies with antibiotics and biologic agents (see next section) have produced dramatic improvements in response.[46] Rifaximin is a broad-spectrum antibiotic that is not absorbed from the gastrointestinal tract. Rifaximin 800 milligrams twice daily for 12 weeks is effective for mild to moderate disease.[45] However, antibiotics raise concerns about precipitating *C. difficile* colitis infection.

Biologics Patients with medically resistant moderate to severe Crohn's disease may benefit from the antitumor necrosis factor antibody, infliximab (Remicade®) or adalimumab (Humira®).[45,47,48] All biologics increase the risk of infections, especially those caused by intracellular pathogens such as tuberculosis. Concern about the emergence of lymphomas and progressive multifocal leukoencephalopathy has limited the long-term use of these agents.

Maintenance therapy and the effectiveness of various therapeutic agents in Crohn's disease are variable. Glucocorticoids are not used for maintaining a remission because of the lack of sufficient evidence of their efficacy and the potential for long-term complications. A reduced dose of 5-aminosalicyclic acid derivatives is used for the maintenance of remission of colonic disease. The addition of sulfasalazine, azathioprine, and 6-mercaptopurine to prednisone does not improve the response rate and increases side effects. Infliximab or adalimumab and an immunosuppressive (azathioprine, 6-mercaptopurine, and methotrexate) can maintain remission.[45]

Antidiarrheal Agents Diarrhea can be controlled by loperamide (Imodium®) 4 to 16 milligrams per day, diphenoxylate (Lomotil®) 5 to 20 milligrams per day, and in some cases, cholestyramine (Questran®) 4 grams one to six times a day. The mechanism of action of cholestyramine is binding bile acids and eliminating their known cathartic action.

DISEASE COMPLICATIONS

More than three out of four patients with Crohn's disease will require surgery within the first 20 years of the onset of initial symptoms. **Abscess and fissure formation** is common. Abscesses can be characterized as intraperitoneal, visceral, retroperitoneal, interloop, or intramesenteric. Signs and symptoms are worsening abdominal pain and tenderness, fever, and possibly a palpable mass. Retroperitoneal abscesses may cause hip or back pain and difficulty ambulating.

Fistulas are the result of extension of the intestinal fissures seen in Crohn's disease into adjacent structures. The most common sites are between the ileum and the sigmoid colon, the cecum, another ileal segment, urinary bladder, vagina, or the skin. Suspect an internal fistula when there are changes in the patient's symptom complex, such as bowel movement frequency, amount of pain, or weight loss.

Obstruction is the result of both stricture formation due to the inflammatory process and of edema of the bowel wall. The distal small bowel is the most common site of obstruction. Symptoms include crampy abdominal pain, distention, nausea, and bloating.

Perianal complications include perianal or ischiorectal abscesses, fissures, fistulas, rectovaginal fistulas, and rectal prolapse. These are more commonly seen in patients with colonic involvement.

Major gastrointestinal bleeding is rare. Bleeding results from erosion into a vessel in the bowel wall. Toxic megacolon is also uncommon, but is associated with massive gastrointestinal bleeding in over half the cases.

When bowel symptoms are present, malnutrition, malabsorption, hypocalcemia, and vitamin deficiency can be severe. In addition to the complications of the disease itself are complications associated with the treatment of the disease with mesalamine, steroids, immunosuppressive agents, and antibiotics. These include leukopenia, thrombocytopenia, fever, infection, profuse diarrhea, pancreatitis, renal insufficiency, and liver failure.

The incidence of malignant neoplasm of the gastrointestinal tract is three times higher in patients with Crohn's disease than for the general population.

DISPOSITION

Patients with colitis, peritonitis, or complications such as obstruction, significant gastrointestinal hemorrhage, severe dehydration, or fluid/electrolyte imbalance should be hospitalized. Hospital admission should be considered in less severe cases that cannot be managed successfully

with outpatient management. Surgical intervention is indicated in those patients with complications of the disease, including intestinal obstruction or hemorrhage, perforation, abscess or fistula formation, toxic megacolon, and perianal disease.

Before discharging patients with Crohn's disease, discuss alterations in the therapeutic regimen with the gastroenterologist. Assure close follow-up after discharge.

ULCERATIVE COLITIS

INTRODUCTION AND EPIDEMIOLOGY

Ulcerative colitis is a chronic inflammatory disease of the colon. The inflammation tends to be progressively more severe from the proximal to the distal colon. The rectum is involved nearly 100% of the time. The characteristic symptom is bloody diarrhea. The cause is unknown.

The disease is more prevalent in the United States and northern Europe than in other parts of the world, and peak incidence occurs in the second and third decades of life. It is more common in men. First-degree relatives of patients with ulcerative colitis have a 15-fold risk of developing ulcerative colitis and a 3.5-fold risk of developing Crohn's disease.

PATHOPHYSIOLOGY

Ulcerative colitis involves primarily the mucosa and submucosa. Microscopically, the disease is characterized by mucosal inflammation with the formation of crypt abscesses, epithelial necrosis, and mucosal ulceration. The submucosa, muscular layer, and serosa are usually spared. In the usual case, the disease increases in severity more distally, the rectosigmoid being involved in the vast majority of cases. In the early stages of the disease, the mucous membranes appear finely granular and friable. In more severe cases, the mucosa appears as a red, spongy surface dotted with small ulcerations oozing blood and purulent exudate. In very advanced disease, one sees large, oozing ulcerations, and pseudopolyps (areas of hyperplastic overgrowth surrounded by inflamed mucosa).

CLINICAL FEATURES

The clinical features and course of ulcerative colitis vary and depend on the anatomical distribution of the disease in the colon. Crampy abdominal pain, bloody diarrhea, and tenesmus are typical symptoms. The disease is classified as mild, moderate, or severe depending on the clinical manifestations. Patients with mild disease have fewer than four bowel movements per day, no systemic symptoms, and few extraintestinal manifestations. Of all patients with ulcerative colitis, 60% have mild disease; in 80% of cases, the disease is limited to the rectum. Occasionally, constipation and rectal bleeding are the presenting complaints. Progression to pancolitis occurs in 10% to 15% of patients with mild disease.

Moderate disease is seen in 25% of patients. Patients demonstrate a good response to therapy. These patients usually have colitis extending to the splenic flexure (left-sided colitis), but may develop pancolitis.

Patients with severe disease constitute 15% of those with ulcerative colitis. Severe disease is associated with frequent bowel movements, anemia, fever, weight loss, tachycardia, low serum albumin, and more frequent extraintestinal manifestations. Patients with severe disease account for 90% of the mortality from ulcerative colitis. Virtually all severely affected patients have pancolitis.

Ulcerative colitis is usually characterized by intermittent attacks of acute disease with complete remission between attacks. Sometimes, the first attack is followed by a prolonged period of inactivity, or the disease is chronically active. The factors associated with an unfavorable prognosis and increased mortality include higher severity and extent of disease, a short interval between attacks, systemic symptoms, and onset of the disease after 60 years of age.

Extraintestinal complications are listed in **Table 73-4**.

DIAGNOSIS

Laboratory findings in patients with ulcerative colitis are nonspecific and may include leukocytosis, anemia, thrombocytosis, decreased serum albumin, and abnormal liver function studies. There are many biomarkers for diagnosis and prognosis,[40] but none are available in the ED. Therefore, the diagnosis of ulcerative colitis rests on the following: a history of abdominal cramps and diarrhea, mucoid stools, stool examination negative for ova and parasites, stool cultures negative for enteric pathogens, and confirmation of diagnosis by colonoscopy.

Differential Diagnosis The major diseases that should be considered in the differential diagnosis of ulcerative colitis include infectious colitis, Crohn's colitis, ischemic colitis, radiation colitis, toxic colitis from antineoplastic agents, and pseudomembranous colitis. When the disease is limited to the rectum, consider rectal syphilis, gonococcal proctitis, lymphogranuloma venereum, and inflammations caused by herpes simplex virus, *Entamoeba histolytica, Shigella,* and *Campylobacter.*

TREATMENT

Patients with severe ulcerative colitis should be treated with IV steroids, replacement of fluids, correction of electrolyte abnormalities, broad-spectrum antibiotics, mesalamine, and steroids (**Table 73-5**). IV cyclosporine (4 milligrams/kg per day) or infliximab can be effective in fulminant colitis nonresponsive to IV corticosteroids.[45]

When toxic megacolon is suspected, place a nasogastric tube and obtain imaging and surgical consultation.

The majority of those with mild and moderate disease can be treated as outpatients. In the treatment of patients with mild active proctitis, proctosigmoiditis, and left-sided colitis (<60 cm of active disease), topical treatment with mesalamine suppositories or enemas is effective. Although not as effective for inducing remission as mesalamine, topical steroid preparations (beclomethasone, hydrocortisone, tixocortol, and budesonide) are successful and better tolerated.[45] If topical therapy is unsuccessful, glucocorticoids are effective in inducing a remission in the majority of cases. Daily doses of 40 to 60 milligrams of prednisone are usually sufficient and can be adjusted depending on the severity of the disease.

A combination of oral (2.4 grams/day) and topical mesalamine is used in the treatment of acute mild to moderate attacks but is inferior to steroids in the more severe cases. In addition to sulfasalazine, the newer 5-aminosalicylic derivatives are quite effective in inducing remission of ulcerative colitis as well as maintaining it. The choice of agents available for the treatment of ulcerative colitis is very similar to that in Crohn's disease (mesalamine [Pentasa®, Asacol®, Lialda®], olsalazine [Dipentum®], and balsalazide). Topical glucocorticoid enemas or 5-aminosalicylic enemas (Rowasa®, 2 to 4 grams/60 mL per day for 3 weeks) or suppositories (500 milligrams twice a day) are quite effective in distal proctosigmoiditis and have lower systemic side-effect profiles.

Infliximab (5 milligrams/kg) is the only biologic indicated for ulcerative colitis. It should be considered for use in patients with mild to moderate disease who are corticosteroid dependent or refractory and in patients who have immunomodulator refractory disease.[47]

Hydrophilic bulk agents such as psyllium (Metamucil®) can be used in some patients to improve stool consistency. Antidiarrheal agents are generally ineffective and may precipitate toxic megacolon.

DISEASE COMPLICATIONS

Blood loss from sustained hemorrhage is the most common complication, but toxic megacolon must not be missed.

Toxic megacolon develops in advanced cases of colitis when the disease process extends through all layers of the colon (**Figure 73-1**).The result is a loss of muscular tone within the colon, with dilatation and localized peritonitis. If the colon continues to dilate without treatment, signs of toxicity will develop. Plain radiography of the abdomen demonstrates a long, continuous segment of air-filled colon greater than 6 cm in diameter. Loss of colonic haustra and "thumb printing," representing bowel wall edema, may also be seen. The distended portion of the atonic colon can perforate, causing peritonitis and septicemia. Mortality is high.

A patient with toxic megacolon appears severely ill; the abdomen is distended, tender, and tympanic. Severe diarrhea (>10 bowel movements per day) is often seen but may have ceased. Fever, tachycardia, and hypotension are typically part of the clinical picture. Leukocytosis, anemia, electrolyte disturbances, and hypoalbuminemia are the supporting laboratory results.

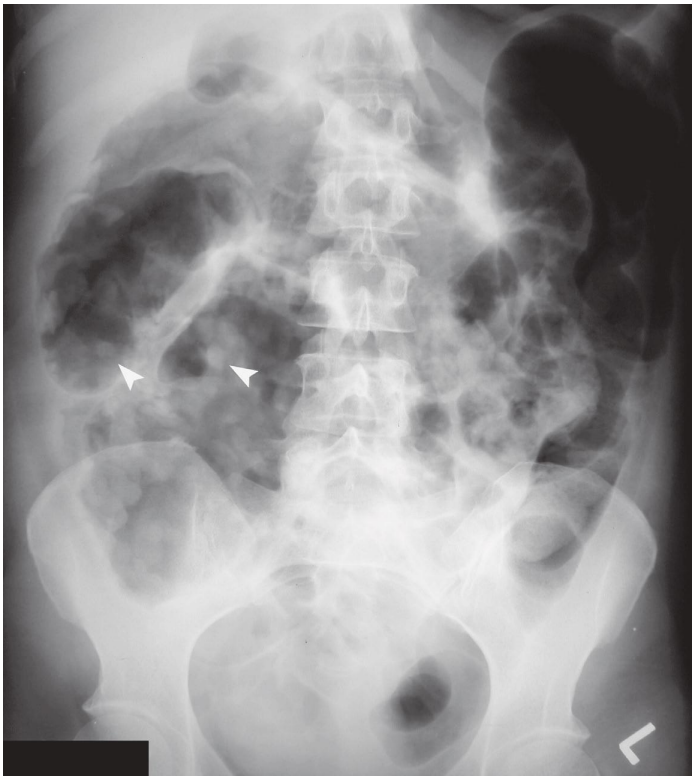

FIGURE 73-1. Abdominal distention due to toxic megacolon. Arrows point to mucosal nodules. [Reproduced with permission from Schwartz DT (Ed): *Emergency Radiology: Case Studies.* © McGraw-Hill, Inc., 2008. Chapter II-2, Fig. 23.]

Some of the more prominent features of toxic megacolon, such as leukocytosis and peritonitis, can be masked in the patient taking corticosteroids. Antidiarrheal agents, hypokalemia, narcotics, cathartics, pregnancy, enemas, and recent colonoscopy have been implicated as precipitating factors in toxic megacolon. Medical therapy with nasogastric suction, IV prednisolone 60 milligrams per day, or hydrocortisone 300 milligrams per day, parenteral broad-spectrum antibiotics active against coliforms and anaerobes, and IV fluids should be attempted as initial therapy, along with early surgical consultation.

Perirectal fistulas and abscesses may occur in up to 20% of patients with ulcerative colitis. Massive gastrointestinal hemorrhage, obstruction secondary to stricture formation, and acute perforation are other complications of the disease.

There is a 10- to 30-fold increase in the development of carcinoma of the colon in patients with ulcerative colitis. The major risk factors for the development of carcinoma of the colon are extensive involvement and prolonged duration of the disease. The cumulative risk of cancer after 20 and 30 years is 5% to 10% and 12% to 20%, respectively. Additional factors that constitute increased risk of cancer in patients with ulcerative colitis include early onset of the disease and a family history of colon cancer.

DISPOSITION

Patients with fulminant attacks of ulcerative colitis need hospitalization for aggressive fluid and electrolyte resuscitation and careful observation for the development of complications. Patients with complications such as gastrointestinal hemorrhage, toxic megacolon, and bowel perforation should also be admitted with consultation to both a gastroenterologist and a surgeon. In addition to toxic megacolon, the indications for surgery include colonic perforation, massive lower gastrointestinal bleeding, suspicion of colon cancer, and disease that is refractory to medical therapy (large doses of steroids required to control the disease).

Patients with mild to moderate disease can be discharged from the ED. Close follow-up should be arranged with the patient's physician or gastroenterologist, and any adjustment in medical therapy should be discussed prior to discharge.

CHAPTER 74

Constipation

Vito Rocco
Arash Armin

INTRODUCTION AND EPIDEMIOLOGY

Constipation is an extraordinarily common cause of patient morbidity in the United States.[1-4] The incidence of constipation increases with age, with 30% to 40% of persons >65 years old citing constipation as a problem.[4,5] Constipation affects as many as 80% of critically ill patients and is directly associated with patient mortality in this population.[6]

Physicians and patients define constipation differently. Physicians have traditionally defined constipation as fewer than three bowel movements per week. In contrast, patients commonly define constipation in terms such as abdominal discomfort, bloating, straining during bowel movements, or the sensation of incomplete evacuation. Consequently, constipation should not be defined simply by stool frequency alone, because doing so maximizes the potential to underdiagnose a significant number of patients who suffer from the condition.[7] The Rome criteria for the definition of constipation consist of two or more of the following signs or symptoms: (1) straining at defecation at least 25% of the time, (2) hard stools at least 25% of the time, (3) incomplete evacuation at least 25% of the time, (4) fewer than three bowel movements per week, (5) symptoms for at least 12 weeks (consecutive or nonconsecutive) in the preceding 12 months for chronic constipation.[8]

PATHOPHYSIOLOGY

Constipation is a complicated condition with multiple, often overlapping causes (**Table 74-1**). Gut motility is affected by diet, activity level, anatomic lesions, neurologic conditions, medications, toxins, hormone levels, rheumatologic conditions, microorganisms, and psychiatric conditions. Constipation is best thought of as either acute or chronic, as doing so helps formulate a differential diagnosis. Due to the rapidity of symptom onset, acute constipation is intestinal obstruction until proven otherwise. Common causes of intestinal obstruction include quickly growing tumors, strictures, hernias, adhesions, inflammatory conditions, and volvulus. Other causes of acute constipation include the addition of a new medicine (e.g., narcotic analgesic, antipsychotic, anticholinergic, antacid, antihistamine), change in exercise or diet (e.g., decreased level of exercise, fiber intake, or fluid intake), and painful rectal conditions (e.g., anal fissure, hemorrhoids, anorectal abscesses, proctitis). Chronic constipation can be caused by many of the same conditions that cause acute constipation. However, some specific causes of chronic constipation include neurologic conditions (e.g., neuropathies, Parkinson's disease, cerebral palsy, paraplegia), endocrine abnormalities (e.g., hypothyroidism, hyperparathyroidism, diabetes), electrolyte abnormalities (e.g., hypomagnesia, hypercalcemia, hypokalemia), rheumatologic conditions (e.g., amyloidosis, scleroderma), and toxicologic causes (e.g., iron, lead).

TABLE 74-1 Differential Diagnosis of Constipation

Acute causes
Gastrointestinal: quickly growing tumors, strictures, hernias, adhesions, inflammatory conditions, and volvulus
Medicinal: narcotic analgesic, antipsychotic, anticholinergic, antacid, antihistamine
Exercise and nutrition: decrease in level of exercise, fiber intake, fluid intake
Painful anal pathology: anal fissure, hemorrhoids, anorectal abscesses, proctitis
Chronic causes
Gastrointestinal: slowly growing tumor, colonic dysmotility, chronic anal pathology
Medicinal: chronic laxative abuse, narcotic analgesic, antipsychotic, anticholinergic, antacid, antihistamine
Neurologic: neuropathies, Parkinson's disease, cerebral palsy, paraplegia
Endocrine: hypothyroidism, hyperparathyroidism, diabetes
Electrolyte abnormalities: hypomagnesia, hypercalcemia, hypokalemia
Rheumatologic: amyloidosis, scleroderma
Toxicologic: lead, iron

CLINICAL FEATURES

HISTORY

The differential diagnosis of constipation is broad, so obtain a thorough history. Determine when the symptoms started and then determine whether there are any temporally related clues that can help narrow the differential diagnosis. Was a new medication or dietary supplement added at that time? Was there a decrease in fiber or fluid intake? Was there a change in activity level? Past medical and family history can help shed light on the cause of the constipation. Is there a history of hypothyroidism or diabetes? Does the patient have frequent kidney stones, which would point toward hyperparathyroidism? Although most patients who present with constipation do not have emergent conditions and may be treated symptomatically as outpatients, there are several historical elements that hint to a more ominous cause of symptoms, such as intestinal obstruction. Worrisome findings in addition to constipation include rapid onset, nausea or vomiting, inability to pass flatus, severe abdominal pain and distention, unexplained weight loss, rectal bleeding, unexplained iron-deficiency anemia, or a family history of colon cancer.[2] Any of these findings should prompt a more rigorous evaluation. Diarrhea alone does not rule out constipation/obstruction, as liquid stool can be passing past an obstructive source.

PHYSICAL EXAMINATION

In addition to a focused abdominal and pelvic examination, a rectal examination is essential. Examine the patient thoroughly for the presence of hernias and abdominal or pelvic masses. Bowel sounds will be decreased in cases of slow gut transit and increased in cases of obstruction. Ascites in the presence of constipation can be a sign of ovarian or uterine neoplasm in postmenopausal women. External rectal examination may demonstrate anal fissures, hemorrhoids, abscesses, or protruding masses. Digital rectal examination is useful in that it may demonstrate fecal impaction or an obstructing rectal mass. Especially common in the elderly is watery stool making its way around an overt impaction. Normal rectal tone is useful in ruling out neurologic causes of obstruction. Any stool retrieved from the rectal vault should be visually inspected and tested for occult blood. The finding of grossly bloody or guaiac-positive stool in the setting of constipation suggests concern for cancer, bowel ischemia, stercoral ulcer, or inflammatory bowel disease.

LABORATORY EVALUATION AND IMAGING

The evaluation of a constipated patient depends on the level of concern for an organic cause of constipation. If the patient is chronically constipated, little is usually gained from any testing so long as the history and physical examination do not point toward an organic cause. If the patient has a history concerning for intestinal obstruction (e.g., acute onset of symptoms, vomiting, significant abdominal distention or pain), an upright chest film and abdominal flat and erect films are useful. In cases of complete or partial intestinal obstruction, these films may demonstrate air-fluid levels or dilated bowel. If there continues to be high clinical suspicion for intestinal obstruction despite a normal chest and abdominal series of radiographs, then abdominal CT with PO and IV contrast may be necessary to make the diagnosis. In cases of suspected fecal impaction, an abdominal film should be obtained (**Figure 74-1**). In a constipated patient, such a film will demonstrate colonic or rectal dilation with or without air-fluid levels. Normal maximum diameter of the colon is 6 cm, whereas normal maximum diameter of the rectum is 4 cm.[2] In all patients in whom an organic cause of constipation is suspected, laboratory evaluation should include a CBC and electrolytes. CBC is useful to screen for anemia, and electrolytes are useful to identify hypomagnesia, hypercalcemia, and hypokalemia. Obtain thyroid function tests for suspected hypothyroidism. Obtain serum lead and iron levels for suspected heavy metal toxicity.

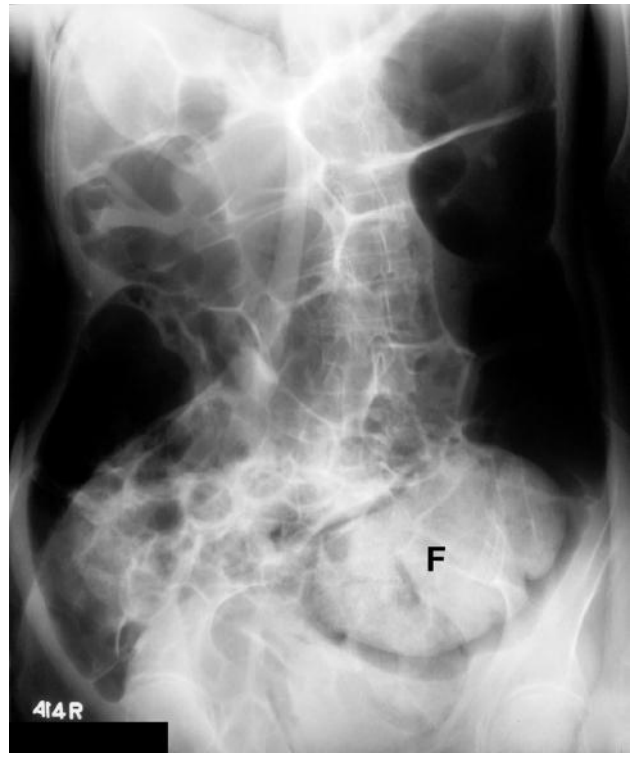

FIGURE 74-1. Large bowel obstruction due to fecal impaction (F). [Reused with permission from Schwartz DT (Ed): *Emergency Radiology: Case Studies.* © McGraw-Hill, Inc., 2008. Chapter II-2, Fig. 19.]

SPECIAL CONSIDERATIONS

FUNCTIONAL CONSTIPATION

The treatment of chronic (functional) constipation requires a multidisciplinary approach. There is no quick medication fix to alleviate the problem. The most important thing a physician can do for the ED patient is to stress lifestyle and diet modification. A strict dietary and exercise regimen is important, because without adequate fluid (1.5 L per day), fiber (10 grams per day), and exercise, medicinal methods usually fail.[4] Both fiber and laxatives modestly improve bowel movement frequency in adults with chronic constipation. There is inadequate evidence to determine whether fiber is superior to laxatives or one laxative class is superior to another.[9]

TABLE 74-2 Medical Adjuncts for the Treatment of Constipation

Type	Generic Name	Trade Name	PRN Doses	Side Effects	Mechanism
Fiber	Bran	NA	1 cup daily	Bloating, flatulence	Increases stool bulk or transit time; increases gut motility
	Psyllium	Metamucil®	1 teaspoon three times a day	Bloating, flatulence	
Emollient	Docusate sodium	Colace®	100 milligrams daily/twice a day	Cramping	Facilitates mixture of stool fat and water
Stimulants	Bisacodyl	Dulcolax®	10 milligrams PR three times a day	Incontinence, rectal burning	Stimulates the myenteric plexus, thereby increasing intestinal motility
	Anthraquinones	Peri-Colace®	One to two tablets PO daily/twice a day	Melanosis coli, degeneration of myenteric plexus	
	Senna	Senokot®, Ex-lax®	Two tablets PO daily/twice a day or 15–30 mL daily/twice a day	Laxative abuse, nausea, melanosis coli, cramping	
Saline laxative	Magnesium	Milk of magnesia	15–30 mL daily/twice a day	Magnesium toxicity, especially in renal insufficiency	Decreased colonic transit time
		Magnesium citrate	100–240 mL daily/twice a day	Cramping, flatulence, hypermagnesemia	
Suppository	Glycerin suppository	NA	1 PR daily	Rectal irritation	Local rectal stimulation
Hyperosmolar agents	Lactulose	NA	15–30 mL daily/twice a day	Cramps, flatulence, belching, nausea	Osmotically active nonabsorbable sugars pull fluid into the gut
	Sorbitol	NA	15–30 mL daily/twice a day	Cramps, flatulence	
	Polyethylene glycol	GoLYTELY®	1 gallon/4 h	Nausea, cramping, anal irritation	
		MiraLAX®	17 grams daily, onset of effect 1-3 days		
Enemas	Mineral oil	NA	100–250 mL PR	Local trauma	Colonic distention encourages evacuation
	Tap water	NA	500 mL PR	Local trauma

Medications often employed in the treatment of constipation are listed in **Table 74-2**. Of note, insufficient evidence exists supporting that laxative treatment is better than placebo in children with constipation or probiotics as a natural alternative. No current recommendations support one laxative over another for childhood constipation.[10] Also, there is no "best" management of constipation in palliative care and no evidence to support the use of one laxative, or combinations of laxatives, over another.[11] There has been some promise recently with the subcutaneous use of methylnaltrexone in multiple studies.[12-14] The effectiveness of rectal irrigation for functional bowel disorders is not clear.[15] In its extreme form, functional constipation can result in a variety of potentially life-threatening complications, especially fecal impaction and intestinal pseudo-obstruction (Ogilvie's syndrome[13]).

OPIOID-INDUCED BOWEL DYSFUNCTION

Opioid-induced bowel dysfunction is a frequent condition in patients receiving opioids for chronic pain or even acute postoperative pain.[16] Nearly half of patients taking opioid therapy for pain of noncancerous origin report constipation related to opioid therapy (<3 complete bowel movements per week), compared with 7.6% in a control group.[17]

FECAL IMPACTION

Physician resistance to manual disimpaction does the patient a disservice, as enemas provide little or no relief. Diarrhea does not rule out fecal impaction, especially in the elderly, debilitated patient, and failure to perform a rectal examination will result in misdiagnosis. Manual disimpaction is a painful procedure for which patients may require sedation. After disimpaction, prescribe a regimen of medications and medical adjuncts to properly reestablish fecal flow.

INTESTINAL PSEUDO-OBSTRUCTION (OGILVIE'S SYNDROME)

Ogilvie's syndrome, or acute colonic pseudo-obstruction, is a clinical disorder with the signs, symptoms, and radiographic appearance of an acute large bowel obstruction with no evidence of distal colonic obstruction. The colon may become massively dilated >10 cm. If the bowel is not decompressed, the patient risks perforation, peritonitis, and death.[18,19] The exact mechanism is not known but is thought to be secondary to a dysregulation of colonic motor activity by the autonomic nervous system. Predisposing factors include recent surgery, underlying neurologic disorders, and critical illness.[20] Treatment is varied and determined with surgical consultation. The symptoms may resolve with conservative management but may require operative or colonoscopic decompression of the dilated intestine.

ORGANIC CONSTIPATION

Symptoms suggestive of organic constipation are acute onset, weight loss, rectal bleeding/melena, nausea/vomiting, fever, rectal pain, and change in stool caliber.[21] Intestinal obstruction or carcinoma is the primary consideration. If fecal impaction is the cause, manual disimpaction is the treatment.

DISPOSITION AND FOLLOW-UP

Many constipated patients can be safely discharged from the ED with the caveat that certain key aspects have been adequately addressed[22] (**Table 74-3**). Fecal impaction requires disimpaction before discharge. Patients with organic constipation of a nonobstructive cause also can be managed safely as outpatients. The primary care provider should be

Possible obstructing lesion
Systemic illness
Medication interaction/effect
Electrolyte imbalance
Potential for intestinal perforation with self-administered enemas

contacted to ensure follow-up and to communicate concern for an organic process.

Referral to a gastroenterologist is warranted for patients with nonorganic constipation of recent onset; chronic constipation associated with weight loss, anemia, or change in stool caliber; refractory constipation; and constipation requiring chronic laxative use.[23] Patients with organic constipation of obstructive origin require hospitalization and surgical evaluation.

CHAPTER 75

Upper Gastrointestinal Bleeding

Christopher M. Ziebell
Andy Kitlowski
Janna M. Welch
Phillip A. Friesen

INTRODUCTION AND EPIDEMIOLOGY

Upper GI (UGI) bleeding is any GI bleeding originating proximal to the ligament of Treitz. The overall annual incidence of UGI bleeding ranges from 39 to 172 per 100,000 in Western countries.[1-3] Difference in prevalence between countries is attributed to variations in *Helicobacter pylori* rates, socioeconomic conditions, and prescription patterns of ulcer-healing and ulcer-promoting medications.[2] Increasing age, coexistent organ system disease, and recurrent hemorrhage are factors associated with increased morbidity and mortality.[3]

PATHOPHYSIOLOGY

PEPTIC ULCER DISEASE

Despite a downward trend in prevalence over the past 20 years, peptic ulcer disease, which includes gastric, duodenal, esophageal, and stomal ulcers, is still considered the most common cause of UGI bleeding.[2,4] However, the Analysis of Clinical Outcomes Research Initiative found gastric and duodenal ulcers in only 20.6% of 7822 endoscopies performed for suspected UGI bleeding.[4] This number is much lower than previous estimates of up to 50%.[5,6] Awareness that aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and smoking cause bleeding and increased recognition and treatment of *H. pylori* infection may be responsible for decreased incidence.[7-10]

EROSIVE GASTRITIS AND ESOPHAGITIS

Erosive gastritis, esophagitis, and duodenitis are also common causes of GI hemorrhage.[11] Common predisposing factors include alcohol, salicylates, and NSAIDs. Infection, toxic ingestion, radiation, and stress from severe illness may also cause erosive gastritis. Stress-related mucosal disease occurs in patients with overwhelming sepsis, trauma, or respiratory failure requiring mechanical ventilation. *Candida*, herpes simplex virus, cytomegalovirus, and human immunodeficiency virus are potential sources of esophageal bleeding from infection.

ESOPHAGEAL AND GASTRIC VARICES

Esophageal and gastric varices result from portal hypertension and, in the United States, are most often a result of alcoholic liver disease.[12] Although varices account for a small percentage of all cases of UGI hemorrhage, they can rebleed and carry a high mortality rate. However, many patients with end-stage cirrhosis never develop varices; many patients with documented varices never bleed; and many patients with a documented history of varices presenting with UGI bleeding will actually bleed from nonvariceal sites. Variceal bleeding is the cause of UGI bleeding in cirrhotics 59% of the time, followed by peptic ulcer disease in 16% of cases.[13] In-hospital mortality rates for any type of GI bleed in cirrhotics are essentially double those of noncirrhotic patients.[14]

MALLORY-WEISS SYNDROME

Mallory-Weiss syndrome is bleeding secondary to a longitudinal mucosal tear at the gastroesophageal junction. The classic history is repeated vomiting followed by bright red hematemesis. The syndrome can be associated with alcoholic binge drinking, diabetic ketoacidosis, or chemotherapy administration. The Valsalva maneuver, such as from coughing or seizures, is also a reported cause.

DIEULAFOY LESIONS

Dieulafoy lesions are arteries of the GI tract that protrude through the submucosa. They are most commonly found in the lesser curvature of the stomach but may be found anywhere in the GI tract; 80% to 95% are found within 6 cm of the gastroesophageal junction.[15] These lesions are characterized by intermittent massive GI bleeding, without the standard predisposing factors of liver disease or NSAID use. Dieulafoy lesions are difficult to diagnose endoscopically, and sometimes patients report multiple previous diagnostic maneuvers with negative results.

OTHER CAUSES

Arteriovenous malformation and malignancy are other causes of UGI hemorrhage. Significant bleeding from ear, nose, and throat sources can also masquerade as GI hemorrhage. An aortoenteric fistula secondary to a preexisting aortic graft is an unusual but important cause of bleeding to keep in mind. Classically, this presents as a self-limited "herald" bleed with hematemesis or hematochezia, which precedes massive hemorrhage and exsanguination.

DIAGNOSIS

HISTORY

Ask about hematemesis, coffee-ground emesis, or melena. Classically, hematemesis and coffee-ground emesis suggest a UGI source. The presence of melena and age <50 years old more likely indicate an upper GI bleed versus a lower GI bleed, even in patients without hematemesis.[16] Vomiting and retching, followed by hematemesis, suggest a Mallory-Weiss tear. Be sure to ask about prior episodes of GI bleeding and any interventions performed. A history of an aortic graft should suggest bleeding from an aortoenteric fistula. Review the patient's medication list carefully. Salicylates, glucocorticoids, NSAIDs, and anticoagulants all place the patient at high risk for GI bleed. Alcohol abuse is strongly associated with a number of causes of bleeding, including peptic ulcer disease, erosive gastritis, and esophageal varices. Ingestion of iron or bismuth can simulate melena. Liquid medications with red dye, as well as certain foods, such as beets, can simulate hematochezia. In such cases, stool guaiac testing will be negative. Inquire about past history of GI bleeding, even though recurrent bleeding episodes may originate from different sources.

Although the medical history may suggest the source of bleeding, history can also be misleading. For instance, what initially appears to be lower GI bleeding may actually be a UGI bleed in disguise. **Bright red or maroon rectal bleeding unexpectedly originates from UGI sources about 14% of the time.**[16] Although patients volunteer complaints of hematemesis or melena, if there is no vomiting or the patient has not noted tarry stools, signs may be subtle. Patients with hypotension, tachycardia, angina, syncope, weakness, confusion, or cardiac arrest may have underlying GI hemorrhage.

PHYSICAL EXAMINATION

Visual inspection of the vomitus for a bloody, maroon, or coffee-ground appearance is the most reliable way to diagnose UGI bleeding in the ED. Consider keeping a sample of the vomitus or nasogastric (NG) aspirate at bedside for the gastroenterologist to view.

Vital signs may reveal obvious hypotension and tachycardia or more subtle findings such as decreased pulse pressure or tachypnea. Younger patients and those without comorbidities can tolerate substantial volume loss with minimal or no changes in vital signs. Paradoxical bradycardia may occur even in the face of profound hypovolemia. Remember that comorbid conditions and medications may mask the body's physiologic response to volume loss. β-Blockers, for example, will prevent tachycardia. Patients with baseline hypertension may have relatively normal blood pressure in the setting of hypovolemia.

Cool, clammy skin is an obvious sign of shock. Spider angiomas, palmar erythema, jaundice, and gynecomastia suggest liver disease. Petechiae and purpura suggest an underlying coagulopathy. Facial lesions, cutaneous macules, or telangiectasias may be suggestive of the Peutz-Jeghers, Rendu-Osler-Weber, or Gardner's syndromes. A careful ear, nose, and throat examination can reveal an occult bleeding source that has resulted in swallowed blood and subsequent coffee-ground emesis. Abdominal examination may disclose tenderness, masses, ascites, or organomegaly.

Perform rectal examination to detect the presence of blood and its appearance, whether bright red, maroon, or melanotic.

LABORATORY TESTING

In patients with significant bleeding, the single most important laboratory test is to obtain blood for type and cross-match in case transfusion is needed. A CBC is also important, although the initial hematocrit level may not reflect the actual amount of acute blood loss. In addition, consider BUN, creatinine, electrolyte, glucose, coagulation, and liver function studies. UGI hemorrhage will elevate BUN levels through digestion and absorption of hemoglobin. A BUN:creatinine ratio ≥30 suggests a UGI source of bleeding.[17] Coagulation studies, including INR, partial thromboplastin time, and platelet count, are useful in patients taking anticoagulants and those with underlying hepatic disease. Obtain an ECG in patients with underlying coronary artery disease. Silent cardiac or mesenteric ischemia can develop if bleeding decreases cardiac or mesenteric perfusion. A single elevated lactate level is a sentinel sign of severe illness. The success or failure of resuscitation efforts can be assessed by following dynamic lactate levels, because a rising lactate level in the hospital setting is a clear predictor of in-hospital mortality.[18]

Routine abdominal and chest radiographs are of limited value and are not needed in the absence of specific clinical indications. Barium contrast studies are contraindicated because barium may hinder subsequent endoscopy or angiography.

In cases where traditional endoscopy is unavailable or endoscopic visualization is unable to find the source, consider tagged red-cell scintigraphy or visceral angiography. Both of these tests will demonstrate the source only in cases of active bleeding. Scintigraphy and angiography help localize the source of bleeding to determine whether medical or surgical management is optimal.

NASOGASTRIC LAVAGE

NG intubation and aspiration are diagnostic and therapeutic.[19] In patients without a history of hematemesis, a positive aspirate provides strong evidence for a UGI source of bleeding. High-risk lesions are more likely in patients with bloody aspirates. Visual inspection of the aspirate to identify bloody, maroon, or coffee-ground material verifies UGI bleeding. Early NG lavage is associated with decreased time to endoscopy.[20] NG tube placement and lavage can confirm the diagnosis of UGI bleeding and stratify risk.

A negative NG aspirate does not conclusively exclude a UGI source. Intermittent bleeding, pyloric spasm, or edema preventing reflux of duodenal blood can cause false-negative results. Ultimately, NG aspiration yields a positive result in only 23% of patients without hematemesis who have occult UGI bleeding.[21]

Guaiac testing of NG aspirate can yield both false-negative and false-positive results. Conventional stool guaiac cards may be falsely negative. However, guaiac cards specifically designed for UGI sources are available. Conversely, even minimally traumatic NG intubation can result in positive guaiac testing even in the face of a clear aspirate. **Visual inspection of the aspirate for a bloody, maroon, or coffee-ground appearance is the most reliable way to diagnose UGI bleeding in the ED.**

If bright red blood or clots are found in the NG aspirate, perform gentle gastric lavage. Room temperature water is the preferred irrigant. Maintain the NG tube on mild, intermittent suction. Suction that is too vigorous may produce gastric erosions that can confuse findings on subsequent endoscopy.

As of this writing, there is no evidence to support concerns that NG tube passage may provoke bleeding in patients with varices.

TABLE 75-1 Upper GI Bleeding Risk

Very Low Risk	High Risk
<60 y old	Advanced age
No major comorbidities	Comorbidities and prior endoscopic or transjugular intrahepatic portosystemic shunt procedures
No history of red hematemesis	Red hematemesis
No hematochezia	Hematochezia or melena
Negative nasogastric (NG) aspirate	Positive NG aspirate
Hemodynamically stable at ED presentation	Hemodynamically unstable
Normal laboratory studies	Abnormal laboratory studies

RISK STRATIFICATION

Risk stratification depends on clinical judgment. There are no universally accepted pre-endoscopy risk stratification practice guidelines. However, the literature does seem to agree on those individuals that qualify as very low risk (**Table 75-1**). Pre-endoscopic predictors of higher risk include advanced age, comorbidities, red hematemesis, hematochezia, red blood on NG aspirate, hemodynamic instability, and abnormal laboratory studies.[22-26] Other high-risk factors include prior variceal banding, clamping or cauterization of an ulcer bed, or the transjugular intrahepatic portosystemic shunt procedure.

TREATMENT

Initial management is stabilization. Patients in hemorrhagic shock require emergent resuscitation, including two large-bore IVs, typed and cross-matched blood with the consideration of massive transfusion protocols, and in selected cases, early airway management. Intubating a patient with a UGI bleed who is hemodynamically unstable can be a perilous procedure. Aggressively resuscitate prior to intubation, and consider using smaller doses of the induction agent to minimize peri-intubation hypotension or arrest.[27] ED treatment is summarized in **Table 75-2**.

BLOOD TRANSFUSIONS

When UGI bleeding is severe, blood transfusions can be lifesaving. If a large amount of blood product is anticipated, use massive transfusion protocols.[28] See chapter 13, "Fluid and Blood Resuscitation in Traumatic Shock" for discussion of massive transfusion. In less severe

TABLE 75-2 Treatment of Upper GI Bleed

Treatment	Dose	Comments
Blood transfusion		Transfuse if ≤7 grams/dL in most; ≤9 grams/dL in older patients or patients with comorbidities
Correct coagulopathy		Correct if INR is elevated or platelets <50,000; or if bleeding severe, correct coagulopathy unless contraindications to correction (e.g., stents)
Omeprazole	80-milligram IV bolus then infusion of 8 milligrams/h	Labeled use for ulcer bleeding
Octreotide	50-microgram bolus then infusion of 25–50 micrograms/h	Unlabeled use for varices; for elderly, begin at lower dose range of 25-microgram bolus and infusion of 25 micrograms/h
Antibiotics	Ciprofloxacin 400 milligrams IV or ceftriaxone 1 gram IV	Antibiotics for cirrhotics with UGI bleeding

cases, the decision to transfuse can be difficult because hemoglobin concentrations do not fall until after hemodilution has occurred. Individualize thresholds for transfusion based on underlying comorbidities and hemodynamic status.[29] Liberally transfusing all bleeding patients using a high threshold (hemoglobin <9 grams/dL) can cause harm.[5] A restrictive transfusion threshold using hemoglobin concentrations of <7 grams/dL in most patients and <9 grams/dL in older patients with comorbidities who are not tolerating the acute anemia is recommended.[5,29]

COAGULOPATHY

In patients with life-threatening bleeding receiving anticoagulants, reverse the coagulopathy without concern for the INR unless there are contraindications to reversal, such as cardiac or vascular stents. In less severe bleeding, carefully consider the risks of reversal therapy. An INR ≥1.5 is a significant predictor of mortality in patients with a UGI bleed who are receiving anticoagulants.[30] International consensus guidelines recommend reversal of coagulopathy for UGI bleed patients who have an elevated INR or platelet counts <50,000/μL.[29,31] Coagulopathies from other causes such as the newer oral antithrombin and Xa inhibitors should be managed according to institutional protocols. See Figure 239-1 and Table 239-4 in chapter titled "Thrombotics and Antithrombotics" for recommendations for anticoagulant reversal. Reversal should not delay time to endoscopy. Tranexamic acid, an antifibrinolytic agent, has shown no benefit in the management UGI bleeding.[32]

PROTON PUMP INHIBITORS

Consensus guidelines continue to recommend proton pump inhibitors for patients with nonvariceal bleeding from peptic ulcer disease.[23] When proton pump inhibitors are given at high dose, the gastric pH remains neutral. Clot formation from platelet aggregation is dependent on a pH >6.0.[33] Administer a high-dose proton pump inhibitor such as omeprazole 80 milligrams IV bolus followed by infusion of 8 milligrams/h[34] because the cause of bleeding cannot be determined without endoscopy. In patients with peptic ulcer bleeding, proton pump inhibitors reduce the need for surgery, the length of stay in the hospital, and signs of bleeding.[35]

SOMATOSTATIN ANALOGS/OCTREOTIDE

Octreotide is a long-acting analog of somatostatin that elicits several actions in patients with UGI bleeding. It inhibits the secretion of gastric acid, reduces blood flow to the gastroduodenal mucosa, and causes splanchnic vasoconstriction.[36] The dose is a 50-microgram bolus followed by a continuous infusion of 25 to 50 micrograms/h. Despite its widespread use in the United States, octreotide does not appear to provide a clear benefit on mortality.[37] In contrast, terlipressin is preferred in countries where it is available because it is the only drug treatment associated with a reduction in mortality.[38]

ANTIBIOTICS

Patients with cirrhosis have an impaired immune system and have an increased risk of gut bacterial translocation during an acute bleeding episode. Prophylactic antibiotics (e.g., ciprofloxacin 400 milligrams IV or ceftriaxone 1 gram IV) reduce infectious complications, may decrease mortality,[39] and should be started as soon as possible.

PROMOTILITY AGENTS

Erythromycin and metoclopramide are examples of promotility agents used to enhance endoscopic visualization.[40] However, they are not recommended for routine use, but may be considered if the patient is undergoing endoscopy in the ED and the patient is suspected to have large amounts of blood in the UGI tract.[29]

ENDOSCOPY

UGI endoscopy is the diagnostic study of choice. Endoscopy allows visualization of the source of bleeding (in most cases) and administration of hemostatic therapy.[41] The optimal timing relates to the severity of the bleeding. Early endoscopy (within 24 hours of presentation) is recommended for most patients because it is associated with a significant cost reduction and decreased length of stay.[19,20,41-43] An unstable patient may benefit from emergent endoscopy immediately following resuscitation.

Endoscopic treatment options commonly used for variceal bleeding include variceal ligation and sclerotherapy. Clips, thermocoagulation, and sclerosant injections alone or in combination with epinephrine injections are commonly used in ulcerative lesions.

In some practices, the ED physician is asked to provide sedation for the endoscopist. Pretreat with an antiemetic such as ondansetron. Use short-acting titratable drugs with both analgesic properties (fentanyl) and sedative properties (versed or propofol). Ideal agents can be reversed if the patient's condition changes.[44-46] In unstable patients, one must consider using cardiovascular stable agents such as etomidate or ketamine. While providing sedation, consider that the most noxious part of the procedure is when the scope is passed around the tongue.

BALLOON TAMPONADE

Balloon tamponade is an effective short-term solution for life-threatening variceal bleeding. Because of the high rate of complications, it should be reserved for temporary stabilization of patients for transfer to an appropriate institution or until endoscopy can be done. The **Sengstaken-Blakemore tube** (which has a 250-cc gastric balloon, an esophageal balloon, and a single gastric suction port) (**Figure 75-1**) and the **Minnesota tube** (with an added esophageal suction port above the esophageal balloon) are examples of balloons that have been used. Adverse reactions include mucosal ulceration, esophageal or gastric rupture, asphyxiation from tracheal compression, and aspiration. Strongly consider intubation prior to balloon tamponade.

The device can be inserted either nasally or orally. The gastric balloon is inflated first. It is critical to know that one is in the stomach before fully inflating the gastric balloon. If bleeding does not stop, inflate the esophageal balloon while using a manometer to ensure the pressure does not exceed 50 mm Hg. Confirm tube placement by x-ray. To secure the tube, apply 1 kg of traction by attaching the distal end of the tube to a 1-L bag of saline hung from an IV pole. Alternatively, the tube can be secured directly to a football helmet.

SURGERY

Patients who do not respond to both pharmacologic and endoscopic treatments may require emergent surgery. In patients with variceal bleeding, there are two basic types of operations: shunt operations (transjugular intrahepatic portosystemic shunt procedure) and nonshunt operations (esophageal transection or gastroesophageal junction devascularization). In nonvariceal bleeding, percutaneous embolization or subtotal or total gastrectomy can be performed. Emergent surgical consultation is considered prudent in case of uncontrolled bleeding.

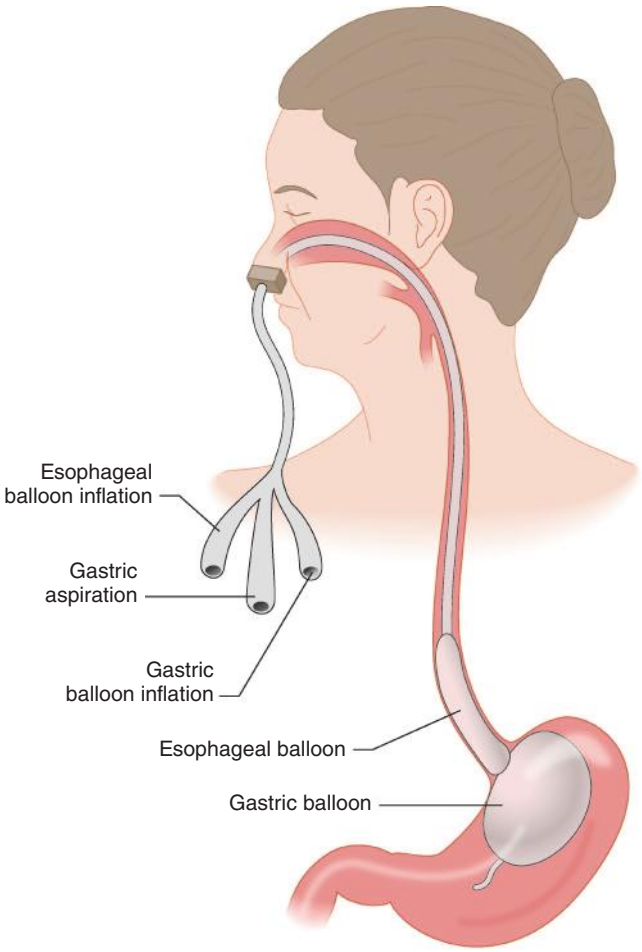

FIGURE 75-1. Sengstaken-Blakemore tube.

DISPOSITION AND FOLLOW-UP

Patients with significant UGI bleeding require intensive care unit admission and early endoscopy. Very-low-risk patients (Table 75-1) may be eligible for ED observation or be discharged home with adequate outpatient follow-up.

CHAPTER 76

Lower Gastrointestinal Bleeding

Bruce M. Lo

INTRODUCTION AND EPIDEMIOLOGY

Lower GI (LGI) bleeding is the loss of blood from the GI tract distal to the ligament of Treitz. LGI bleeding is a common problem in emergency medicine and should be considered potentially life threatening until proven otherwise.

LGI bleeding occurs less often than upper GI (UGI) bleeding, with an annual incidence of approximately 36 per 100,000.[1] Because blood must travel through the UGI tract down to the LGI system, UGI bleeds are the most common source for all causes of blood detected in the LGI system. **Among patients with an established LGI source of bleeding (i.e., bleeding past the ligament of Treitz), the most common cause is diverticular disease, followed by colitis, adenomatous polyps, and malignancies.**[2,3] LGI bleeding is more common among females and increases significantly in the elderly.[1]

About 80% of episodes of LGI bleeding resolve spontaneously.[4] However, one cannot predict which episodes will spontaneously resolve or which episodes will result in complications. This is partly due to the difficulty in establishing a pathophysiologic diagnosis. In one study, a cause for bleeding was found in <50% of the cases.[5]

PATHOPHYSIOLOGY

Hematochezia is either bright red or maroon-colored rectal bleeding. If hematochezia originates from a UGI source, it indicates brisk UGI bleeding, which may be accompanied by hematemesis and hemodynamic instability. Approximately 10% of hematochezia episodes may be associated with UGI bleeding.[6] **Melena** is dark or black-colored stools and usually represents bleeding from a UGI source (proximal to the ligament of Treitz) but may also represent slow bleeding from an LGI source.

DIVERTICULOSIS

Diverticular bleeding is usually painless and results from erosion into the penetrating artery of the diverticulum. Diverticular bleeding may be massive, but up to 90% of episodes will resolve spontaneously. Bleeding can recur in up to half.[7,8] Although most diverticula are located on the left colon, right-sided diverticula are thought to be more likely to bleed.[9] Elderly patients with underlying medical illnesses, those with increased needs for transfusion, and those taking anticoagulants or nonsteroidal anti-inflammatory drugs have increased morbidity and mortality.[7]

VASCULAR ECTASIA

Vascular ectasia, which includes arteriovenous malformations and angiodysplasias of the colon, is a common cause of LGI bleeding. Vascular ectasia can also be present in the small bowel and is difficult to diagnose. The development of vascular ectasia in the large bowel seems to be due to a chronic process and increases with aging. Inherited conditions can also give rise to arteriovenous malformations. There is also a suggestion that valvular heart disease is a risk factor for developing bleeding vascular ectasias, although this is an area of debate.[4]

ISCHEMIC COLITIS AND MESENTERIC ISCHEMIA

Ischemic colitis is the most common cause of intestinal ischemia and is usually transient. The colon is predisposed to ischemia because of its poor vascular circulation and high bacterial content. Aneurysmal rupture, vasculitis, hypercoagulable states, prolonged strenuous exercise, cardiovascular insult, irritable bowel syndrome, and certain medications that cause vasoconstriction or slow bowel motility are known risk factors. Diagnosis is usually made by endoscopy. Although most cases will resolve on their own, up to 20% will require surgical intervention.[10]

Mesenteric ischemia can lead to bowel necrosis. Causes include thrombosis or embolism of the superior mesenteric artery, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia associated with low arterial flow with vasoconstriction. Diagnosis is difficult, and the presentation can mimic other intra-abdominal pathologies. Diagnosis requires a high index of suspicion, especially in patients >60 years old and in those with atrial fibrillation, congestive heart failure, recent myocardial infarction, postprandial abdominal pain, or unexplained weight loss. CT has a specificity of 92% but only a sensitivity of 64%. Angiography remains the diagnostic study of choice. Despite aggressive treatment, prognosis is poor, with a survival of 50% if diagnosed within 24 hours.[11]

MECKEL'S DIVERTICULUM

Meckel's diverticulum consists of embryonic tissue, most commonly found in the terminal ileum. More than half of lesions contain ectopic

gastric tissue, which can secrete gastric enzymes, eroding the mucosal wall and causing bleeding. It is a rare but important condition, especially in the younger population.

OTHER CAUSES OF LOWER GI BLEEDING

Numerous other lesions may result in LGI hemorrhage (**Table 76-1**), including infectious colitis, radiation colitis, rectal ulcers, trauma, and inflammatory bowel disease. Polyps and carcinomas can cause LGI bleeding and are usually a source of chronic anemia. Delayed hemorrhage can occur up to 3 weeks after polypectomy. Patients with left ventricular assist devices are prone to GI bleeding especially due to anticoagulation, risk of arteriovenous malformations, and acquired von Willebrand's disease.[12] Although hemorrhoids are the most common source of anorectal bleeding, massive hemorrhage is unusual.[10] For further discussion of hemorrhoids, see chapter 85, "Anorectal Disorders."

DIAGNOSIS

As with any emergency, the medical history, physical examination, and diagnostics often must be accomplished simultaneously with resuscitation and stabilization. **Factors associated with a high morbidity rate are hemodynamic instability, repeated hematochezia, gross blood on initial rectal examination, initial hematocrit <35%, syncope, nontender abdomen (predictive of severe bleeding), aspirin or nonsteroidal anti-inflammatory drug use (predictive of diverticular hemorrhage), and more than two comorbid conditions.**[2,3,13]

HISTORY

Although most patients will volunteer complaints of hematochezia or melena, signs and symptoms of hypotension, tachycardia, angina, syncope, weakness, or altered mental status can all occur as a result of LGI bleeding.

Ask about previous GI bleeding as well as a history of pain, trauma, ingestion or insertion of foreign bodies, and recent colonoscopies. Weight loss and changes in bowel habits may suggest malignancy. A history of an aortic graft may suggest the possibility of an aortoenteric fistula. Medications, such as salicylates, nonsteroidal anti-inflammatory drugs, and warfarin, increase the risk of LGI bleeding.[14-16] Ingestion of iron or bismuth can simulate melena, and certain foods, such as beets, can simulate hematochezia. However, stool guaiac testing in those cases will be negative.

PHYSICAL EXAMINATION

Hypotension and tachycardia, or decreased pulse pressure or tachypnea, develop with significant bleeding. However, changes in vital signs may be masked by concurrent medications, such as β-blockers, or medical conditions such as poorly controlled hypertension. Thus, relative tachycardia and hypotension may represent subtle clues to ongoing bleeding. Some patients can tolerate substantial volume losses with minimal or no changes in vital signs.

Cool, pale skin and an increase in capillary refill can be signs of shock. Physical findings of liver disease, as well as petechiae and purpura, suggest an underlying coagulopathy. The abdominal examination may disclose tenderness, masses, ascites, or organomegaly. In patients with LGI bleeding, a lack of abdominal tenderness suggests bleeding from disorders involving the vasculature, such as diverticulosis or angiodysplasia. Inflammatory bowel disorders with LGI bleeding are associated with abdominal tenderness on examination.

Thorough examination of the rectal area may reveal an obvious source of bleeding, such as a laceration, masses, trauma, anal fissures, or external hemorrhoids. A vaginal or urinary source of bleeding mistaken for a GI source will be identified by examination and testing. Perform a digital rectal examination to detect gross blood (either bright red or maroon) and for guaiac testing. Rectal examination can also detect the presence of masses.

Anoscopy can also be performed at the bedside. A source of bleeding such as hemorrhoids can sometimes be elucidated by anoscopy. However, blood originating beyond the level of visualization should raise the suspicion for other causes.[10]

LABORATORY TESTING

The most important laboratory tests are the CBC, coagulation studies, and typed and cross-matched blood. Coagulation studies, including prothrombin time, partial thromboplastin time, and platelet count, are of obvious benefit in patients taking anticoagulants or those with underlying hepatic disease. In addition, obtain blood urea nitrogen, creatinine, electrolytes, glucose, and liver function studies. In acute, brisk bleeding, the initial hematocrit level may not reflect the actual amount of blood loss. **Bleeding from a source higher in the GI tract may elevate blood urea nitrogen levels through digestion and absorption of hemoglobin.**

Obtain an ECG in patients with coronary artery disease. **Silent ischemia can occur secondary to the decreased oxygen delivery accompanying significant GI bleeding.**

IMAGING

Routine abdominal radiographs are of limited value without specific indications such as perforation, obstruction, or foreign bodies. Similarly, routine admission chest x-rays for patients with acute GI hemorrhage, even those admitted to the intensive care unit, are of limited utility in the absence of known pulmonary disease or abnormal findings on lung examination.[17] Barium contrast studies are not helpful and can interfere with subsequent emergent endoscopy or angiography.

The initial diagnostic procedure of choice—angiography, scintigraphy, or endoscopy—depends upon resource ability and consultant preference.[18-21] Angiography can sometimes detect the site of bleeding and help guide surgical management. Moreover, angiography permits therapeutic options such as transcatheter arterial embolization or the infusion of vasoconstrictive agents. However, **angiographic diagnosis and therapy require a relatively brisk bleeding rate (at least 0.5 mL/min). Serious complications can also occur with angiography in up to 10% of cases.**[10]

Technetium-labeled red cell scans can also localize the site of bleeding in obscure hemorrhage. Such localization can be used to help determine

if angiography or surgery is the optimal approach. **Scintigraphy appears more sensitive than angiography and can localize the site of bleeding at as low a rate as 0.1 mL/min. It also has potential value over angiography if bleeding occurs intermittently but requires a minimum of 3 mL of blood to pool.**[22]

Multidetector CT angiography has a sensitivity and specificity of up to 100% and 99%, respectively, for detecting active or recent GI bleeding and is about 93% accurate in determining the site of bleeding.[23,24] It can be a useful tool prior to treatment with conventional angiography.

TREATMENT

Resuscitate unstable or actively bleeding patients. Administer oxygen and institute cardiac monitoring. Place two large-bore IV lines and replace volume with crystalloids. Correct coagulopathy. Blood transfusion should be based on the clinical findings of volume depletion or continued bleeding rather than on initial hematocrit values. In acute bleeding, hematocrit values may not represent true blood volume status, because it takes several hours for the hematocrit to decrease. **General guidelines for initiation of blood transfusion are continued active bleeding and failure to improve perfusion and vital signs after the infusion of 2 L of crystalloid.** The threshold for blood transfusion should be lower in the elderly.

Consider the placement of a nasogastric tube if LGI bleeding is significant. **Hematochezia unexpectedly originates from UGI sources approximately 10% to 14% of the time.**[6,25] Factors that suggest a UGI source for hematochezia include anemia and previous history of UGI bleeding.[6] Nasogastric aspiration has low sensitivity and negative predictive value for UGI bleeding.[26] In one study, 15% of patients with hematochezia had a negative nasogastric aspirate but had a UGI source of bleeding.[26] A nasogastric tube is likely beneficial only for those with significant ongoing UGI bleeding in whom immediate intervention will occur.[10,26]

Obtain early consultation for severe LGI bleeding to expedite the next steps of care. Surgical consultation along with consultation from the gastroenterologist is prudent for uncontrollable bleeding.

ENDOSCOPY AND SURGERY

Flexible sigmoidoscopy can evaluate possible distal colonic and rectal sources of bleeding but cannot identify more proximal sources of bleeding. Colonoscopy can diagnose various sources of LGI bleeding, such as diverticulosis or angiodysplasia, and may allow ablation of bleeding sites with various endoscopic hemostasis methods (injection sclerotherapy, electrocoagulation, heater probe therapy, banding, and clipping). If colonoscopy fails to determine the source of bleeding, the specialists may consider upper endoscopy to evaluate for a UGI source of bleeding, although upper endoscopy may be indicated first in certain situations.[27] Timing of endoscopy can vary. Some studies suggest that urgent colonoscopy is both safe and accurate within 12 to 24 hours of admission, but others report that delayed colonoscopy is appropriate in stable patients.[8-10,27]

Patients with continued bleeding and failure of endoscopic hemostasis may need emergency surgery. The reported proportion of patients requiring surgery varies from 5% to 25%.[10,18]

DISPOSITION AND FOLLOW-UP

Patients with LGI hemorrhage will often require hospital admission and early referral to an endoscopist. Those who are unstable or with active bleeding may require admission to the intensive care unit. Variables associated with morbidity include **hemodynamic instability, repeated hematochezia within 4 hours of evaluation, nontender abdomen, aspirin use, and more than two comorbid conditions**.[2,3] Although risk stratification scores have been developed for UGI bleeding for possible outpatient management, **no reliable scoring system exists to risk stratify which patients with LGI bleeding may be discharged home safely**. However, those with an obvious cause of mild bleeding (such as mild bleeding from hemorrhoids or anal fissures), or who have no bright red blood or maroon or melanotic stool on rectal examination and are hemodynamically stable and without major comorbidities, may be candidates for outpatient treatment.

CHAPTER 77

Esophageal Emergencies

Moss Mendelson

ESOPHAGEAL EMERGENCIES

The complaints of dysphagia, odynophagia, and ingested foreign body immediately implicate the esophagus. The esophagus also is often the site of pathology in patients who present with chest pain, upper GI bleeding (see chapter 75, "Upper Gastrointestinal Bleeding"), malignancy, and mediastinitis. Many diseases of the esophagus can be evaluated over time in an outpatient setting, but several, such as esophageal foreign body and esophageal perforation, require emergent intervention.

ANATOMY AND PATHOPHYSIOLOGY

The esophagus is a muscular tube approximately 20 to 25 cm long, primarily located in the mediastinum, posterior and slightly lateral to the trachea, with smaller cervical and abdominal components, as shown in **Figure 77-1**. There is an outer longitudinal muscle layer and an inner

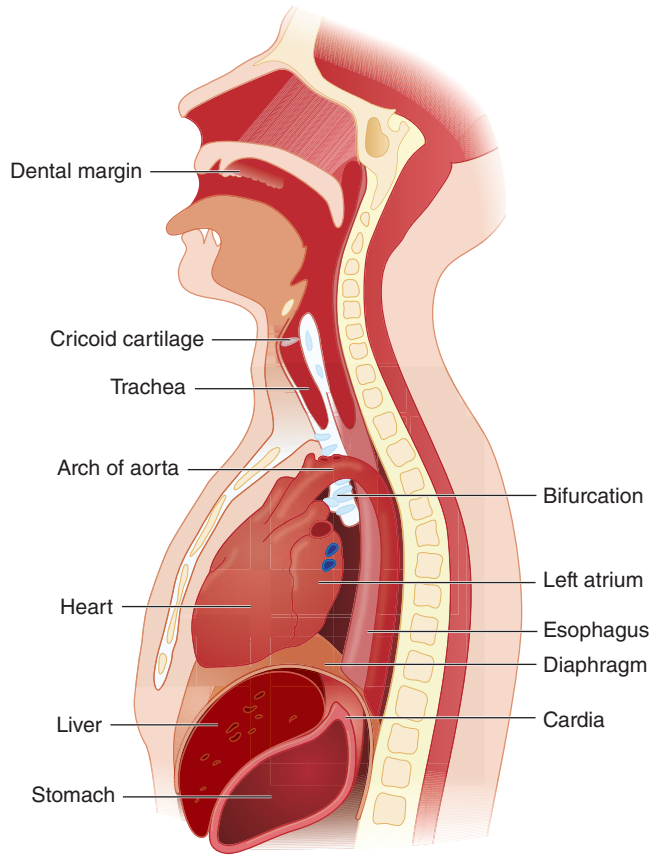

FIGURE 77-1. Anatomic relations of the esophagus (seen from the left side). The distance from the upper incisor teeth to the beginning of the esophagus (cricoid cartilage) is about 15 cm (6 in); from the upper incisors to the level of the bronchi, 22 to 23 cm (9 in); and to the cardia, 40 cm (16 in). Structures contiguous to the esophagus that affect esophageal function are shown.

circular muscle layer. The upper third of the esophagus is striated muscle, while the lower half is all smooth muscle (including the lower esophageal sphincter). The esophagus is lined with stratified squamous epithelial cells that have no secretory function.

Two sphincters regulate the passage of material into and out of the esophagus. The upper esophageal sphincter prevents air from entering the esophagus and food from refluxing into the pharynx. The lower esophageal sphincter regulates the passage of food into the stomach and prevents stomach contents from refluxing into the esophagus. The upper sphincter is composed primarily of the cricopharyngeus muscle, with a resting pressure of around 100 mm Hg. The lower sphincter is not anatomically discrete. The smooth muscle of the lower 1 to 2 cm of the esophagus, in combination with the skeletal muscle of the diaphragmatic hiatus, functions as the sphincter, with a lower resting pressure around 25 mm Hg. An empty esophagus collapses, but three anatomic constrictions affect the adult esophagus:

1. At the cricopharyngeus muscle (C6)
2. At the level of the aortic arch (T4)
3. At the gastroesophageal junction (T10 to T11)

The pediatric esophagus gets two additional areas of constriction:

1. At the thoracic inlet (T1)
2. At the tracheal bifurcation (T6)

The innervation of the heart mirrors that of the esophagus, with visceral and somatic stimuli converging within the sympathetic system. This anatomy makes pain of esophageal and cardiac origin similar. The esophageal venous circulation includes a submucosal plexus of veins that drains into a separate plexus of veins surrounding the esophagus. Blood flows from this outer plexus in part to the gastric venous system, an important link between portal and systemic circulation. Variceal dilatation of the submucosal system can lead to massive upper GI bleeding.

DYSPHAGIA

Dysphagia is difficulty with swallowing. Most patients with dysphagia have an identifiable, organic cause.

Oropharyngeal (transfer) and esophageal (transport) dysphagia describe two broad pathophysiologic types. **Transfer dysphagia** occurs very early in swallowing (as the food bolus moves from the oropharynx through the upper sphincter) and is often reported as difficulty in initiating a swallow. **Transport dysphagia** is impaired movement of the bolus down the esophagus and through the lower sphincter. Transport dysphagia is perceived later in the swallowing process, usually 2 to 4 seconds or longer after swallowing is initiated, and most commonly results in the feeling of the food "getting stuck." A history geared toward discerning transfer from transport dysphagia provides a differential of the likely underlying pathology (**Table 77-1**). Another useful classification scheme divides dysphagia into that due to obstructive disease and that due to motor dysfunction. Functional or motility disorders usually cause dysphagia that is intermittent and variable. Mechanical or obstructive disease is usually progressive (difficulty swallowing solids, then liquids).[1]

TABLE 77-1 Dysphagia

Transfer Dysphagia (Oropharyngeal)	Transport Dysphagia (Esophageal)
Discoordination in transferring bolus from pharynx to esophagus	Improper transfer of the bolus from the upper esophagus into the stomach
Swallowing symptoms—gagging, coughing, nasal regurgitation, inability to initiate swallow, need for repeated swallows	Swallowing symptoms—food "sticking," retrosternal fullness with solids (and eventually liquids), possibly odynophagia
Risk of aspiration present	Risk of aspiration present, generally less pronounced than in transfer dysphagia
Long term—weight loss, malnutrition, chronic bronchitis, asthma, multiple episodes of pneumonia	Long term—malnutrition, dehydration, weight loss, systemic effects of cancer
Neuromuscular disease (80%)—cerebrovascular accident, polymyositis and dermatomyositis, scleroderma, myasthenia gravis, tetanus, Parkinson's disease, botulism, lead poisoning, thyroid disease	Obstructive disease (85%)—foreign body, carcinoma, webs, strictures, thyroid enlargement, diverticulum, congenital or acquired large-vessel abnormalities
Localized disease—pharyngitis; aphthous ulcers; candidal infection; peritonsillar and retropharyngeal abscesses; carcinoma of tongue, pharynx, larynx; Zenker's diverticulum; cricopharyngeal bar; cervical osteophytes	Motor disorder—achalasia, peristaltic dysfunction (nutcracker esophagus), diffuse esophageal spasm, scleroderma
Inadequate lubrication—scleroderma	Inflammatory disease

CLINICAL FEATURES

Although often an independent symptom, dysphagia can be associated with odynophagia, which is painful swallowing (suggesting an inflammatory process), or with chest pain that is esophageal in nature, suggesting gastroesophageal reflux disease (GERD) or a motility disorder. Question the patient regarding the course of symptoms (acute, subacute, or chronic, intermittent, progressive); food patterns (solids, liquids); location; and previous disease. Transport dysphagia that is present for solids only generally suggests a mechanical or obstructive process. Motility disorders typically cause transport dysphagia for solids and liquids.

Impaction of a poorly chewed meat bolus in the esophagus is a well-recognized complication of esophageal disease. A history of dysphagia may or may not be present. An impacted food bolus can be the presenting complaint for a variety of underlying esophageal pathologies. Patients are generally accurate in identifying location if the bolus is in the upper third of the esophagus. Esophageal filling proximal to the impacted bolus can cause inability to swallow secretions and can present an airway/aspiration risk.

Focus the physical examination on the head and neck and perform the neurologic examination. Assess for signs of previous stroke, muscle disease, or Parkinson's disease. Cachexia and cervical or supraclavicular nodes can be observed in patients with cancer of the esophagus. The physical findings are often normal in patients with dysphagia.[2] Watch the patient take a small sip of water. Inability to swallow water generally confirms at least a partial obstruction.

DIAGNOSIS

The diagnosis of the underlying pathology is most often made outside of the ED. Initial evaluation of dysphagia in the ED can include anteroposterior and lateral neck radiographs, which can be helpful in transfer dysphagia and cases in which the transport dysfunction seems proximal. Obtain a chest x-ray if considering transport dysphagia. Direct laryngoscopy can be used to identify proximal lesions.

Diagnosis of oropharyngeal dysphagia uses a variety of tools. Traditional barium swallow is often recommended as a first test. Video esophagography is a specialized form of barium swallow study in which videotaped images are played at low speed to allow detailed analysis. Manometry and esophagoscopy are also used, depending on the clinical picture.[2] If a foreign body is suspected, the diagnostic evaluation takes yet another path (see later section, "Swallowed Foreign Bodies and Food Impaction").

Neoplasm **Neoplasms** are a common cause of both transfer and transport dysphagia. The esophagus or surrounding structures can be the primary site. A large majority of esophageal neoplasms are squamous cell; the remaining are adenocarcinomas. Risk factors for squamous cell disease include alcohol, smoking, achalasia, and previous ingestion of caustic material with lye. Barrett's esophagus predisposes to adenocarcinoma. Surgery and radiation therapy for head and neck cancer are also important associations.[3]

There is usually a fairly rapid progression of dysphagia from solids to liquids (6 months). Bleeding is another sign suggesting neoplasm. Assume neoplasia in patients >40 years old with new-onset dysphagia. Definitive diagnosis is made by endoscopy with biopsy.

Anatomic Causes **Esophageal stricture** develops as a result of scarring from GERD or other chronic inflammation. Generally strictures occur in the distal esophagus proximal to the gastroesophageal junction

and may interfere with lower sphincter function. Symptoms may build over years and are often noted solely with solids. Stricture can serve as a barrier to reflux, so heartburn may decrease as dysphagia increases. Evaluation involves ruling out malignancy, and treatment is dilatation.[4]

Schatzki ring is the most common cause of intermittent dysphagia with solids. This stricture near the gastroesophageal junction is present in up to 15% of the population, and most are asymptomatic. A ring may form over time in response to GERD. Food impaction in the esophagus is a frequent presenting event with a Schatzki ring. The treatment is dilatation.[4]

Esophageal webs are thin structures of mucosa and submucosa found most often in the middle or proximal esophagus. They can be congenital or acquired. Esophageal webs also occur as a component of Plummer-Vinson syndrome (along with iron deficiency anemia) and can be seen in patients with pemphigoid and epidermolysis bullosa. Treatment is dilatation.

Diverticula can be found throughout the esophagus. Pharyngoesophageal or Zenker's diverticulum is a progressive out-pouching of pharyngeal mucosa, just above the upper sphincter, caused by increased pressures during the hypopharyngeal phase of swallowing. Symptom onset is often after age 50, as most diverticula are acquired rather than congenital. Patients complain of typical transfer dysfunction or halitosis and the feeling of a neck mass. Diverticula can also be seen in the mid or distal esophagus, the latter usually in association with a motility disorder.[5]

Neuromuscular and Motility Disorders **Neuromuscular disorders** typically result in misdirection of food boluses with repeated swallowing attempts. Liquids, especially at the extremes of temperature, are generally more difficult to handle than solids, and symptoms are often intermittent. Stroke is the most common cause of this type of dysphagia. Oropharyngeal muscle weakness is often the mechanism, although upper sphincter dysfunction can also contribute. Polymyositis and dermatomyositis are also common causes of transfer dysphagia.

Achalasia is a dysmotility disorder of unknown cause and the most common motility disorder producing dysphagia. Impaired swallowing-induced relaxation of the lower sphincter is noted, along with the absence of esophageal peristalsis. Symptom onset is usually between 20 and 40 years of age. Achalasia may be associated with esophageal spasm and chest pain and with odynophagia. Associated symptoms can include regurgitation and weight loss. Dilation of the esophagus can be massive enough to impinge on the trachea and cause airway symptoms.[6] Therapy includes reduction of lower sphincter pressure by oral medications, endoscopic injection of botulinum toxin into the muscle of the sphincter, dilatations, or surgical myotomy.

Diffuse esophageal spasm is the intermittent interruption of normal peristalsis by nonperistaltic contraction. Dysphagia is intermittent and does not progress over time. Chest pain is a common symptom. Therapy involves control of acid reflux and consideration of smooth muscle relaxants and/or antidepressants, although effectiveness is unclear.[6]

Esophageal dysmotility is the excessive, uncoordinated contraction of esophageal smooth muscle. Clinically, chest pain is the usual presenting symptom of esophageal dysmotility. The onset is usually in the fifth decade. Pain often occurs at rest and is dull or colicky, and stress or ingestion of very hot or very cold liquids may serve as triggers. Acute pain may be followed by hours of dull, residual discomfort. Many patients also have dysphagia, usually intermittent. Pain from spasm may respond to nitroglycerin. Calcium channel blockers and anticholinergic agents can also be used. The other motility disorders commonly recognized include ineffective esophageal motility, hypertensive lower esophageal sphincter, and nutcracker esophagus. Nutcracker esophagus is a motility disorder in which there are high-amplitude, long-duration peristaltic contractions in the distal body of the esophagus or the lower sphincter. The cause is unknown.[6]

CHEST PAIN OF ESOPHAGEAL ORIGIN

Differentiating esophageal pain from ischemic chest pain is difficult at best and may be impossible in the ED. Patients with esophageal disease often report spontaneous onset of pain or pain at night, regurgitation, odynophagia, dysphagia, or meal-induced heartburn, but these symptoms are also found in patients with coronary artery disease, and there are no historical features with enough predictive value to allow accurate differentiation.

The ED working assumption is often that the pain is cardiac in nature. However, the incidence of esophageal disease in patients with chest pain and normal coronary arteries has been reported as up to 80%.[7] The use of ED observation units can help sort patients out with protocol-driven, rapid rule-out of infarction, followed by risk stratification for underlying acute coronary syndrome via a variety of modalities (see chapters 48, "Chest Pain" and 49, "Acute Coronary Syndrome" for further discussion). If a patient's presentation can be determined to be noncardiac in nature, treatment for reflux is often initiated empirically.[7]

GASTROESOPHAGEAL REFLUX DISEASE

Reflux of gastric contents into the esophagus causes a wide array of symptoms and long-term effects. Classically, a weak lower esophageal sphincter has been the mechanism held responsible for reflux, and this is seen in some patients. However, transient relaxation of the lower esophageal sphincter complex (with normal tone in between periods of relaxation) is the primary mechanism causing reflux. Hiatal hernia, prolonged gastric emptying, agents that decrease lower sphincter pressure, and impaired esophageal motility predispose to reflux.[8] **Table 77-2** highlights some common contributors.

Heartburn is the classic symptom of GERD, and chest discomfort may be the only symptom of the disease. The burning nature of the discomfort is probably due to localized lower esophageal mucosal inflammation. Many GERD patients report other associated GI symptoms, such as odynophagia, dysphagia, acid regurgitation, and hypersalivation. Pain and discomfort with meals point to GERD. Reflux symptoms can sometimes be dramatically exacerbated with a head-down position or an increase in intra-abdominal pressure. Symptoms are often relieved by antacids, but pain can return after the transient antacid effect wears off. Some patients with symptoms due to ischemic disease also report improvement with the same therapy. Unfortunately, like cardiac pain, GERD pain may be squeezing and pressure-like, and the history may include pain onset with exertion and offset with rest. Both types of pain may be accompanied by diaphoresis, pallor, and nausea and vomiting. Radiation of esophageal pain can occur to one or both arms, the neck, the shoulders, or the back. Given the serious outcome of unrecognized ischemic disease, a cautious approach is warranted.

Over time, GERD can cause complications including strictures, dysphagia, and inflammatory esophagitis. A severe consequence of GERD, Barrett's esophagus, is present in up to 10% of patients with GERD.[9,10] Less obvious presentations of GERD also occur such as asthma exacerbations, sore throat, and other ear, nose, and throat symptoms. GERD has also been implicated in dental erosion, vocal cord ulcers and granulomas, laryngitis with hoarseness, chronic sinusitis, and chronic cough.

Treatment of reflux disease involves decreasing acid production in the stomach, enhancing upper tract motility, and eliminating risk factors. Mild disease is often treated empirically. Histamine-2 blockers (histamine-2 antagonists) or proton pump inhibitors are mainstays of therapy. A prokinetic drug may help. ED discharge instructions given to patients thought to be experiencing reflux-related symptoms should include: avoid agents that exacerbate GERD (ethanol, caffeine,

TABLE 77-2 Causes of Gastroesophageal Reflux Disease

Decreased Pressure of Lower Esophageal Sphincter	Decreased Esophageal Motility	Prolonged Gastric Emptying
High-fat food	Achalasia	Medicines (anticholinergics)
Nicotine	Scleroderma	Outlet obstruction
Ethanol	Presbyesophagus	Diabetic gastroparesis
Caffeine	Diabetes mellitus	High-fat food
Medicines (nitrates, calcium channel blockers, anticholinergics, progesterone, estrogen)		
Pregnancy		

nicotine, chocolate, fatty foods), sleep with the head of the bed elevated (30 degrees), and avoid eating within 3 hours of going to bed at night. The need for additional testing can be determined at outpatient follow-up care.

ESOPHAGITIS

Esophagitis can cause prolonged periods of chest pain and almost always causes odynophagia as well. Diagnosis of more established esophagitis is by endoscopy. Low-grade disease can be seen by histopathologic examination.

INFLAMMATORY ESOPHAGITIS

GERD may induce an inflammatory response in the lower esophageal mucosa. Over time, esophageal ulcerations, scarring, and stricture formation can develop. The presence of reflux-induced esophagitis warrants aggressive pharmacologic therapy with acid-suppressive medications. If this treatment regimen is not sufficient, surgical options are considered.[8] Ingested medications can also be a source of inflammatory esophagitis, usually from prolonged contact of the medication with the esophageal mucosa. Ulcerations can form. Multiple medications have been implicated. Common offenders include nonsteroidal anti-inflammatory drugs and other anti-inflammatory drugs, potassium chloride, and some antibiotics (e.g., doxycycline, tetracycline, and clindamycin). Risk factors for pill-induced esophageal injury include swallowing position, fluid intake, capsule size, and age. Withdrawal of the offending agent is generally curative. Eosinophilic esophagitis is a chronic allergic-inflammatory condition in which eosinophils and other immune system cells infiltrate the esophagus and induce an inflammatory response.[10] Diagnosis is by endoscopy. Treatment is avoidance of allergens and swallowed liquid corticosteroids. Dilatation is necessary if strictures form.

INFECTIOUS ESOPHAGITIS

Patients with immunosuppression can develop infectious esophagitis. The diagnosis of infectious esophagitis in an otherwise seemingly healthy host should prompt an evaluation of immune status. Candidal species are the most common pathogens, often associated with dysphagia as a primary symptom. Herpes simplex or cytomegalovirus infection and aphthous ulceration are also seen and may be more frequently associated with odynophagia. Other causative agents are rare and include fungi, mycobacteria, and other viral pathogens such as varicella-zoster virus and Epstein-Barr virus. Endoscopy with biopsy and specimen culture is used to establish this diagnosis.[11]

ESOPHAGEAL PERFORATION

Perforation of the esophagus can occur secondary to a number of disparate processes (**Table 77-3**). Iatrogenic perforation is the most frequent.[12]

Boerhaave's syndrome is full-thickness perforation of the esophagus after a sudden rise in intraesophageal pressure. The mechanism is sudden, forceful emesis in about three fourths of the cases; coughing, straining, seizures, and childbirth have been reported as causing perforations as well. Alcohol consumption is frequently an antecedent to this syndrome. The perforation is usually in the distal esophagus on the left side.

Blunt or penetrating **neck trauma** can cause esophageal perforation. Rupture from blunt injury is rare. Penetrating esophageal wounds are often masked by injury to the airway and major vessels. A combination of esophagography and esophagoscopy is used to assess patients for potential esophageal injury.

Foreign-body ingestion or food impaction may result in perforation of the esophagus as well (see below).

The perforation rate from endoscopy is lower in an esophagus free of disease than in a diseased esophagus. Dilation of strictures increases the risk of perforation greatly. Other intraluminal procedures, such as variceal therapy and palliative laser treatment for cancer, are also associated with perforation. **Boerhaave's syndrome** is responsible for roughly 10% to 15% of esophageal perforations and is discussed above.

TABLE 77-3 Causes of Esophageal Perforation

Cause of Perforation	Description
Iatrogenic	Intraluminal procedures Endoscopy Dilatation Variceal therapy Gastric intubation Intraoperative injury
Boerhaave's syndrome	"Spontaneous," usually associated with transient increase in intraesophageal pressure
Trauma	Penetrating Blunt (rare) Caustic ingestion
Foreign body	Includes pill-related injury
Infection	Rare
Tumor	May be intrinsic or extrinsic cancer
Aortic pathology	Aneurysm Aberrant right subclavian artery
Miscellaneous	Barrett's esophagus Zollinger-Ellison syndrome

PATHOPHYSIOLOGY

Perforation causes a dramatic presentation if esophageal contents leak into the mediastinal, pleural, or peritoneal space. Fulminant, necrotizing mediastinitis, pneumonitis, or peritonitis can rapidly lead to shock. If the perforation is small and leakage is contained by contiguous structures, the course may be significantly more indolent. Most spontaneous perforations occur through the left posterolateral wall of the distal esophagus.[12] Proximal perforation, seen mostly with instrumentation, tends to be less severe than distal perforation and can form a periesophageal abscess with minimal systemic toxicity.

CLINICAL FEATURES

The pain of rupture is classically described as acute, severe, unrelenting, and diffuse, and is reported in the chest, neck, and abdomen. Pain can radiate to the back and shoulders. Back pain may be a very predominant symptom. The pain is often exacerbated by swallowing. Dysphagia, dyspnea, hematemesis, and cyanosis can be present as well.

Physical examination varies with the severity of the rupture and the elapsed time to presentation. Abdominal rigidity with hypotension and fever often occur early. Tachycardia and tachypnea are common. Cervical subcutaneous emphysema is common in cervical esophageal perforations. **Mediastinal emphysema takes time to develop. It is less commonly detected by examination or radiography in lower esophageal perforation, and its absence does not rule out perforation.** Hamman's crunch, caused by air in the mediastinum that is being moved by the beating heart, can sometimes be auscultated. Pleural effusion develops in half of patients with intrathoracic perforations but is uncommon in those with cervical perforations. Pleural fluid can be due to either direct contamination of the pleural space or a sympathetic serous effusion from mediastinitis.

DIAGNOSIS

Timely diagnosis in an ill patient with esophageal perforation requires suspicion on the clinician's part. Mistaking perforation for acute myocardial infarction, pulmonary embolism, or an acute abdomen can lead to delays in therapy. Chest radiographs can suggest the diagnosis. CT of the chest or emergency endoscopy is most often used to confirm the diagnosis. Perforation of the esophagus is associated with a high mortality rate regardless of the underlying cause. The pace of care and the location and etiology of the perforation all affect outcome. In the ED, resuscitate

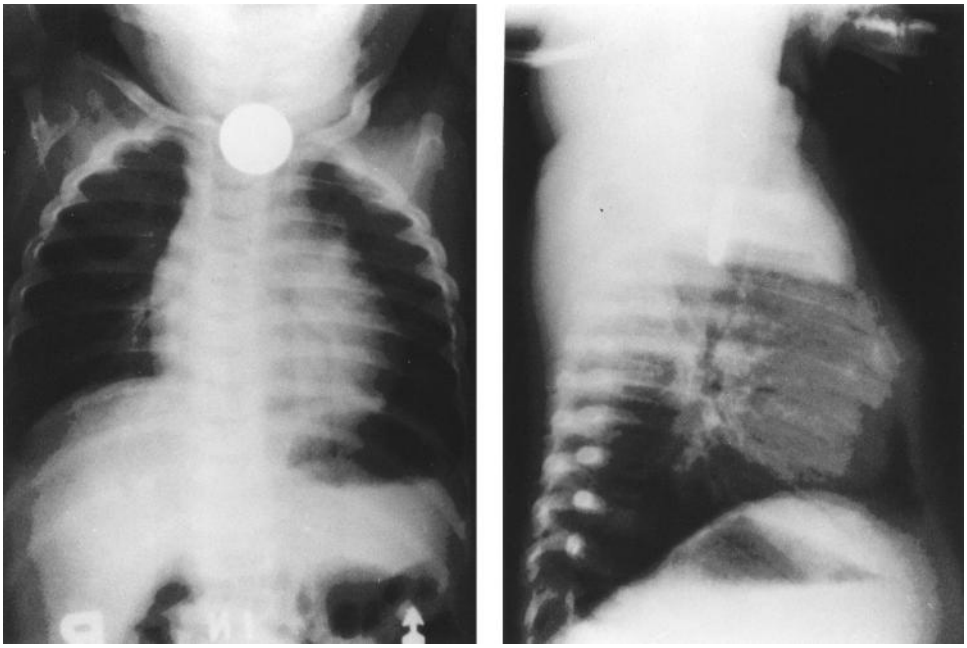

FIGURE 77-2. A coin lodged in a child's esophagus is visible on an anteroposterior radiograph. [Reproduced with permission from Effron D (ed): *Pediatric Photo and X-Ray Stimuli for Emergency Medicine*, vol II. Columbus, OH, Ohio Chapter of the American College of Emergency Physicians, 1997, case 27.]

the patient from shock, administer broad-spectrum parenteral antibiotics, and obtain emergency surgical consultation as soon as the diagnosis is seriously entertained. Patients with systemic symptoms and signs after perforation need operative management.[12]

SWALLOWED FOREIGN BODIES AND FOOD IMPACTION

PATHOPHYSIOLOGY

Children 18 to 48 months of age and those with mental illness account for most cases of ingested foreign bodies. Small objects, such as coins, toys, and crayons, typically lodge in the anatomically narrow proximal esophagus. In adults, dentures are sometimes swallowed, because diminished palatal sensitivity leads to unintentional ingestion. Adult candidates for swallowed foreign bodies are those with esophageal disease, prisoners, and psychiatric patients. In adults, most impactions are distal. In children and adults, once an object has traversed the pylorus, it usually continues through the GI tract and is passed without issue. If, however, the object has irregular or sharp edges or is particularly wide (>2.5 cm) or long (>6 cm), it may become lodged distal to the pylorous.[13] Esophageal impaction can result in airway obstruction, stricture, or perforation, the latter being the result of direct mechanical erosion (e.g., ingested bones) or chemical corrosion (e.g., ingested button batteries). Esophageal mucosal irritation (often mechanical from a swallowed bone, for example) can be perceived as a foreign body by the patient as well.

CLINICAL FEATURES

Adults with an esophageal foreign body generally provide unequivocal history. Patients often complain of retrosternal pain and may localize the object (often accurately in the upper third of the esophagus). Patients may have dysphagia, vomiting, and choking. If the patient attempts to wash down the object with liquid or if swallowed secretions pool proximal to the obstruction, coughing or aspiration can occur. **In children, the history can be unclear. Signs and symptoms can include refusal or inability to eat, vomiting, gagging and choking, stridor, neck or throat pain, and drooling. A high degree of suspicion is necessary for unwitnessed ingestions in children, especially in those <2 years of age.** Physical examination starts with an assessment of the airway. The nasopharynx, oropharynx, neck, and chest should also be examined but are often unremarkable. Occasionally, a foreign body can be directly visualized in the oropharynx.

DIAGNOSIS

Plain films are used to screen for radiopaque objects. Coins in the esophagus generally present their circular face on anteroposterior films (coronal alignment), as opposed to coins in the trachea, which show that face on lateral films (**Figure 77-2**). Obtaining plain films in patients with food impaction is rarely helpful and can generally be omitted. CT scanning is a very high-yield test for esophageal foreign body and has generally replaced the barium swallow test to evaluate ingestion of nonradiopaque objects. CT also delivers excellent information regarding perforation and subsequent infection.

TREATMENT

Endoscopy Patients in extremis or with pending airway compromise are resuscitated and often require active airway management. Complete obstruction of the esophagus (often distal esophageal food impactions) can lead to proximal pooling of secretions and aspiration. Emergent endoscopy is needed. **Table 77-4** lists other situations that require urgent endoscopy, even if patients are clinically stable. Some of these ingestions are discussed in more detail in the sections "Food Impaction," "Coin Ingestion," "Button Battery Ingestion," "Ingestion of Sharp Objects," and "Narcotics Ingestion" later in the chapter. In general, if endoscopy is clearly indicated, performing advanced imaging studies delays definitive intervention while adding little value to the care of the patient. In the vast majority of cases, the foreign body can be removed relatively easily with endoscopy without complication. Hospital admission is generally not needed.

Laryngoscopy In stable patients, indirect laryngoscopy or visualization of the oropharynx using a fiberoptic scope may allow removal of very proximal objects. For more distal objects, imaging studies are used

TABLE 77-4 Circumstances Warranting Urgent Endoscopy for Esophageal Foreign Bodies

Ingestion of sharp or elongated objects (including toothpicks, aluminum soda can tabs)
Ingestion of multiple foreign bodies
Ingestion of button batteries
Evidence of perforation

Airway compromise
Presence of a foreign body for >24 h

to define the location and nature of the ingestion. Objects that persist over time or are in the upper half of the esophagus are less likely to pass, and consultation for endoscopy is prudent.

Expectant Treatment If the object is distal to the pylorus, has a benign shape and nature, and the patient is comfortable and tolerating intake by mouth, treatment is expectant. For worrisome foreign bodies that are in the more distal GI tract, surgery consultation may be necessary.

Foley Catheter Removal Alternatives to endoscopy have been advocated by some authors. These include use of a Foley catheter to remove coins (see section "Coin Ingestion" later in the chapter) and bougienage to advance the object from the esophagus into the stomach. Generally, the Foley catheter technique and bougienage should only be attempted in patients with blunt foreign bodies present for <24 hours and in patients without underlying esophageal disease. Provider comfort with the procedure likely influences the generally low complication rates in published series.[14]

Glucagon For distal esophageal objects, **glucagon, 1 to 2 mg IV in adults,** has been used to relax the lower sphincter and allow passage of the object. **Success rates of glucagon therapy are generally reported as poor, however, and it may be no better than watchful waiting without other intervention.**[15]

SPECIAL CONSIDERATIONS

FOOD IMPACTION

Meat is the food most commonly identified in food impaction. Food impaction with complete esophageal obstruction or impaction of food containing bony fragments requires emergency endoscopy. Uncomplicated food impaction may be treated expectantly. Time and sedation often allow the bolus to pass into the stomach, but the bolus should not be allowed to remain impacted for >12 to 24 hours. **The use of proteolytic enzymes (e.g., Adolph's Meat Tenderizer®, which contains papain) to dissolve a meat bolus is *contraindicated*, because of the potential for severe mucosal damage and esophageal perforation, and the availability of superior alternatives.** If **glucagon** therapy is attempted, an initial dose of 1 to 2 milligrams IV is given (for adults). If the food bolus is not passed in 20 minutes, an additional dose can given.[15]

COIN INGESTION

Many centers use endoscopy to remove esophageal coins in children. Removal with a Foley catheter is done under fluoroscopy, and advanced airway management should be immediately available. The patient is placed in the Trendelenburg position to prevent aspiration of the object. The catheter is passed down the esophagus beyond the object, the balloon inflated, and the catheter slowly withdrawn, bringing the object with it. Complications can include airway compromise and mucosal injury, although in experienced hands, the rate of these events is low.[14]

BUTTON BATTERY INGESTION

A button battery lodged in the esophagus is a true emergency requiring prompt removal, because the battery may quickly induce mucosal injury and necrosis. Perforation can occur within 6 hours of ingestion. Morbidity caused by the battery is likely related to the flow of electricity through a locally formed external circuit. Lithium cells are associated disproportionately with adverse outcome, probably due to higher voltage.[14]

Figure 77-3 outlines a management algorithm for button battery ingestion. Button batteries that have passed the esophagus can be managed expectantly, as long as follow-up in 24 hours can be assured. Repeat films should be obtained at 48 hours to ensure that the cell has passed through the pylorus (which may not occur if the battery is of large diameter and/or the patient is <6 years old). Most batteries pass completely through the body within 48 to 72 hours, although passage can take longer. Any patient with symptoms or signs of GI tract injury requires immediate surgical consultation. The National Button Battery Ingestion Hotline (National Capital Poison Center, Washington, DC) at 202-625-3333 is a 24-hour/7-day-a-week resource for help in management decisions.

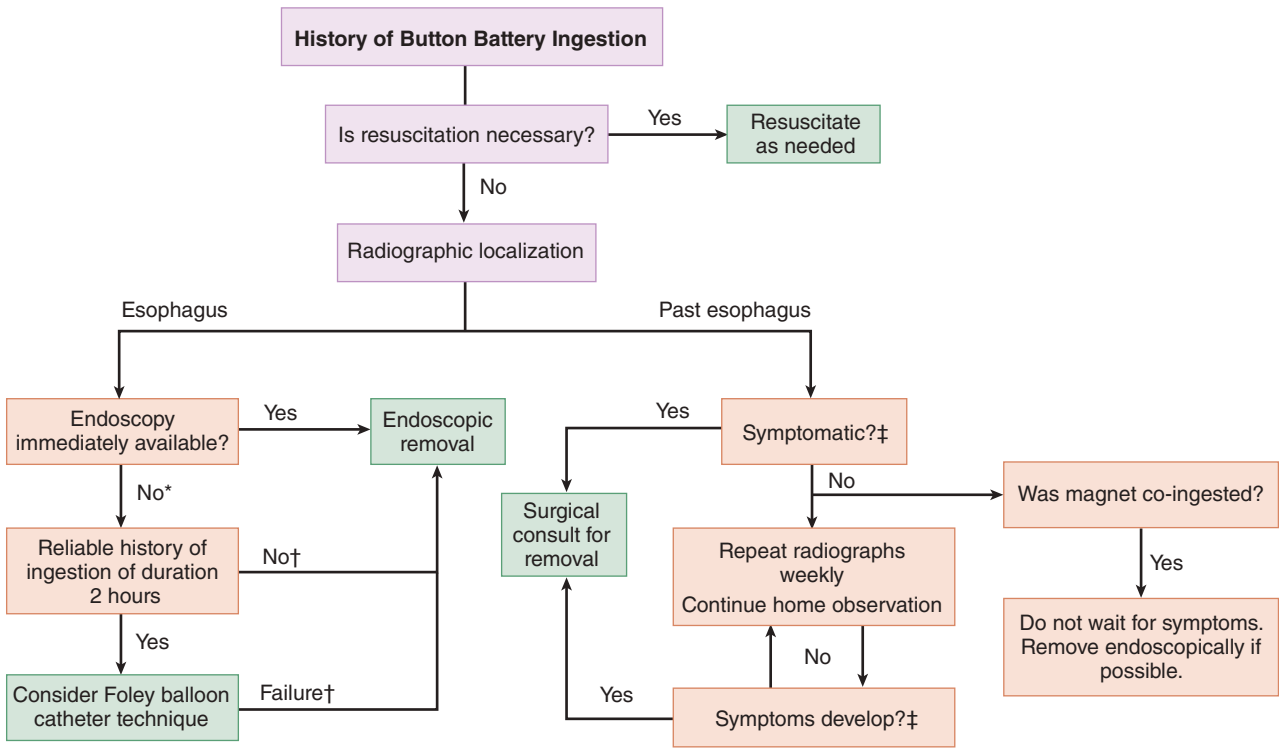

FIGURE 77-3. Algorithm for management of button battery ingestion. *Button batteries in the esophagus must be removed. Endoscopy should be used, if available. The balloon catheter technique can be used if the ingestion occurred ≤2 hours previously, but it should not be used after this period, because it may increase the amount of damage to the weakened esophagus. †When the Foley technique fails or is contraindicated because >2 hours have elapsed, the button battery should be removed endoscopically. This may require transfer of the patient. ‡Acute abdomen, tarry or bloody stools, fever,

INGESTION OF SHARP OBJECTS

Sharp objects in the esophagus need immediate removal. Sharp objects may pass into the stomach spontaneously. **Because intestinal perforation from ingested sharp objects that pass distal to the stomach is common, the American Society for Gastrointestinal Endoscopy guidelines recommend removal of sharp objects by endoscopy while they are in the stomach or duodenum.** If intestinal perforation occurs, it is usually at the ileocecal valve.

If the object is distal to the duodenum at presentation and the patient is asymptomatic, the object's passage should be documented with daily plain films. Surgical removal should be considered if 3 days elapse without passage. The development of symptoms or signs of intestinal injury (e.g., pain, emesis, fever, GI bleeding) requires immediate surgical consultation.[13]

NARCOTICS INGESTION

Narcotic couriers (body packers) ingest multiple small packets of a drug in order to conceal transport. A favored packet is the condom, which may hold up to 5 grams of narcotic. These packets are often visible on plain films. Rupture of even one such packet may be fatal, and endoscopy is contraindicated because of the risk of iatrogenic packet rupture. If the packet(s) appears to be passing intact through the intestinal tract, observation until the packet reaches the rectum is the favored treatment. Some authors advocate the use of whole-bowel irrigation to aid the process.

CHAPTER 78

Peptic Ulcer Disease and Gastritis

Matthew C. Gratton
Angela Bogle

INTRODUCTION AND EPIDEMIOLOGY

Peptic ulcer disease is a chronic illness manifested by recurrent ulcerations in the stomach and proximal duodenum. Acid and pepsin are thought to be crucial to ulcer development, but the great majority of peptic ulcers are directly related to infection with *Helicobacter pylori* or nonsteroidal anti-inflammatory drug (NSAID) use.[1,2] **Gastritis** is acute or chronic inflammation of the gastric mucosa and has various etiologies. **Dyspepsia** is continuous or recurrent upper abdominal pain or discomfort with or without associated symptoms (e.g., nausea, bloating).[3] Dyspepsia may be caused by a number of diseases or may be functional.

Uncomplicated peptic ulcer disease has an incidence of more than 5 cases per 1000 persons per year, and about 10% of people living in the Western world will experience a peptic ulcer at some point during their lives.[4,5] In the United States, peptic ulcer disease costs an estimated $5.65 billion per year in total direct and indirect costs.[6] *H. pylori* infection, one of the main risk factors of peptic ulcer disease, is one of the most prevalent human infections in the world, affecting at least 50% of the world's population.[7] The age-adjusted prevalence of *H. pylori* infection is decreasing in industrialized countries, likely due to an improved standard of living[7] and the increased use of proton pump inhibitors (PPIs) and antimicrobial therapy.[2,8] This may explain the decreasing incidence of peptic ulcer disease in the United States, but this may be partially offset by the widespread use of low-dose aspirin and NSAIDs.[2,9] Over 70 million prescriptions for NSAIDs are written, and over 30 billion tablets are sold over the counter annually in the United States.[10] Risk factors for ulcers not due to *H. pylori* or NSAIDs include antiplatelet agents, stress, *Helicobacter heilmannii*, cytomegalovirus infections, Behçet's disease, Zollinger-Ellison syndrome, Crohn's disease, cirrhosis with portal hypertension, older age, and African American ethnicity.[2]

Dyspepsia affects 20% to 40% of the world's population.[3] There is no consistent association with sex, age, socioeconomic status, smoking, or alcohol use; however, it is more common in people infected with *H. pylori* and who take NSAIDs, as well as some other medications.[3]

PATHOPHYSIOLOGY

Hydrochloric acid and pepsin destroy gastric and duodenal mucosa. Mucus and bicarbonate ion secretions protect mucosa. Prostaglandins protect mucosa by enhancing mucus and bicarbonate production and by enhancing mucosal blood flow, thereby supporting metabolism. The balance between these protective and destructive forces determines whether peptic ulcer disease occurs. *H. pylori* bacteria or NSAIDs are thought to be the causal agents of peptic ulcer disease in most cases.[1,2] Although traditional treatment of peptic ulcers by various modalities heals most ulcers, eradication of *H. pylori* cures peptic ulcers in over 80% of patients whose ulcers are not associated with the use of NSAIDs.[7,11]

H. pylori is a spiral, gram-negative, urease-producing, flagellated bacterium that is found living between the mucous gel and the mucosa. The bacterium's production of urease, cytotoxins, proteases, and other compounds is thought to disturb the mucous gel and cause tissue injury. In addition, increased gastrin levels and decreased mucus and bicarbonate production are associated with *H. pylori* infection. Chronic active (usually asymptomatic) gastritis is an almost universal finding with *H. pylori* infection, but only 1% to 10% of infected people develop peptic ulcer disease.[7] It is unclear why most infected persons do not develop symptomatic peptic ulcer disease, but it most likely reflects an interaction of factors, including characteristics of host and pathogen (different virulence of strains of bacteria). In 2005, Marshal and Warren were awarded the Nobel Prize in Physiology or Medicine for their discovery of *H. pylori* and its role in gastritis and peptic ulcer disease.

H. pylori is a causative agent of mucosa-associated lymphoid tissue lymphoma, and eradication of infection causes a remission in a sizable percentage of patients with low-grade tumors.[7] In addition, *H. pylori* infection is a risk factor for adenocarcinoma of the stomach, and as such, the World Health Organization has classified it as a human carcinogen.[7] However, because the prevalence of gastric cancer in the United States is very low and the *H. pylori* infection rate is high, other factors undoubtedly are involved. It is not clear whether eradication of the infection reduces the risk of gastric cancer.[7] *H. pylori* infection has been associated with the development of iron deficiency anemia, with possible mechanisms including decreased iron absorption and/or occult blood loss from chronic gastritis. A direct cause-and-effect relationship is yet to be determined.[12,13] Improvement in the platelet count in some patients with idiopathic thrombocytopenic purpura has been demonstrated with *H. pylori* eradication, but much more work remains to be done in this regard.[12,14]

NSAIDs inhibit prostaglandin synthesis, thereby decreasing mucus and bicarbonate production and mucosal blood flow, which allows ulcer formation. Gastrin-secreting tumors produce ulceration due to high levels of acid and pepsin production, but acid alone rarely causes ulceration. However, inhibition of acid secretion may allow ulcers to heal and is the basis for traditional ulcer treatments.

Hereditary factors cause a predisposition to peptic ulcer disease, as does smoking. There is an association between chronic renal failure, renal transplantation, cirrhosis, chronic obstructive pulmonary disease, and peptic ulceration, but the precise mechanism is unclear. Emotional stress may predispose to peptic ulcer disease, but diet and alcohol use do not.

Acute gastritis may be related to ischemia from severe illness (e.g., shock, trauma, severe burns, organ failure) or to the direct toxic effects of agents (e.g., NSAIDs, steroids, bile acids). *H. pylori* infection causes acute and chronic gastritis (both usually asymptomatic). Chronic gastritis may also be caused by autoimmune factors that destroy gastric parietal cells; this results in the loss of acid production

and the loss of intrinsic factor production, which in turn cause malabsorption of vitamin B_{12} and, hence, pernicious anemia.

Dyspepsia has multiple causes. Endoscopy of patients with dyspepsia demonstrates that about 13% have erosive esophagitis, 8% have peptic ulcer disease, and less than 0.3% have gastric or esophageal cancer.[3] Other abnormalities such as gastritis, duodenitis, and gastric erosions may be present, but these may or may not be related to symptoms. About 70% to 80% of patients have no definite abnormal findings on endoscopy and are said to have "functional dyspepsia."[3] Patients with functional dyspepsia have evidence of abnormal gastric emptying, abnormal sensitivity to distention, abnormal ability of the stomach to distend with a meal, abnormalities in acid clearance, and abnormal duodenal sensitivity to acid. In addition, there appears to be an as yet poorly characterized interaction between the stomach and intestine and the central nervous system, which may contribute to symptoms.[3]

CLINICAL FEATURES

Burning epigastric pain is the most classic symptom of peptic ulcer disease. The pain also may be described as sharp, dull, an ache, or an "empty" or "hungry" feeling. Pain may be relieved by ingestion of milk, food, or antacids, presumably due to buffering and/or dilution of acid. **Pain recurs as the gastric contents empty, and the recurrent pain may classically awaken the patient at night.** Pain tends to occur daily for weeks, resolve, and then recur in weeks to months. Postprandial pain, food intolerance, nausea, retrosternal pain, and belching are not related to peptic ulcer disease. Atypical presentations are common in those >65 years old, including no pain, epigastric pain not relieved by eating, nausea, vomiting, anorexia, weight loss, and bleeding.

A change in the character of typical pain may herald a complication. Abrupt onset of severe or generalized pain may indicate perforation with peritoneal spillage of gastric or duodenal contents. Rapid onset of mid-back pain may be due to posterior penetration into the pancreas, resulting in pancreatitis. Nausea and vomiting may indicate gastric outlet obstruction from scarring or edema. Vomiting of bright red blood or coffee-ground emesis or passage of tarry or melanotic stool or hematochezia may indicate ulcer bleeding.

On physical examination, the only positive finding in patients with uncomplicated peptic ulcer disease may be epigastric tenderness. This finding is neither sensitive nor specific for the diagnosis. Other physical findings may be indicative of complications: a rigid abdomen consistent with peritonitis in perforation; abdominal distention or a succussion splash due to obstruction; or occult or gross rectal blood or blood in the nasogastric aspirate signaling ulcer bleeding.

Epigastric pain, nausea, and vomiting may be present with acute gastritis, but the most common presentation of gastritis is GI bleeding, ranging from occult blood loss in the stool to massive upper GI hemorrhage. Physical findings may be normal, may reflect only the GI bleeding, or may reflect a severe underlying associated illness (as listed earlier).

DIAGNOSIS

A definitive diagnosis of peptic ulcer disease cannot be made on clinical grounds alone. Uncomplicated peptic ulcer disease can be strongly suspected in the presence of a "classic" history, including epigastric burning pain; relief of pain with ingestion of milk, food, or antacids; and night pain accompanied by "benign" physical examination findings, including normal vital signs with or without mild epigastric tenderness. The differential diagnosis of epigastric pain is extensive and, in addition to peptic ulcer disease, includes gastritis, gastroesophageal reflux disease, cholelithiasis, pancreatitis, hepatitis, abdominal aortic aneurysm, gastroparesis, and functional dyspepsia. Careful history taking may elicit features that point away from peptic ulcer disease: burning pain radiating into the chest, water brash, and belching may suggest gastroesophageal reflux disease; more severe pain radiating to the right upper quadrant and around the right or left side suggests cholelithiasis; radiation through to the back indicates pancreatitis or abdominal aortic aneurysm; chronic pain, anorexia, or weight loss may indicate gastric cancer. Myocardial ischemic pain may also present as epigastric pain and should be strongly considered in the appropriate clinical setting.

Physical examination findings may suggest other diagnoses: right upper quadrant tenderness points to cholelithiasis or hepatitis, an epigastric mass to pancreatitis (pseudocyst) or pancreatic or gastric neoplasm, a pulsatile mass to abdominal aortic aneurysm, jaundice to hepatitis, and peritoneal findings to an acute abdomen.

ANCILLARY TESTING

Ancillary tests may help exclude peptic ulcer disease complications and narrow the differential diagnosis. Normal results for CBC rule out anemia from chronic GI bleeding due to peptic ulcer disease, gastritis, or cancer (but do not rule out acute blood loss). Elevated liver function test results may indicate hepatitis, and an elevated lipase level may indicate pancreatitis. An acute abdominal series may show free air associated with perforation. A limited ED US examination may show gallstones or an abdominal aortic aneurysm. An ECG and cardiac enzyme determination are indicated if there is a suspicion of myocardial ischemic pain.

The gold standard for diagnosis of peptic ulcer disease is visualization of an ulcer by **upper GI endoscopy**.[2,4] Although not all patients with undiagnosed dyspepsia require endoscopy, those with "alarm features" do[3,4] (**Table 78-1**). Alarm features raise the index of suspicion for gastric or esophageal cancer, as well as other potentially serious conditions, but the features are not specific.[3]

***H. pylori* Tests** Because most peptic ulcers are caused by *H. pylori* infection and eradication of *H. pylori* dramatically decreases the ulcer recurrence rate, it is important to know how to diagnose infection. *H. pylori* infection can be diagnosed by endoscopic tests, including the rapid urease test, histologic study, and culture, all of which rely on a biopsy of the gastric mucosa.[1,7,11] Noninvasive tests include serologic tests, urea breath tests, and stool antigen tests.[1,7,11]

The **rapid urease test** detects the presence of urease in a biopsy specimen (presumptive evidence of *H. pylori* infection) with >90% sensitivity and >95% specificity.[7] Histologic studies allow direct assessment of *H. pylori* infection and culture of the organism, but these tests require highly trained technicians and appropriate facilities and are not widely available.[7,11] The major disadvantage of all the aforementioned tests is the cost in time, dollars, and potential complications of endoscopy.

Serologic studies detect **immunoglobulin G antibodies to *H. pylori*** and are readily available, but the sensitivity and specificity are not very good (85% and 79%, respectively).[7,11] Serologic studies are not useful as a test of cure, because antibodies remain for several months to years after eradication of infection.

The **urea breath test** relies on the presence of urease produced by *H. pylori*. Urea labeled with carbon-13 or carbon-14 instead of carbon-12 is ingested and, in the presence of bacterial urease, is broken down into labeled carbon dioxide and ammonia. The labeled carbon dioxide is detected in the breath later. Sensitivity and specificity are >95%.[7,11] The urea breath test can be used to determine the presence of infection after eradication therapy.[11]

H. pylori antigens can be detected in the stool with >90% sensitivity and specificity.[1,7] Testing performed ≥4 weeks after completion of *H. pylori* eradication therapy is useful as a test of cure. The sensitivity of all tests that rely on active infection with *H. pylori* is decreased significantly by recent treatment with PPIs, histamine-2 (H_2) antagonists, antibiotics, and bismuth compounds.[7,11]

TABLE 78-1 "Alarm Features" for Endoscopy

Family history of upper GI malignancy

TREATMENT

After peptic ulcer disease is diagnosed, the goal of treatment is to heal the ulcer while relieving pain and preventing complications and recurrence. Traditional ulcer therapy heals the ulcer, relieves pain, and prevents complications, but does not prevent recurrence. Treatment of *H. pylori* infection, when present, dramatically decreases the recurrence rate.[7,11] If NSAID-associated ulcers are present, the offending agent should be stopped whenever possible. Traditional therapy includes PPIs, H_2 receptor antagonists (H_2RAs), sucralfate, and antacids.

Traditional ED treatment would entail initiating a trial of a PPI or an H_2RA, with antacids for breakthrough pain, and referring to a primary care provider to direct evaluation and subsequent treatment. This usually remains the best option. There is some evidence that a short course of a PPI provides better symptomatic relief than an H_2RA for undiagnosed dyspepsia, although the evidence is not from an ED setting.[3] Immediate referral for definite diagnosis is mandated if alarm features are present[3,4] (Table 78-1). Practice guidelines and reviews support treatment of *H. pylori*–positive dyspeptic patients with antimicrobial and antisecretory therapy followed by endoscopic study only in those with persistent symptoms.[3] It might be reasonable for the ED physician to begin symptomatic therapy, order a test for *H. pylori*, and refer the patient for early follow-up with a primary care provider for initiation of antibacterial therapy if the test results are positive. However, this strategy has not been tested.

PPIs

PPIs decrease acid production by irreversibly binding with an H^+K^+ ATPase molecule (proton pump) located on the gastric parietal cell, thus blocking hydrogen ion secretion.[1] PPIs are most effective if taken 30 to 60 minutes prior to a meal. **PPIs generally heal ulcers faster than do H_2RAs and also have some in vitro inhibitory effect against *H. pylori*.**[1] PPIs are metabolized in the liver by the cytochrome P-450 system and therefore may decrease the metabolism of many other drugs. In addition, PPIs may inhibit the absorption of drugs that rely on gastric acidity. PPIs are well tolerated by most patients.[1] There are six U.S. Food and Drug Administration–approved PPIs, and two (omeprazole and lansoprazole) have "over-the-counter" formulations.[1] If a patient develops an ulcer while taking NSAIDs and must continue therapy, PPIs heal ulcers faster than any other potential treatment.[1]

H_2RAs

H_2RAs competitively inhibit the actions of histamine on the H_2 receptors of the gastric parietal cells. All four H_2RAs (cimetidine, famotidine, nizatidine, and ranitidine) heal ulcers approximately equally and are available in over-the-counter preparations.[1] **Because of renal excretion, make dosage adjustments in patients with renal failure.** Side effects are uncommon but can include headache, confusion, lethargy, depression, and hallucinations.[1] Cimetidine has more significant drug interactions than do the other H_2RAs due to inhibition of cytochrome P-450 activity.[1]

OTHER AGENTS

Sucralfate, an aluminum hydroxide complex of sucrose, appears to protect the ulcer from acid exposure by forming a sticky gel that adheres to the ulcer crater and allows healing to occur but does not relieve pain as well as PPIs and H_2RAs.[1] Sucralfate has few side effects but can cause constipation and aluminum toxicity, as well as inhibit absorption of a number of medications.[1] **Antacids** heal ulcers by buffering gastric acid. Magnesium- and aluminum-containing antacids can inhibit absorption of drugs and should be avoided in patients with renal insufficiency or renal failure. In renal failure, aluminum can accumulate and cause osteoporosis and encephalopathy, and hypermagnesemia can also result. Due to the simplicity of PPI and H_2RA dosing requirements, antacids currently are used mainly on an as-needed basis for ulcer pain until healing occurs.

Although NSAIDs should be stopped in patients with peptic ulcer disease whenever possible, **misoprostol** may prevent ulcer formation in those concurrently receiving NSAID therapy. Misoprostol is a prostaglandin analog that may act by increasing mucus and bicarbonate production and by increasing mucosal blood flow. Because it is an abortifacient, do not use misoprostol in women who could become pregnant.[1]

H. PYLORI ERADICATION

If *H. pylori* infection is diagnosed in the presence of peptic ulcer disease, eradication is clearly indicated.[1,7,11] Multiple regimens have been proposed and studied, most commonly "triple therapy" with a PPI, clarithromycin, and either amoxicillin or metronidazole.[1,7,11] Authorities in the United States recommend 10- to 14-day regimens for the best cure rates.[1,7,11] In areas where clarithromycin resistance is high, quadruple therapy or sequential therapy may be the preferred option.[1,7,12]

Patients generally do not present to the ED with a definitive diagnosis of peptic ulcer disease but rather with a symptom, such as epigastric pain. If appropriate history, physical examination, and laboratory evaluation result in a physician's impression of "possible peptic ulcer disease" or "dyspepsia," the physician is left with three main options: empiric treatment with conventional antiulcer medication, immediate referral for definite diagnosis (endoscopic study), or noninvasive testing for *H. pylori* followed by antibiotic therapy for patients with positive test results.

COMPLICATIONS

HEMORRHAGE

About 400,000 patients per year are admitted to the hospital in the United States due to nonvariceal upper GI bleeding, and peptic ulcer disease is the most common cause.[15,16] As many as 15% of peptic ulcers bleed, resulting in an overall mortality rate of 10%.[2] Bleeding from peptic ulcers is most common in the elderly.

ED treatment for ulcer bleeding focuses on restoring hemodynamic stability by IV administration of isotonic saline solution and packed red blood cells (see chapter 75, "Upper Gastrointestinal Bleeding" for details of treatment). Early upper endoscopy is recommended in most patients to confirm the diagnosis and target endoscopic treatment.[8,15,16] Before endoscopy, a bolus dose of a PPI followed by a continuous infusion can be considered, as can use of a prokinetic agent, such as erythromycin, given IV. Neither has been consistently shown to improve clinical outcomes.[8,16] Nasogastric or orogastric lavage is not required for diagnosis. Up to 18% of upper GI bleeds may have clear or bile-stained aspirate.[16] Likewise neither is required for prognostic purposes, to improve visualization, or for specific therapy.[16]

Most patients should undergo upper GI endoscopy within 24 hours for diagnostic, prognostic, and treatment purposes.[8,15,16] Lesions can be described using the Forrest classification or descriptive terms.[16] Ranging from highest to lowest risk of rebleeding, these classifications include an ulcer with active spurting of blood; active oozing; nonbleeding visible vessel; adherent clot; flat pigmented spot; and an ulcer with a clean base.[16] Actively bleeding ulcers (including both active spurting and oozing ulcers) have a 55% risk of rebleeding and an 11% mortality rate, whereas those with a clean base have rates of 5% and 2%, respectively.[16] Treatment through endoscopy includes injection therapy (epinephrine, sclerosing agents), thermal therapy (electrocoagulation, heater probe), and mechanical clipping.[16] All of these treatments stop bleeding, prevent recurrences, and decrease transfusion rates and length of hospital stay. The technique chosen depends on the equipment available and the experience of the endoscopist.

Rebleeding after endoscopic therapy can be treated by repeat endoscopy.[16] If further bleeding occurs, then surgery or transcatheter arterial embolization should be considered.[16]

Hospitalization in an intensive care setting is indicated for patients with significant upper GI bleeding due to peptic ulcers. If clinical and endoscopic features suggest a low risk of rebleeding, a ward bed may be acceptable.

PERFORATION

Perforation is heralded by the abrupt onset of severe epigastric pain as gastric or duodenal contents spill into the peritoneal cavity, followed by the development of chemical and then bacterial peritonitis. Patients may not have a history of peptic ulcer disease and may in fact have no history of ulcer-like symptoms. Elderly patients may not have dramatic pain or impressive peritoneal findings.

When the diagnosis is suspected, obtain appropriate laboratory tests, including a CBC, type, and cross-match, and a lipase level determination; place two large-bore IV lines; provide oxygen for hypoxemia, and place a cardiac monitor; insert a nasogastric tube with suction; and obtain an acute abdominal series. Free air is not always evident. Give broad-spectrum antibiotics and obtain a surgical consult promptly. In some cases, nonsurgical therapy has been successful, but operative intervention is the standard in the United States.

OBSTRUCTION

Obstruction occurs because of scarring of the gastric outlet due to chronic peptic ulcer disease, edema due to an active ulcer, or some combination of both. Resulting symptoms include abdominal fullness, nausea, and vomiting, and signs may include abdominal distention and a succussion splash. Dehydration and electrolyte imbalances may occur. Treatment includes rehydration with IV fluids, correction of electrolyte abnormalities, and relief of distention with nasogastric suction. Hospitalization is almost always indicated. The outlet may open as edema subsides, but surgical correction is often necessary.

DISPOSITION AND FOLLOW-UP

Patients with complications always require consultation, and most require admission to an appropriate inpatient unit based on the diagnosis and hemodynamic stability. Most patients with epigastric pain or dyspepsia do not leave the ED with a definitive diagnosis, but, if critical diagnoses (e.g., abdominal aortic aneurysm or myocardial ischemia) are still in the differential, obtain consultation for admission, and further evaluation is indicated. When uncomplicated peptic ulcer disease, gastritis, or dyspepsia is strongly suspected, the great majority of patients can be discharged with acid-suppressive therapy with a PPI or an H_2RA and instructions to follow up with their primary care providers. If alarm features (indicating possible cancer or bleeding) are present, obtain consultation for early endoscopy.

Discharge instructions should include an explanation of the diagnosis and home treatment, specific follow-up instructions, and warning symptoms that should prompt immediate reevaluation. The explanation of the diagnosis should specify that peptic ulcer disease is a presumptive diagnosis and that more definitive diagnostic testing may be necessary. Instructions for home treatment should include a reminder to take medications as directed; a warning against use of alcohol, tobacco products, and aspirin or other NSAIDs; and a recommendation to avoid foods that appear to upset the individual's "stomach." Specific follow-up instructions should include the name and phone number of the appropriate provider whenever possible and a time frame for reevaluation, generally 24 to 48 hours if not improving or 1 to 2 weeks if improving. Warning symptoms that merit immediate reevaluation include those that may be attributed to ulcer complications or confounding illness: worsening pain, increased vomiting, hematemesis or melena, weakness or syncope, fever, chest pain, radiation of pain to the neck or back, and shortness of breath.

CHAPTER 79

Pancreatitis and Cholecystitis

Bart Besinger
Christine R. Stehman

PANCREATITIS

INTRODUCTION/EPIDEMIOLOGY

Pancreatitis is an inflammatory process of the pancreas that may be limited to just the pancreas, may affect surrounding tissues, or may cause remote organ system dysfunction. Most patients will only have one episode of acute pancreatitis, whereas 15% to 30% will have at least one recurrence.[1-3] Between 5% and 25% of patients will ultimately develop chronic pancreatitis.[2,3]

Most cases (~80%) involve only mild inflammation of the pancreas, a disease state with a mortality rate of <1%, which generally resolves with only supportive care.[1,4] A small proportion of patients suffer from more severe disease that may involve pancreatic necrosis, inflammation of surrounding tissues, and organ failure, leading to a 30% mortality rate.[5,6]

The annual incidence of pancreatitis varies among nations and regions. Developed countries have a higher incidence of pancreatitis than developing countries. In general, men and women suffer from acute pancreatitis with equal frequency, although alcohol-associated acute pancreatitis is more common in men, while gallstone-induced pancreatitis is more common in women.[7] Blacks are affected two- to threefold more often than whites but have a mortality rate equal to the general population.[3,8] The incidence of acute pancreatitis varies with age, with a peak in middle age.[9] Other risk factors include smoking, obesity, and diabetes mellitus.[9,10]

Factors associated with acute pancreatitis are listed in **Table 79-1**. Most cases are related to either gallstones or alcohol consumption. About 5% of all patients who undergo endoscopic retrograde cholangiopancreatography for treatment of gallstones develop pancreatitis within 30 days.[11]

The nature of the association between alcohol use and acute pancreatitis is unclear. Some studies suggest that consumption of a large amount of alcohol over a short period of time is a more important factor than chronic alcohol use.[16] However, others suggest that at least 5 years of heavy alcohol use are required before alcohol can reliably be considered the cause.[17]

TABLE 79-1 Causes of Acute Pancreatitis

Common	Gallstones (35%–75%)[9,12] Alcohol (25%–35%)[9,12] Idiopathic (10%–20%)[13]
Uncommon	Hypertriglyceridemia (triglycerides >1000 milligrams/dL) (1%–4%)[14] Endoscopic retrograde cholangiopancreatography[11] Drugs (1.4%–2%)
More uncommon (total <8% of cases)	Abdominal trauma Postoperative complications Hyperparathyroidism Infection (bacterial, viral, or parasitic) Autoimmune disease Tumor (pancreatic, ampullary) Hypercalcemia Cystic fibrosis
Rare	Ischemia Posterior penetrating ulcer Toxin exposure
Unknown	Congenital abnormalities[15]

TABLE 79-2 Commonly Used Drugs Associated with Acute Pancreatitis[18,19]

Acetaminophen
Amiodarone
Cannabis
Carbamazepine
Chlorothiazide/hydrochlorothiazide
Codeine (and other opiates)
Dexamethasone (and other steroids)
Enalapril
Estrogens

Furosemide
Losartan
Methimazole
Metronidazole
Pravastatin/simvastatin
Procainamide
Tetracycline
Trimethoprim-sulfamethoxazole
Tuberculosis antibiotics (dapsone, isoniazid, rifampin)

More than 120 drugs have been linked to acute pancreatitis but together account for fewer than 2% of cases. **Table 79-2** lists the commonly used drugs found by two sets of authors to be most well linked to acute pancreatitis based on number of case reports and recurrence after drug reexposure.[18,19]

PATHOPHYSIOLOGY

The pathophysiology of pancreatitis is not completely understood. Under normal circumstances, trypsinogen is produced in the pancreas and secreted into the duodenum where it is converted into the protease trypsin. In acute pancreatitis, for unclear reasons, trypsin is activated within the pancreatic acinar cells. Activation continues in an unregulated fashion and elimination of activated trypsin is inhibited, resulting in high pancreatic levels of activated trypsin. Activated trypsin in turn activates other digestive enzymes, complements, and kinins, leading to pancreatic autodigestion, injury, and inflammation. Pancreatic injury activates local production of inflammatory mediators, which cause further inflammation.[20,21] Fortunately, most cases never progress beyond local inflammation. However, in a minority of cases, termed necrotizing pancreatitis, pancreatic injury progresses to involve surrounding tissue or possibly remote organ systems.[22] The release of inflammatory mediators from the pancreas, in particular from the acinar cells, and extrapancreatic organs such as the liver leads to remote organ injury and failure, the systemic inflammatory response syndrome, multiorgan failure, and even death.[20-22]

CLINICAL FEATURES

HISTORY AND PHYSICAL EXAMINATION

Acute pancreatitis causes acute, severe, and persistent abdominal pain, usually associated with nausea, vomiting, anorexia, and decreased oral intake.[23] The pain is located in the epigastrium or occasionally in the left or right upper quadrants. Pain may radiate to the back, chest, or flanks. Pain may worsen with oral intake or laying supine and may improve with sitting up with the knees flexed.[24-26] Other symptoms include abdominal swelling, diaphoresis, hematemesis, and shortness of breath. **Pain described as lower abdominal pain or dull or colicky pain is highly unlikely to be pancreatitis**.[25]

The vital signs may be abnormal, with tachycardia, tachypnea, fever, or hypotension. Pain is confined to the epigastrium or upper abdomen, often with guarding and decreased bowel sounds.[23] Occasionally patients will be jaundiced, pale, or diaphoretic.

Rare physical findings associated with late, severe necrotizing pancreatitis include Cullen's sign (bluish discoloration around the umbilicus signifying hemoperitoneum), Grey-Turner sign (reddish-brown discoloration along the flanks signifying retroperitoneal blood or extravasation of pancreatic exudate), and erythematous skin nodules from focal subcutaneous fat necrosis.[26,27]

DIAGNOSIS

Formal diagnosis is based on at least two of three criteria: (1) clinical presentation consistent with acute pancreatitis, (2) a serum lipase or amylase value elevated above the upper limit of normal, or (3) imaging findings characteristic of acute pancreatitis (IV contrast-enhanced CT, MRI, or transabdominal US).[25,28] The differential diagnosis is wide and consists of all causes of upper abdominal pain, as detailed in chapter 71, "Acute Abdominal Pain."

LABORATORY STUDIES

There is no gold standard laboratory diagnosis for acute pancreatitis. Two current guidelines recommend that the amylase or lipase value be at least three times the upper limit of normal;[25,28] some recommend a lipase of two times normal or an amylase of three times normal in a patient with the appropriate clinical presentation;[29] and some recommend that any elevation above normal is consistent with the diagnosis.[23] Normal levels for amylase and lipase are based on values in young, healthy patients, making it difficult to determine applicable levels for older patients or those with multiple comorbidities.[29] Consequently, the combination of an elevated laboratory value with a clinical presentation consistent with pancreatitis is key for diagnosis.[25]

Amylase is not a good choice for diagnosis.[25] Amylase rises within a few hours after the onset of symptoms, peaks within 48 hours, and normalizes in 3 to 5 days.[29] About 20% of patients with pancreatitis, most of whom have alcohol- and hypertriglyceridemia-related disease, will have a normal amylase.[30] This fact, along with the rapid decrease in amylase after symptom onset, gives amylase a sensitivity of about 70%, with a positive predictive value ranging from 15% to 72%. [23] Amylase can be elevated in multiple non–pancreas-related diseases, such as renal insufficiency, salivary gland diseases, acute appendicitis, cholecystitis, intestinal obstruction or ischemia, and gynecologic diseases, lowering specificity for pancreatitis.[23,30]

Lipase is more specific to pancreatic injury and remains elevated for longer after onset of symptoms than amylase. Lipase may be elevated in diabetics at baseline and in other nonpancreatic diseases such as renal disease, appendicitis, and cholecystitis, but it is less associated with nonpancreatic diseases than amylase.[25,31] Lipase is more sensitive in patients with a delayed presentation and in cases of alcoholic or hypertriglyceridemic pancreatitis.[29]

When an elevation of both **lipase and amylase** is required to diagnose pancreatitis, specificity is increased and sensitivity is decreased compared to using either test alone, but there is no evidence that adding amylase to a nondiagnostic lipase improves diagnostic accuracy over lipase alone.[29]

The urine trypsinogen-2 dipstick test is a rapid, noninvasive test with high sensitivity (82%) and specificity (94%).[32] However, given its current limited availability, it is not included as part of the diagnostic criteria for pancreatitis.[28]

In addition to serum lipase and amylase, obtain blood studies to evaluate renal and liver function, electrolyte status, glucose level, WBC count, and hemoglobin/hematocrit. These lab results help the clinician predict disease severity and outcome (detailed below), optimize the clinical status of the patient, identify complications that need immediate treatment (cholangitis, organ failure), and assess effectiveness of treatment.

An **alanine aminotransferase** of >150 U/L within the first 48 hours of symptoms predicts gallstone pancreatitis with a greater than 85% positive predictive value.[33]

IMAGING

Imaging can identify the cause of pancreatitis and can identify complications and severity. For patients with acute pancreatitis where gallstones have not been excluded, obtain a transabdominal US in the ED to detect

gallstone pancreatitis.[3,28,34] For any patient with respiratory complaints, obtain a chest radiograph to evaluate for pleural effusions and pulmonary infiltrates, both associated with more severe pancreatitis.

In patients who meet the clinical presentation and laboratory criteria, routine early CT, with or without IV or PO contrast, is not recommended for multiple reasons. Most patients have uncomplicated disease and are readily diagnosed by clinical and laboratory criteria. There is no evidence that early CT, with or without contrast, improves clinical outcomes.[28,35,36] Peripancreatic fluid collections or pancreatic necrosis detected by CT of any kind within the first few days of symptoms generally require no treatment, and the complete extent of these local complications is usually not appreciated until at least 3 days after onset of symptoms. The magnitude of morphologic change on imaging studies does not necessarily correlate with disease severity.[37] Finally, IV contrast infusion can cause allergic reactions, nephrotoxicity, and worsening of pancreatitis.[38]

If the clinical diagnosis of acute pancreatitis is in doubt, consider further evaluation with IV contrast **abdominal CT**. Characteristic findings include: (1) pancreatic parenchymal inflammation with or without peripancreatic fat inflammation; (2) pancreatic parenchymal necrosis or peripancreatic necrosis; (3) peripancreatic fluid collection; or (4) pancreatic pseudocyst.[25,39] **Figure 79-1A–D** compares CT image of a normal pancreas to images in various complications. Although noncontrast MRI is not readily available to the ED, this imaging modality can identify the complications of pancreatitis and choledocholithiasis. It can be an alternative for patients with renal failure, patients who are allergic to IV contrast, or pregnant patients.[40]

TREATMENT

Treatment is supportive and symptomatic therapy (Table 79-3). No specific medication effectively treats acute pancreatitis; however, early aggressive hydration decreases morbidity and mortality.[41-43] The benefit of fluid resuscitation may result from increased micro- and macrocirculatory support of the pancreas, which prevents complications such as pancreatic necrosis.[44]

Provide fluid resuscitation. Fluid loss results from vomiting, third spacing, increased insensible losses, and decreased oral intake. Patients generally need 2.5 to 4 L of fluid with at least one third delivered in the first 12 to 24 hours.[25,28] The specific rate of fluid delivery depends on the patient's clinical status. In the situation of renal or heart failure, deliver fluid more slowly to prevent complications such as volume overload, pulmonary edema, and abdominal compartment syndrome. Crystalloids are the resuscitation fluids of choice. Normal saline in large volumes may cause a nongap hyperchloremic acidosis and can worsen pancreatitis, possibly by activating trypsinogen and making acinar cells more susceptible to injury.[25,45] A single randomized study showed a decreased incidence of systemic inflammatory response syndrome in patients who received lactated Ringer's instead of 0.9% normal saline.[45] Regardless of which fluid is selected, monitor vital signs and urine output as responses to hydration.

Control pain and nausea. Pain control is best achieved with IV opioid analgesics. Initially, place patients on NPO (nothing by mouth) status and administer antiemetics. There is no benefit to nasogastric intubation.

Prolonged bowel and pancreas rest increases gut atrophy and bacterial translocation, leading to infection and increasing morbidity and mortality.[46] In the ED, if nausea and vomiting have resolved and pain has decreased, transition the patient to oral pain medications and small amounts of food.[47] A low-fat solid foods diet provides more calories than a clear liquid diet and is safe.[48]

Acute pancreatitis by itself is not a source of infection, and prophylactic use of antibiotics and antifungals is not recommended.[49] Administer antibiotics if a source of infection is demonstrated, such as cholangitis, urinary tract infection, pneumonia, or infected pancreatic necrosis.[49]

SEVERITY CLASSIFICATIONS OF ACUTE PANCREATITIS

Although most patients with acute pancreatitis have mild uncomplicated disease, a small percentage of patients have more severe disease. In the ED, it is difficult to distinguish disease severity, because most patients present so early in the disease course that complications that define moderately severe or severe disease are not evident. Moderately severe acute pancreatitis is characterized by transient organ failure (<48 hours), local complications, or systemic complications. Severe disease includes one or more local or systemic complications and persistent organ failure (>48 hours). Critical acute pancreatitis is persistent organ failure and infected pancreatic necrosis.[50]

Local complications involve the pancreas and surrounding tissues and include acute peripancreatic fluid collections, pancreatic pseudocyst, acute pancreatic or peripancreatic necrosis, walled off necrosis, gastric outlet dysfunction, splenic and portal vein thrombosis, and colonic inflammation/necrosis.[22] These are not usually well demonstrated on CT scan until at least 72 hours after the onset of symptoms. Suspect local complications in patients who have persistent or recurrent abdominal pain, an increase in pancreatic enzyme levels after an initial decrease, new or worsening organ dysfunction, or sepsis (fever, increased WBC count).

Organ failure can be seen in any system, but three organ systems are particularly susceptible: cardiovascular, respiratory, and renal. Because of the susceptibility of these three organ systems, pay special attention during the patient's initial evaluation.

Other possible complications of acute pancreatitis are listed in **Table 79-4.**

PREDICTION OF DISEASE SEVERITY

A number of different scoring systems exist, including the Ranson criteria, Acute Physiology and Chronic Health Examination-II, modified Glasgow score, Bedside Index for Severity in Acute Pancreatitis, and Balthazar CT Severity Index. These scoring systems include many data points, some of which are not collected until at least 48 hours after presentation, limiting their utility in the ED.[51] None of these scoring systems is superior to another.[52] **Systemic inflammatory response syndrome at admission and persistent at 48 hours predicts severe acute pancreatitis more simply and as accurately as the various scoring systems.[6,52,53] Besides systemic inflammatory response syndrome, a number of other clinical findings at initial assessment are associated with severe disease. These findings include patient characteristics (age >55 years, obesity, altered mental status, comorbidities), laboratory findings (BUN >20 milligrams/dL or rising; hematocrit >44% or rising; increased creatinine), and radiologic findings (many or large extrapancreatic fluid collections, pleural effusions, pulmonary infiltrates).[22,41,54]**

Overall, acute pancreatitis has a mortality rate of approximately 1%.[4] Moderately severe and severe disease mortality rates are 5% and 30%, respectively.[6,55] Most patients who die do so from multiorgan failure. The sensitivity of systemic inflammatory response syndrome on admission for mortality is 100% with a specificity of 31%, whereas the sensitivity and specificity of systemic inflammatory response syndrome at 48 hours (persistent systemic inflammatory response syndrome) are 77% to 89% and 79% to 86%, respectively.[6,53] Systemic inflammatory response syndrome at admission and 48 hours, combined with patient characteristics (age, comorbidities, and obesity) and response to treatment, helps predict outcome.

DISPOSITION AND FOLLOW-UP

Patients with nonbiliary pancreatitis whose pain can be controlled in the ED and who can tolerate oral feeding can be discharged. Patients who are discharged from the ED should be referred for appropriate follow-up to help prevent recurrence.

Consider **admission for a first bout of acute pancreatitis, for any case of biliary pancreatitis, and for patients needing frequent IV pain medication, not tolerating oral intake because of vomiting or increasing pain, with persistent abnormal vital signs, or with any signs of organ insufficiency (e.g., increased creatinine)**.

Admit to the intensive care unit a patient with severe pancreatitis or anyone who meets local criteria for an intensive care unit admission. Any patient who has any signs, symptoms, laboratory values, or imaging results suggesting the need for intensive care should also receive consideration for intensive care unit admission or at least an intermediate care unit admission.

Biliary pancreatitis requires either admission by surgeon or early surgical consultation for consideration of early cholecystectomy.[56] Cholecystectomies in patients not suffering from documented gallstone pancreatitis are associated with increased recurrence of acute pancreatitis.[57]

Patients with cholangitis or known biliary obstruction on admission may benefit from early endoscopic retrograde cholangiopancreatography.[58] Early routine endoscopic retrograde cholangiopancreatography in patients without one of these two complications does not improve mortality or modify or prevent local complications.[58]

SPECIAL CONSIDERATIONS

MEDICATIONS

Medications associated with acute pancreatitis can be categorized into three groups: antiretrovirals, chemotherapy, and immunosuppressants. Patients taking these medications are at particular risk of severe disease because of the underlying disease combined with the medication side effects. 2′,3′-Dideoxyinosine can cause potentially fatal pancreatitis, whereas patients receiving the antiretrovirals lamivudine and nelfinavir are at lower risk.[18,19]

TABLE 79-3 Treatment of Acute Pancreatitis

Treatment	Comments
Aggressive crystalloid therapy	Lactated Ringer's preferably 2.5–4 L, at least 250–500 mL/h or 5–10 mL/kg/h Use caution in congestive heart failure, renal insufficiency Monitor response: – Hematocrit 35%–44% – Maintain normal creatinine – Heart rate <120 beats/min – Mean arterial pressure 65–85 mm Hg – Urine output 0.5–1 mL/kg/h (if no renal failure)
Vital signs/pulse oximetry	Monitor closely/frequently; initially at least every 2 h, but patients may require more frequent monitoring
Electrolyte repletion	Correct low ionized calcium, hypomagnesemia Control hyperglycemia
Pain control	Parenteral narcotics
Supplemental oxygen	As needed for respiratory insufficiency
Antiemetics	Control nausea/vomiting NPO status Nasogastric tube/suction typically not indicated
Antibiotics	If known or strongly suspected infection, give appropriate antibiotics based on cause Prophylactic antibiotics and antibiotics for mild pancreatitis not indicated
Consultation for endoscopic retrograde cholangiopancreatography	In first 24 h for those with documented biliary obstruction or cholangitis

Abbreviation: NPO = nothing by mouth.

Cancer patients undergoing chemotherapy with one or more of seven medications have a risk of pancreatitis complicating the disease course. These medications are L-asparaginase, cisplatin, cytarabine, ifosfamide, mercaptopurine, pegaspargase, and tamoxifen.[18,19] These agents are used to treat leukemias, lymphomas, sarcomas, and breast, cervical, lung, ovarian, and testicular cancers.

Patients receiving azathioprine for posttransplantation immunosuppression or treatment of inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease are also at risk of developing pancreatitis.[18,19]

CHRONIC PANCREATITIS

Chronic pancreatitis is a continuum of acute pancreatitis. From 5% to 25% of patients can progress to chronic pancreatitis.[2,3] Progression is most common in alcohol-induced disease, but may happen in any situation.[2,3]

Attacks are similar to acute pancreatitis. The goal of treatment is hydration and pain and nausea control. The mortality risk of chronic pancreatitis recurrences is generally lower than that of acute pancreatitis[2,3]

CHOLECYSTITIS

INTRODUCTION AND EPIDEMIOLOGY

Cholecystitis is inflammation of the gallbladder that is usually caused by an obstructing gallstone.

Gallstones produce disease states, including acute calculous cholecystitis, that vary considerably in their severity, clinical presentation, and management strategies. In the United States, the prevalence of gallstones is 8% among men and 17% among women.[59] Prevalence increases with age and with increasing body mass index. Bariatric surgery is also a risk factor for the development of gallstones.[60] The vast majority of gallstones are asymptomatic. *Asymptomatic gallstones* may be discovered incidentally on diagnostic imaging performed for another purpose. The risk of developing symptoms or complications is 1% to 4% per year.[61]

Biliary colic is the most common complication of gallstone disease. Patients experience recurrent attacks of steady upper abdominal pain that typically last no more than a few hours and resolve spontaneously when the gallstone moves from its obstructing position. If the obstructing stone remains in place, acute cholecystitis may develop over time as the gallbladder becomes distended, inflamed, and in some cases infected. As acute cholecystitis evolves, it may result in necrosis and gangrene of the gallbladder wall (**gangrenous cholecystitis**). **Emphysematous cholecystitis** occurs when the inflamed gallbladder becomes infected with gas-producing organisms. **Gallbladder perforation** is an uncommon but life-threatening complication of cholecystitis. Gangrenous cholecystitis, emphysematous cholecystitis, and gallbladder perforation may occur with or without the presence of gallstones.

Choledocholithiasis, gallstones within the common bile duct, may be either primary (arising from within the bile ducts) or, more commonly, secondary (forming in the gallbladder and then migrating to the common bile duct). Choledocholithiasis or other causes of common bile duct obstruction, such as stricture or tumor, may be complicated by *cholangitis*, an infection of the biliary tree. **Chronic cholecystitis** is a state of prolonged gallbladder inflammation typically caused by recurrent episodes of cystic duct obstruction by gallstones. Fibrotic thickening of the gallbladder wall develops. **Biliary sludge** is

TABLE 79-4 Complications of Acute Pancreatitis

Pancreatic	Peripancreatic	Extrapancreatic	
Fluid collection	Fluid collection	*Cardiovascular*	*GI*
Necrosis	Necrosis	Hypotension	Peptic ulcer disease/erosive gastritis
Sterile or infected	Intra-abdominal or retroperitoneal hemorrhage	Hypovolemia	GI perforation
Acute or walled off	Pseudoaneurysm (of contiguous visceral arteries, e.g., the splenic)	Myocardial depression	GI bleeding
Abscess	Bowel inflammation, infarction, or necrosis	Myocardial infarction	Duodenal or stomach obstruction
Ascites	Biliary obstruction with jaundice	Pericardial effusion	Splenic infarction
	Splenic or portal vein thrombosis	*Pulmonary*	*Renal*
		Hypoxemia	Oliguria
		Atelectasis	Azotemia
		Pleural effusion (with or without fistula)	Acute renal failure
		Pulmonary infiltrates	Thrombosis of renal artery or vein
		Acute respiratory distress syndrome	*Metabolic*
		Respiratory failure	Hyperglycemia
		Hematologic	Hypocalcemia
		Disseminated intravascular coagulation	Hypertriglyceridemia

TABLE 79-5 Gallstone Types

	Cholesterol Stones	Pigment Stones
Composition	Cholesterol monohydrate crystals	Black: Calcium bilirubinate Brown: Mixed composition; usually occur in setting of bacterial or helminthic infection of bile
Relative frequency	80%	20%
Radiographic appearance	Radiolucent	Radiopaque
Typical patients	Obese, female, elderly, rapid weight loss	Black: Chronic liver disease or hemolytic disease Brown: Bile duct stasis (sclerosing cholangitis, strictures); more common in Asia

microlithiasis composed of cholesterol crystals, calcium bilirubinate pigment, and other calcium salts. It may be seen on CT or US. The clinical course of biliary sludge is variable. It may resolve spontaneously or progress to cause complications including biliary colic, cholecystitis, cholangitis, or pancreatitis. **Acute acalculous cholecystitis** occurs in the absence of gallstones. It occurs much less commonly than calculous cholecystitis but is more likely to result in complications. It tends to occur in the setting of critical illness such as septic shock, burns, and major trauma or surgery. Old age, diabetes, and immunosuppression are also risk factors.

PATHOPHYSIOLOGY

Bile is produced by hepatocytes and transported via the biliary system to the small intestine where bile acids are necessary for the digestion and absorption of lipids. Bile is also the vehicle for eliminating a number of substances from the body including bile pigments (e.g., bilirubin), cholesterol, and some drugs. Bile is stored and concentrated in the gallbladder. When a meal is eaten, the gallbladder is provoked to contract by cholecystokinin and neural stimulation, resulting in the expulsion of bile into the cystic duct and then to the common bile duct, where it reaches the duodenum at the sphincter of Oddi.

Gallstone formation is a multifactorial process that involves supersaturation of bile components, crystal nucleation, and gallbladder dysmotility.[62] Gallstones are classified based on their composition into two categories: pigment stones and cholesterol stones. Pigment stones may be further divided into brown and black stones (**Table 79-5**).

Nonobstructing gallstones typically do not cause symptoms. As gallstones migrate through the biliary tree, they can obstruct the gallbladder neck, cystic duct, or common bile duct. The resultant distention and increased intraluminal pressure cause pain, nausea, and vomiting. Symptoms are relieved if the gallstone returns to a nonobstructing position within the gallbladder lumen or if it passes through the biliary tree into the duodenum. If the obstruction does not resolve, inflammation results from a complex process that involves mechanical distention, ischemia, and inflammatory mediators including prostaglandins. Interestingly, this long-held notion that gallbladder outlet obstruction is the inciting event in acute cholecystitis has been recently challenged.[63]

Bile cultures are positive in about half of patients with acute cholecystitis.[64-66] Gram-negative organisms predominate (*Escherichia coli*, 39%; *Klebsiella*, 35%), although gram-positive (*Streptococcus*, 18%; *Enterococcus*, 17%) and anaerobic (*Clostridia*, 14%; *Bacteroides*. 3%) infections occur as well.[65] Polymicrobial infections are common.

CLINICAL FEATURES

HISTORY

Biliary colic presents with pain in the epigastrium or right upper quadrant of the abdomen that occasionally radiates to the back. Despite its name, the pain of biliary colic is more often described as steady than colicky. The pain is often accompanied by nausea and vomiting. Its association with food intake is variable. Fatty food intolerance is not a reliable predictor of gallstone presence.[67,68] Biliary colic demonstrates significant circadian periodicity, with a peak in symptom occurrence around midnight.[69]

Symptoms of biliary colic typically last a few hours or less. If pain persists longer, gallstone complications of greater severity, such as acute cholecystitis or cholangitis, must be considered. In acute cholecystitis, pain becomes more localized to the right upper quadrant and increases in severity as peritoneal irritation occurs.[70]

PHYSICAL EXAMINATION

Patients with biliary colic typically have mild right upper quadrant tenderness without peritoneal signs. In acute cholecystitis, tenderness is more severe and may occasionally be accompanied by rigidity or rebound tenderness. Murphy's sign (the sudden cessation of deep inspiration due to pain when examining fingers reach the inflamed gallbladder upon palpation of the right subcostal region) is 65% sensitive and 87% specific for acute cholecystitis.[71] Patients with biliary colic are afebrile. Fever is classically described in acute cholecystitis but is in fact present in only about one third of cases.[71] Jaundice is rarely seen in acute cholecystitis. Jaundice in the setting of biliary tract stone disease implies an obstruction of the common bile duct from choledocholithiasis or extrinsic compression of the bile duct by an impacted cystic duct or gallbladder stone or adjacent inflammation (Mirizzi's syndrome).

DIAGNOSIS

The diagnosis of gallstones can be readily established with radiographic studies. However, it is incumbent upon the emergency physician to distinguish the patient with simple biliary colic from the patient with a more serious gallstone complication such as acute cholecystitis, choledocholithiasis, cholangitis, or gallstone pancreatitis.

Establishing the diagnosis of acute cholecystitis requires the integration of data from the history and physical examination with the results of laboratory and radiographic studies. There is no single clinical or laboratory finding that can be relied upon to rule in or rule out the diagnosis.[71] Diagnostic criteria for acute cholecystitis have been proposed (**Table 79-6**).[72]

The classic presentation of cholangitis is *Charcot's triad*: fever, right upper quadrant abdominal pain, and jaundice. It is present in slightly more than half of the cases.[73] Most patients will have a fever and right upper quadrant pain; the presence of jaundice is less common, occurring in about two thirds of patients. *Reynolds' pentad* adds altered mental status and shock to Charcot's triad.[74] It is seen in less than 10% of patients with cholangitis.[73]

The differential diagnosis of acute cholecystitis includes other diseases of the biliary tract such as biliary colic, choledocholithiasis, and

TABLE 79-6 Diagnostic Criteria for Acute Cholecystitis*

Local signs	Murphy's sign
	Right upper quadrant mass, pain, or tenderness
Systemic signs	Fever
	Elevated C-reactive protein
	Elevated WBC count
Imaging	Imaging findings characteristic of acute cholecystitis (see Table 79-7)
Diagnosis	Suspected: One local sign and one systemic sign Definite: One local sign, one systemic sign, and imaging findings of acute cholecystitis
Accuracy	Sensitivity 91.2%, specificity 96.9% for definite diagnosis criteria compared with surgical pathology gold standard

*Acute hepatitis, chronic cholecystitis, and other acute abdominal disorders should be excluded.

cholangitis and other conditions of the GI tract such as pancreatitis, hepatitis, peptic ulcer disease, gastritis, and functional dyspepsia. Appendicitis may occasionally present with right upper quadrant pain. Chest disease such as pneumonia, pleurisy, or pulmonary embolism may present with pain of the upper abdomen.

LABORATORY TESTING

Laboratory tests are typically normal in biliary colic. A leukocytosis may be seen in acute cholecystitis, but its absence does not exclude the diagnosis. A leukocyte count of >10,000/mm^3 has a 63% sensitivity, 57% specificity, positive likelihood ratio of 1.5, and negative likelihood ratio of 0.6.[71] The mean leukocyte count in cholecystitis is 12,600/mm^3.[75] Elevation of C-reactive protein is associated with acute cholecystitis but is nonspecific.[76]

Liver function tests, including bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and γ-glutamyl transpeptidase, are often normal in acute cholecystitis. They are more likely to be elevated in the setting of choledocholithiasis or other cause of bile duct obstruction.[77,78] Abnormal γ-glutamyl transpeptidase is the most sensitive and specific serum marker of choledocholithiasis.[79] Marked elevations (>1000 IU/L) of alanine aminotransferase or aspartate aminotransferase can occur in the setting of choledocholithiasis but are more suggestive of a hepatocellular necrotic process.[80]

IMAGING

Plain radiography of the abdomen is of minimal value in assessing for biliary tract stone disease. Most gallstones do not contain sufficient amounts of calcium to be visible on plain x-rays. Plain radiography may demonstrate biliary tree air reflective of emphysematous cholecystitis or biliary-enteric fistula, but these are better and more reliably demonstrated with other imaging modalities.

Ultrasound **Abdominal US (Figure 79-2) is the imaging modality of choice for acute cholecystitis.**[81] Its sensitivity and specificity for acute cholecystitis are 81% and 83%, respectively.[82] Advantages of US include its availability, lack of ionizing radiation, short study time, excellent sensitivity for gallstones, and ability to elicit tenderness with placement of the US probe. Sonographic Murphy's sign, maximal tenderness over a sonographically identified gallbladder, is particularly important in the US diagnosis of cholecystitis. The presence of gallstones and a sonographic Murphy's sign has a positive predictive value of 92% for acute cholecystitis. The absence of both gallstones and the sonographic Murphy's sign has a negative predictive value of 95%.[83] Gallbladder wall thickening and pericholecystic fluid are relatively nonspecific for cholecystitis and may result instead from conditions such as ascites, heart failure, liver disease, or pancreatitis.

FIGURE 79-2. Abdominal US demonstrating acute cholecystitis with a gallstone (*arrowhead*), gallbladder sludge (*asterisk*), and pericholecystic fluid (*arrow*). [Image contributed by Bart Besinger, MD, FAAEM.]

FIGURE 79-3. Enhanced abdominal CT showing acute cholecystitis with a radiodense gallstone at the gallbladder neck (*arrow*) and a thickened gallbladder wall (*arrowheads*). [Image contributed by Bart Besinger, MD, FAAEM.]

Bedside US of the right upper quadrant performed by emergency physicians is a useful modality for the diagnosis of cholelithiasis.[84] Its accuracy for diagnosing acute cholecystitis has been questioned.[85,86] However, in the hands of emergency physicians who are highly trained in its use, point-of-care US for cholecystitis is comparable to that performed by US technicians and interpreted by radiologists.[87]

CT, MRI, and Hepatobiliary Iminodiacetic Acid Scanning Acute cholecystitis may be demonstrated on IV contrast-enhanced **abdominal CT**, although the sensitivity and specificity of CT for cholecystitis are ill-defined (**Figure 79-3**). Limitations of CT include its relative insensitivity (~75%) for gallstones and its inability to detect a Murphy's sign.[88] IV contrast-enhanced CT may reveal complications of cholecystitis, such as gangrenous cholecystitis, emphysematous cholecystitis, gallstone ileus, and gallbladder perforation, that are not as reliably demonstrated on US.[89]

Technetium-99m hepatobiliary iminodiacetic acid cholescintigraphy is 96% sensitive and 90% specific for acute cholecystitis.[82] An injected radiotracer is excreted by the liver into bile, allowing visualization of the bile ducts and gallbladder. In acute cholecystitis, the obstructed cystic duct results in nonvisualization of the gallbladder. Cholescintigraphy may also reveal delayed gallbladder emptying (*biliary dyskinesia*). Cholescintigraphy requires hours to perform, limiting its use in the ED.

MRI, including magnetic resonance cholangiopancreatography, may be used to evaluate the gallbladder and biliary tree. The sensitivity and specificity of IV gadolinium-enhanced MRI for cholecystitis are similar to those of US.[82] MRI, however, demonstrates more consistent visualization of the biliary tree, has less interpreter variability, and is a useful alternative to those patients who are difficult to examine with US.[81]

Imaging for Choledocholithiasis Choledocholithiasis is difficult to exclude with US or CT. US fails to visualize the entire extrahepatic biliary tree in many patients and has a sensitivity for choledocholithiasis of about 60%.[90] CT, although limited by its inability to detect poorly calcified stones, performs somewhat better than US.[91,92] On either US or CT, the combined findings of gallbladder stones and common bile duct dilation provide indirect evidence of choledocholithiasis. Normal common bile duct diameter is <5 mm, although diameter is increased in patients with prior cholecystectomy and in the elderly. More definitive evaluation for choledocholithiasis can be accomplished by magnetic resonance cholangiopancreatography, endoscopic US, or endoscopic retrograde cholangiopancreatography.

Imaging findings in acute cholecystitis are summarized in **Table 79-7**.

TABLE 79-7 Imaging for Acute Cholecystitis

Modality	Findings	Comment
US	Sonographic Murphy's sign Gallbladder wall thickening >3 mm Pericholecystic fluid Gallbladder distention: short axis >40 mm	Preferred initial imaging test.
CT	Gallbladder wall thickening >3 mm Pericholecystic fluid Pericholecystic fat stranding Hyperdense gallbladder wall Gallbladder distention	Demonstrates complications such as gangrene, gas formation, and perforation. Insensitive for gallstones. Useful in evaluating alternative diagnoses.
HIDA	Nonvisualization of gallbladder	Excellent sensitivity and specificity. Time consuming, limited availability, ionizing radiation.
MRI/MRCP	Gallbladder wall thickening >3 mm Pericholecystic fluid Pericholecystic fat signal changes Gallbladder distention: short axis >40 mm	Specificity and sensitivity similar to US. Excellent visualization of biliary tree. Time consuming, limited availability.

Abbreviations: HIDA = hepatobiliary iminodiacetic acid cholescintigraphy; MRCP = magnetic resonance cholangiopancreatography.

TREATMENT

Asymptomatic gallstones generally require no treatment. Elective cholecystectomy is occasionally recommended for those at high risk for gallstone complications such as patients with sickle cell disease, patients with planned organ transplantation, or those belonging to ethnic groups at high risk for gallbladder cancer.

ED management of **biliary colic** includes symptom control and referral to a general surgeon for outpatient laparoscopic cholecystectomy. Symptom management in the ED includes antiemetics and analgesics. Nonsteroidal anti-inflammatory drugs are first-line therapy. The analgesic efficacy of parenteral nonsteroidal anti-inflammatory drugs is comparable to that of opioids in biliary colic. Additionally, nonsteroidal anti-inflammatory drugs decrease the frequency of short-term gallstone complications such as cholecystitis.[93] Opioid analgesics are often required for pain control. All opioids cause some degree of sphincter of Oddi spasm and increase in biliary pressure.[94] The clinical significance of this is unclear, and there is no evidence that any particular opioid drug is superior in treating the pain of biliary colic. Anticholinergic agents such as atropine and glycopyrrolate do not improve biliary colic pain.[95,96]

Acute cholecystitis and its complications are managed in the hospital with surgical consultation. Early laparoscopic cholecystectomy is often the treatment of choice. ED treatment includes the provision of analgesia, administration of antiemetics for nausea and vomiting, cessation of oral intake, volume and electrolyte replacement, and administration of antibiotics. Appropriate antibiotic regimens include second- and third-generation cephalosporins, carbapenems, β-lactam/β-lactamase inhibitor combinations, or the combination of metronidazole and a fluoroquinolone.[97-99] The value of antibiotics in mild acute cholecystitis has recently been questioned.[100]

Cholangitis can be a life-threatening disease that demands aggressive care including generous fluid resuscitation, the timely administration of antibiotics, and early biliary decompression. Endoscopic retrograde cholangiopancreatography is the decompression procedure of choice in most instances, and when cholangitis is suspected, emergency consultation with a GI surgeon or gastroenterologist is needed. Percutaneous or surgical drainage is an alternative when endoscopic retrograde cholangiopancreatography is not feasible or is unsuccessful.

DISPOSITION AND FOLLOW-UP

Once symptoms are adequately controlled, patients with biliary colic are typically discharged from the ED to follow up with a general surgeon. They should be instructed to return to the ED if symptoms of gallstone complications (e.g., prolonged pain, fever, jaundice) arise. Patients who present to the ED with acute cholecystitis or cholangitis require hospital admission. For suspected cholangitis, emergency consultation or transfer to an institution with treatment capabilities for endoscopic retrograde cholangiopancreatography is necessary. Patients with severe illness, including many with cholangitis, should be admitted to a critical care unit.

SPECIAL CONSIDERATIONS

Emphysematous cholecystitis is characterized by gas in the gallbladder wall or lumen resulting from infection with gas-producing organisms such as *Clostridium* species, *E. coli*, and *Klebsiella* species (**Figure 79-4**). It is associated with underlying diabetes and is more common in older patients. Its association with gallstones is variable. Gas occupying the gallbladder may be seen on plain x-rays, US, or, more reliably, IV contrast-enhanced CT. Emphysematous cholecystitis is notable for a 15% mortality, which is much higher than the mortality rate in uncomplicated cholecystitis.[101] In addition to broad-spectrum antibiotics, patients with emphysematous cholecystitis require prompt surgical consultation and consideration for urgent cholecystectomy. Percutaneous cholecystostomy is an alternative therapy for severely ill patients.

Gallstone ileus is a mechanical small bowel obstruction caused by an ectopic gallstone that has reached the intestinal lumen via a biliary-enteric fistula. Such a fistula may occur in the setting of inflammation secondary to cholecystitis. Gallstone ileus may be diagnosed on plain films of the abdomen or, more dependably, with CT. The classic radiographic appearance is Rigler's triad: a small bowel obstruction, pneumobilia, and an ectopic gallstone.[102] Operative therapy is typically indicated.

Acalculous cholecystitis represents a small minority of cholecystitis cases and most often occurs in the inpatient setting among patients with critical illness. Nevertheless, it may be occasionally encountered in the ED, particularly in immunocompromised patients. Diagnosis is challenging because the clinical presentation is variable and no test result is pathognomonic. US, IV contrast-enhanced CT, and cholescintigraphy are helpful in establishing the diagnosis, but sensitivity and specificity are less than for calculous cholecystitis. Acalculous cholecystitis runs a more fulminant course than cholecystitis associated with gallstones.

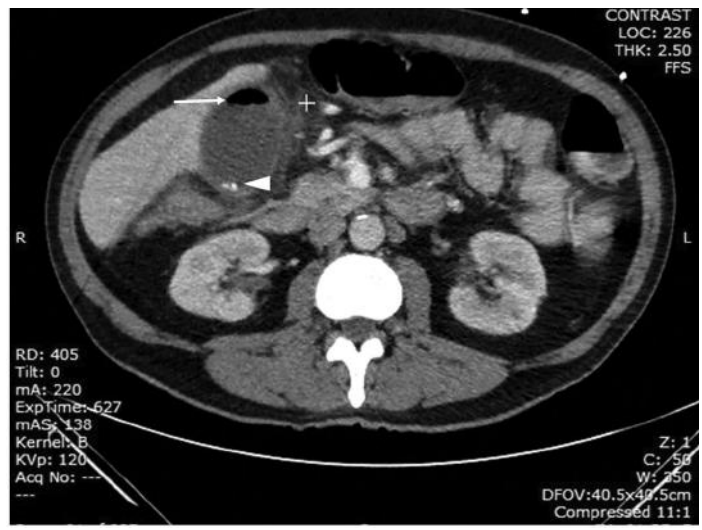

FIGURE 79-4. Contrast-enhanced abdominal CT showing emphysematous cholecystitis with gallstones (*arrowhead*), intraluminal gallbladder gas (*arrow*), and pericholecystic inflammatory changes (*plus sign*). [Images contributed by Bart Besinger, MD, FAAEM.]

Complications such as gangrene and perforation are common, and mortality is high.[103]

Chronic cholecystitis is gallbladder inflammation and scarring that occurs over time, usually secondary to intermittent cystic duct obstruction. It presents in a manner similar to biliary colic or acute cholecystitis, although symptoms and examination findings may be more subtle. Patients may report recurrent episodes of pain.

Postcholecystectomy syndrome refers to a heterogeneous group of disorders that present with persistent abdominal symptoms after removal of the gallbladder. In the early postcholecystectomy period, bile leak is the principal concern. Choledocholithiasis is a common cause of postcholecystectomy pain. Symptom-producing common bile duct stones may be "retained" (present at the time of surgery) or may develop postoperatively, formed primarily in the bile ducts often in the setting of bile stasis.[104] Postcholecystectomy syndrome may result from nonbiliary pain that was erroneously attributed to a biliary cause and therefore not remedied by cholecystectomy.

CHAPTER 80

Hepatic Disorders

Susan R. O'Mara
Kulleni Gebreyes

INTRODUCTION AND EPIDEMIOLOGY

This chapter discusses the ED presentation, evaluation, and treatment of acute and chronic liver disease as well as fulminant liver failure. Specific entities addressed in this chapter include viral and toxic hepatitis, nonalcoholic fatty liver disease (NAFLD), nonalcoholic steatohepatitis (NASH), and complications of cirrhosis including coagulopathy, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatic encephalopathy. Cholecystitis and biliary colic are addressed in chapter 79, "Pancreatitis and Cholecystitis." Variceal bleeding is addressed in chapter 75, "Upper Gastrointestinal Bleeding."

Liver disease is associated with many ED complaints: abdominal pain, vomiting, shortness of breath, altered mental status, GI bleeding, and even nonspecific malaise can all be attributed to malfunction of the liver. Globally, hepatitis A, B, C, D, and E are major public health problems. About two billion people are infected with hepatitis B and 150 million with hepatitis C, and cancer and cirrhosis resulting from these infections account for about 3% of deaths worldwide.[1] Cirrhosis is the 12th leading cause of death in the United States, and hepatitis C is the leading cause of cirrhosis in the United States, followed by alcoholic liver disease.[2] Acute, or fulminant, liver failure is uncommon and is caused primarily by acetaminophen poisoning (46%), with hepatitis B being the most common infectious cause.[3]

PATHOPHYSIOLOGY

Acute hepatitis is caused by an infectious, toxic, or metabolic injury to hepatocytes. The initial injury leads to inflammation, cellular death, and eventual scarring in the liver. In chronic disease, liver parenchyma is replaced by fibrous tissue, which separates the functioning hepatocytes into isolated nodules. This disruption of the normal tissue structure can become severe and lead to the central characteristics of liver failure: loss of metabolic and synthetic function at the cellular level, progressive development of portal hypertension, ascites formation, and portal-systemic shunting at the gross level.

The liver's synthetic functions include the production of **coagulation and anticoagulation factors.** The liver is responsible for production of the vitamin K–dependent clotting factors II, VII, IX, and X; proteins C and S; and other elements of the clotting and thrombolytic processes.[4] Inadequate production of these clotting factors makes uncontrolled bleeding one of the life-threatening features of liver disease and a potentially dramatic complication of hepatic failure.

Portal hypertension is increased hydrostatic pressure in the portal vein and its feeder vessels, caused by resistance to blood flow through the cirrhotic liver. It eventually causes esophageal and gastric varices and portal-systemic shunting. The increased hydrostatic pressure in the intraperitoneal veins, hypoalbuminemia, and poor renal management of sodium and water lead to ascites in the cirrhotic patient. Ascites can cause respiratory compromise and lead to spontaneous bacterial peritonitis (SBP), which occurs when normal flora translocate across an edematous bowel wall into the peritoneum. Bacteremia and infection of preexisting ascitic fluid ensue.[5]

Encephalopathy is a pivotal characteristic of chronic liver disease and is a hallmark of liver failure. Ammonia is often presumed to be the cause of confusion and lethargy in encephalopathic patients, but in fact, the pathophysiology is not completely understood. In cirrhosis, portal hypertension allows ammonia formed by colonic bacteria to enter the general circulation through portal-systemic shunting. Large intestinal protein loads, such as a high protein meal or GI bleeding, fuel this process. Although levels of ammonia do not reliably correlate with mental status, it is reasonable to think of ammonia as a contributing factor to alterations in mental status. In fulminant liver failure, cerebral edema and increased intracranial pressure can develop. In this end-stage state, loss of autoregulation of cerebral blood flow, ammonia-related edema, and a systemic inflammatory response are all thought to contribute to this deadly complication.[6]

Jaundice can be present in any stage of liver disease. Jaundice is caused by elevated levels of bilirubin in the circulation, leading to bile pigment deposits in the skin, sclerae, and mucous membranes. Hyperbilirubinemia can occur for one of three reasons: overproduction, inadequate cellular processing, or decreased excretion of bilirubin. Another way to think about this is prehepatic, hepatic, and posthepatic jaundice. Prehepatic jaundice is caused by any form of hemolysis, including inborn errors of bilirubin metabolism, which overwhelm the liver's ability to conjugate bilirubin. Viral infection and ingested toxins are typical causes of hepatic jaundice. When hepatocytes necrose, the liver's ability to conjugate bilirubin is impaired, and the level of unconjugated bilirubin rises in the blood. Unlike prehepatic and hepatic jaundice, which present with elevated unconjugated or indirect bilirubin, posthepatic jaundice produces a rise in conjugated bilirubin. Typical causes of posthepatic jaundice are a pancreatic tumor or a gallstone in the common bile duct. Parasitic infestation and biliary atresia are rare causes in the United States but are more common in other parts of the world.

CLINICAL FEATURES

Clinical features of hepatitis are listed in **Table 80-1**.

At ED presentation, a **chief complaint** of jaundice, nausea, vomiting, diarrhea, right upper quadrant or epigastric pain, pruritus, inappropriate bruising or bleeding, or altered mental status should raise the question of liver disease. In the **history of present illness**, pay attention to onset of symptoms after eating out or after ingestion of acetaminophen (in one-time overdose or chronically high doses), mushrooms,

or raw oysters. Note the duration of symptoms to characterize acuity. **Past medical history** can identify comorbidities or risk factors for liver disease. Risk factors include chronic hepatitis, transfusion of blood products, positive human immunodeficiency virus status, frequent use of pain medications, or depression. Obesity, type 2 diabetes, and hyperlipidemia are risk factors specific to NASH. High-risk medications include acetaminophen and acetaminophen-containing pain medications, vitamin A, isoniazid, propylthiouracil, phenytoin, and valproate, as well as a variety of herbal remedies.[7] Statins raise concern for hepatic toxicity but are rarely implicated in significant liver injury. Three percent of patients taking statins have mild transaminase elevations; clinically significant hepatotoxicity is rare.[8] A **social history** positive for injection drug use, chronic alcohol abuse, sexual promiscuity, or travel to countries with endemic parasitic liver diseases represents increased risk for liver disease.

The **review of systems** in the patient with suspected liver disease can identify important signs and symptoms. Cholestasis causes white (acholic) stools and brown or tea-colored urine. Stools can be black or bloody from variceal or other GI bleeding. Patients may notice yellow skin or sclerae, indicating elevated bilirubin. Ascites can increase abdominal girth or cause shortness of breath, and portal hypertension leads to generalized weakness, encephalopathic changes in mental status, and lower extremity edema. Lightheadedness or near-syncope can result from intravascular depletion and abnormalities in renal sodium and water excretion.

A number of findings on **physical examination** are hallmarks of liver disease. Liver enlargement and tenderness with or without jaundice are characteristic of acute hepatitis. Chronic liver disease is accompanied by a number of physical findings, including sallow or jaundiced complexion, extremity muscle atrophy, Dupuytren's contracture, palmar erythema, cutaneous spider nevi, distended abdomen with a fluid wave, enlarged veins on the surface of the abdomen (caput medusae), and asterixis. Extraordinary bruising or other signs of bleeding diathesis can be seen in liver failure.

ACUTE, CHRONIC, OR FULMINANT HEPATIC DISEASE

Liver disease can be categorized as acute, chronic, or fulminant. Accurately differentiating the acuity and severity of the disease process guides appropriate evaluation, treatment, and disposition.

Acute hepatitis typically presents with nausea, vomiting, and right upper quadrant abdominal pain. The patient with acute hepatitis can also have fever, jaundice, bilirubinuria, and an enlarged, tender liver. The most common causes are viral infection and toxic ingestion. Alcohol and acetaminophen are the most common toxic causes.

Patients with **chronic hepatitis** display evidence of long-standing hepatocellular damage. Cirrhotic patients with portal hypertension complain of abdominal pain and/or distention, abnormal bleeding (bruising, bleeding gums, epistaxis, blood in the stool), and lower body edema. They may also exhibit signs of infection, encephalopathy, ascites, and electrolyte derangement. Skin examination may reveal spider nevi, caput medusae, and other manifestations of abnormal shunting of blood to surface vessels.

Liver failure is the potential final common pathway for both acute and chronic liver disease. If there is a delay in seeking medical attention or a rapid acute course, **fulminant liver failure** can be the presenting disorder. For cirrhotic patients, the transition to liver failure is marked by the advent of coagulopathy, encephalopathy, abnormal fluid shifts, and hepatorenal syndrome.

ACUTE HEPATITIS—VIRAL

Hepatitis A virus, hepatitis B virus, and hepatitis C virus are the most prevalent forms of viral hepatitis encountered in the ED. **Hepatitis A virus** is transmitted by fecal-oral contamination. Although it is popularly associated with improper food handling or oyster consumption, the most common transmission occurs from asymptomatic children to adults. Implementation of the hepatitis A vaccine in children has dramatically decreased overall rates of infection. Hepatitis A virus infection has an incubation period of 15 to 50 days, followed by a prodrome of nausea, vomiting, and malaise. About a week into the illness, patients may note dark urine (bilirubinuria). A few days later, they develop clay-colored stools and jaundice. Hepatitis A virus does not have a chronic component, and death from hepatic failure is rare.[9]

Hepatitis B virus is transmitted sexually, by blood transfusion, by contaminated needles, and by perinatal transmission. Incubation period is 1 to 3 months, and patients can be infectious for 5 to 15 weeks after onset of symptoms if they clear the infection. Individuals who develop chronic disease will remain infectious indefinitely. Chronic infection occurs in only 6% to 10% of patients who contract hepatitis B virus as adults, whereas 90% of infants and 30% of children under the age of 5 progress to chronic status, which underlines the importance of vaccination of infants and women of childbearing age.[10] In the acute phase of hepatitis B virus, presentation to the ED is similar to that for hepatitis A virus, including complaints of malaise, nausea, vomiting, fever, abdominal pain, and jaundice.

Hepatitis C virus transmission occurs primarily through exposure to contaminated blood or blood products. In contrast to hepatitis A virus and hepatitis B virus, hepatitis C virus is most often asymptomatic in the acute phase of infection, and >75% of patients advance to the chronic stage. The rate of progression to liver failure varies and depends on the natural course of the virus and cofactors such as alcoholism and human immunodeficiency virus. Along with hepatitis B virus, hepatitis C virus is one of the most common causes of hepatocellular carcinoma. Of the

patients who develop chronic hepatitis C virus, 1% to 5% will die of either cirrhosis or liver cancer.[11]

Hepatitis D virus is uncommon and is typically seen in people with preexisting chronic hepatitis B virus infection. Hepatitis D superinfection can result in a rapidly progressive or fulminant form of liver disease that carries a high short-term mortality rate. This variety of infection is most commonly associated with injection drug use.[11]

Acute illness with liver function test abnormalities also occurs with infection by other hepatotropic viruses such as cytomegalovirus, herpes simplex virus, Coxsackie virus, and Epstein-Barr virus. These agents are unlikely to cause clinically significant hepatitis in an otherwise healthy host.

ACUTE HEPATITIS—TOXIC

A toxic insult to the liver can cause acute hepatitis and/or fulminant liver failure. The most common of these is acetaminophen overdose. **Acetaminophen** accounts for >40% of liver failure cases in the United States and one third of deaths secondary to toxic ingestion. Patients develop nausea, vomiting, and abdominal pain. They may also give a history of an acute overdose of acetaminophen or chronic use of one or more acetaminophen-containing pain medicines. Up to 28% of patients with acetaminophen overdose will develop liver failure. The likelihood of liver failure depends on time from ingestion to presentation, the dose ingested, and the baseline health status of the patient.[12] Tylenol overdose is reviewed more completely in chapter 190, "Acetaminophen."

In addition to acetaminophen, there are a variety of **prescription medications** (antibiotics and statins prominent among them), **herbal remedies**, and **dietary supplements** that have been associated with acute hepatitis and liver failure. The list of prescription medications that have been implicated in liver disease is so long that it is prudent to refer to a pharmaceutical database to identify a potential culprit when toxic insult is suspected. Some of the most common herbal remedies that have been implicated in hepatic injury are listed in **Table 80-2**.

Alcoholic liver disease can range from asymptomatic, reversible fatty liver to acute alcoholic hepatitis, cirrhosis, or a combination of acute and cirrhotic features. The diagnosis of alcoholic liver disease carries a 35% 5-year survival rate. If a patient has asymptomatic liver disease (i.e., fatty liver seen on imaging), but the patient's drinking continues and acute alcoholic hepatitis develops, the mortality can be much higher.[13] A history of consistent heavy alcohol use (mean intake at presentation of 100 grams or more) is thought to be required for development of significant alcoholic liver disease.[14] However, information is often difficult to elicit from the patient or family, and the patient may have stopped drinking before ED presentation. Other nonhepatic features of alcohol abuse, such as malnutrition, stocking-glove neuropathy, pityriasis rosea, and cardiomyopathy, can be clues to alcohol-induced liver disease.

Mushroom poisoning is an uncommon but important cause of acute hepatitis with a high risk of liver failure. *Amanita phalloides* ("death cap") is the most lethal of the more than 50 types of mushrooms that are toxic to humans. For detailed discussion, see chapter 219, "Mushroom Poisoning."

CHRONIC HEPATITIS AND CIRRHOSIS

Most patients live for years with hepatitis B virus, hepatitis C virus, NASH, or alcoholic hepatitis without symptoms. During the asymptomatic period, normal liver parenchyma is being gradually replaced by scar tissue, and hepatic disease can manifest as mild transaminase elevation or, in cases of NASH and alcoholic hepatitis, as an incidental finding of fatty liver on abdominal imaging studies. When a critical amount of liver parenchyma is replaced by fibrotic tissue, symptoms of cirrhosis develop, such as abdominal pain, ascites, SBP, general weakness resulting from electrolyte derangement, or altered mental status due to hepatic encephalopathy.

Ascites One of the hallmarks of cirrhosis, ascites causes a protuberant abdomen, and a fluid wave is produced on physical exam. Intra-abdominal fluid can displace the diaphragm upward and produce sympathetic pleural effusion with the possibility of respiratory compromise. Smaller amounts of ascites can be difficult to identify on examination; bedside ultrasound can be particularly helpful in patients in whom the presence of ascites is uncertain (**Figure 80-1**).

Spontaneous Bacterial Peritonitis SBP is a subtle yet crucial complication of ascites. The survival rate for patients with a first episode of SBP is 68.1% at 1 month and 30.8% at 6 months. This is probably a result of acute infection occurring in the fragile setting of advanced liver disease.[15] Although common in cirrhotic patients—roughly 30% of ascitic patients will develop SBP in a given year—SBP is difficult to diagnose because signs of abdominal pain and fever are not always present, and physical examination does not always demonstrate abdominal tenderness. Consequently, patients who are diagnosed with ascites for

TABLE 80-2 Common Herbal Remedies Known to Cause Hepatic Toxicity

Herbal Remedy	Application	Nature of Injury
Black cohosh (*Actea racemosa/cimiifuga racemosa*)	Menopausal symptoms	Hepatic necrosis and bridging fibrosis
Chaparral (*Larrea ridentate*)	Antioxidant, health tonic	Cholestasis, chronic hepatitis, cholangitis, cirrhosis
Comfrey (*Symphytum*)	Broken bones, wound healing, reduce joint inflammation	Hepatic veno-occlusive disease
Echinacea (*E. angustifolia, E. pallida, E. purpurea*)	Respiratory infections, fever, immune booster	Acute cholestatic autoimmune hepatitis
Kava (*Piper methysticum*)	Anxiolytic, sleeping aid	Acute and chronic hepatitis, cholestasis, fulminant hepatic failure
Kombucha "mushroom" tea	Weight loss, increasing T-cell count, well-being, antiaging	Acute liver failure, hepatitis, acute renal failure with hyperthermia and lactic acidosis
Ma huang (*Ephedra sinica*)	Weight loss	Acute hepatitis
Mistletoe (*Viscum album*)	Hypertension, insomnia, epilepsy, asthma, infertility, urinary disorders	Acute hepatitis
Noni juice (*Morinda citrifolia*)	Health tonic	Subacute hepatic failure, acute hepatitis
Prostata (*Serenoa repens*); saw palmetto	Benign prostatic hyperplasia	Cholestatic hepatitis
Senna (*Cassia angustifolia*)	Laxative	Acute hepatitis, acute cholestatic hepatitis, acute liver failure
Skullcap (*Scutellaria baicalensis*)	Sedative, anti-inflammatory	Hepatic veno-occlusive disease, cholestasis, hepatitis
St John's wort (*Hypericum perforatum*)	Anti-depressant	Cytochrome P-450 induction, serotonin syndrome
Valerian (*Valeriana officinalis*)	Sedative, anxiolytic	Hepatitis

the first time, or who have ascites and develop fever, abdominal pain, GI bleeding, or encephalopathy, should undergo paracentesis to check for SBP.

Hepatorenal Syndrome Hepatorenal syndrome is a complication of cirrhosis that often accompanies SBP. It is defined as acute renal failure in a patient with histologically normal kidneys in the presence of preexisting chronic or acute hepatic failure. The cause is not well understood. There are two types of hepatorenal syndrome. Type 1 is more serious and is identified by progressive oliguria and doubling of serum creatinine over a 2-week period. Type 2 is represented by a gradual impairment in renal function that may or may not advance beyond moderate dysfunction. The discovery of abrupt renal failure in a cirrhotic patient that cannot be attributed to any other cause should be viewed as a marker of extreme morbidity. Median survival for type 1 hepatorenal syndrome without medical treatment is 2 weeks.[16]

Hepatic Encephalopathy Hepatic encephalopathy is a poorly understood phenomenon attributed to the accumulation of nitrogenous waste products normally metabolized by the liver. Hepatic encephalopathy causes a spectrum of illness ranging from chronic fatigue or mild confusion to acute lethargy.

The development of hepatic encephalopathy suggests either that the liver is no longer able to metabolize the usual supply of nitrogenous waste or that the supply of such waste has increased. Sources of increased supply include protein loads from a large meal or from occult GI bleeding. In addition to progressive liver disease, constipation, hypo- or hyperglycemia, alcohol withdrawal, hypoperfusion states such as sepsis, and iatrogenic interventions can also compromise the liver's metabolic capacity. Hepatic encephalopathy is a common complication after **transjugular intrahepatic portosystemic shunt**, a procedure in which portal blood is shunted to the inferior vena cava, bypassing the liver. Although this procedure may succeed in reducing portal hypertension and variceal bleeding, it also slows metabolism of nitrogenous wastes by reducing hepatic blood flow. Adding or removing antibiotics from a patient's medicine regimen can also precipitate encephalopathy by changing the intestinal flora and altering the gut's ability to metabolize proteins.[17]

To appreciate the presence or worsening of encephalopathy, determine if there are changes in personality, worsening dementia, a decrease in levels of consciousness, or declining neuromuscular function. **Table 80-3** lists clinical stages of encephalopathy. Asterixis, which characterizes stage II, is elicited by having the patient hold the arms straight up and extending the wrists. The hands begin to flap repetitively. Another manifestation of asterixis is back-and-forth tongue movement when the tongue is extended. A patient with known encephalopathy in stage I or II who is otherwise well and has no other acute comorbidities may be managed as an outpatient after consultation with the primary care physician or gastroenterologist.

TABLE 80-3 Stages of Clinical Hepatic Encephalopathy

Stage	Features
I	General apathy
II	Lethargy, drowsiness, variable orientation, asterixis
III	Stupor with hyperreflexia, extensor plantar reflexes
IV	Coma

Hepatic encephalopathy is a diagnosis of exclusion. In the cirrhotic patient with altered mental status or lethargy, first exclude multiple other causes. This holds true even in the presence of an elevated serum ammonia level. Patients with end-stage liver disease are typically coagulopathic and may develop a spontaneous or traumatic subdural hematoma. Decreased hepatic gluconeogenesis and glycogen stores and poor nutritional status increase the risk of hypoglycemia and nutritional encephalopathies such as Wernicke-Korsakoff syndrome. Cirrhotic patients often are treated with diuretics and can develop hyper- or hyponatremia. Altered mental status can result form decreased hepatic clearance of drugs such as benzodiazepines and opiates, prolonging the effect and resulting in accidental overdose. Renal failure and sepsis are other considerations. Always exclude upper GI bleeding as a precipitant of hepatic encephalopathy, because the protein in the blood can translocate across the bowel of the cirrhotic patient.

Gastroesophageal varices and hemorrhage are complications of cirrhosis that are covered in chapter 75, "Upper Gastrointestinal Bleeding."

HEPATIC FAILURE

Liver failure is the final common pathway for several types of liver disease. Progression to liver failure is varied and depends largely on comorbid entities, such as human immunodeficiency virus/acquired immunodeficiency syndrome, diabetes, obesity, continued injection drug use, and alcohol intake. There are roughly 2000 cases per year in the United States. Patients who develop acute liver failure have an extremely poor prognosis, with survival rates of <30%.[18] Among the most common of the entities that present as acute liver failure in the United States are acetaminophen overdose (46%), indeterminate causes (14%), other drugs (11%), hepatitis B virus (7%), and autoimmune hepatitis.[3]

The clinical hallmarks of acute liver failure are hepatic encephalopathy, hepatorenal syndrome, and coagulopathy. The electrolyte imbalances seen in chronic liver disease can become extreme. Cerebral edema and intracranial hypertension are the most ominous complications. The catabolic nature of liver failure leads to negative nitrogen balance and immunodeficiency. Other clinical findings in acute liver failure include hypotension, hypoglycemia, and relative adrenal insufficiency. ED evaluation should include assessment for sepsis. Recognize when a patient has progressed from cirrhosis to failure or presents with acute hepatic failure, because transfer to a transplant center may be the most appropriate disposition.

GILBERT'S SYNDROME

Gilbert's syndrome is a familial liver disorder that produces occasional elevations in liver function tests and bilirubin. This syndrome does not cause cirrhosis or affect the synthetic or metabolic functions of the liver. Wilson's disease, hemochromatosis, and α_1-antitrypsin deficiency are familial disorders that can lead to severe chronic disease and liver failure. Autoimmune hepatitis is a progressive, chronic disease that is presumably triggered by viral hepatitis or by medications. Primary biliary cirrhosis is a presumably autoimmune disorder with a chronic or chronic-degenerative course.

PRE- AND POSTHEPATIC VENOUS THROMBOSIS

Vascular diseases of the liver are rare but important, because timely diagnosis and treatment can improve outcome. **Portal vein thrombosis** affects the prehepatic portal venous system and is associated with hypercoagulable states such as polycythemia vera; with deficiencies in proteins C and S, antithrombin 3, and factor V Leiden; and with abdominal trauma, sepsis, pancreatitis, cirrhosis, or hepatocellular carcinoma. The major symptom is abdominal pain; occasionally ascites can occur. Splenomegaly can occur without hepatomegaly on physical examination.[19] **Hepatic vein thrombosis (posthepatic), or Budd-Chiari syndrome**, has both acute and chronic presentations, including abdominal pain, hepatomegaly, and ascites. Associated conditions include coagulopathies, polycythemia vera, paroxysmal nocturnal hemoglobinuria, and congenital webs of the vena cava.[20]

LABORATORY EVALUATION AND IMAGING

Laboratory tests for hepatobiliary disease can be divided into four categories: (1) markers of acute hepatocyte injury or death, (2) measurements of hepatocyte synthetic function, (3) indicators of hepatocyte catabolic activity, and (4) tests to diagnose specific disease entities. Traditional liver function panels include a mix of markers of hepatocyte injury, usually including aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase, as well as indicators of hepatocyte catabolic activity (direct and indirect bilirubin). Tests that reflect hepatocyte synthetic function include prothrombin time and albumin. Ammonia reflects catabolic function of the liver. Viral hepatitis serologies are used to differentiate various types of hepatitis; acetaminophen levels can determine whether treatment for poisoning is appropriate; and various tests of ascitic fluid are used to diagnose SBP.

Bilirubin is a metabolite of heme proteins. The total level is usually reported along with the levels of conjugated (direct) and unconjugated (indirect) portions. In a functioning liver, unconjugated bilirubin is taken up by hepatocytes, conjugated, and then secreted into bile. Bilirubin is then excreted in the stool, with a small percentage being recirculated through the liver. An increased total and *indirect* bilirubin signifies either an overwhelming supply of unconjugated bilirubin to the hepatocytes (e.g., hemolytic anemia) or an injury to the hepatocytes themselves that damages their capacity to conjugate a normal supply of bilirubin (e.g., acute or chronic viral hepatitis). Total and *direct* bilirubin is increased when there is some obstruction preventing the secretion of the conjugated bilirubin that is produced by normally functioning hepatocytes (e.g., obstructing gallstone, pancreatic mass, or biliary atresia).

Transaminases (aspartate aminotransferase and alanine aminotransferase) are intracellular enzymes found in hepatocytes and some other cell types. Hepatocyte injury or necrosis releases these enzymes into the circulation. Elevations in the hundreds of units per liter suggest mild injury, or smoldering inflammation. Levels in the thousands suggest extensive acute hepatic necrosis. Less significant elevations, less than five times normal, are typical of alcoholic liver disease and NASH. Marked elevations are commonly seen with acute viral hepatitis. These enzyme levels may be near normal in end-stage liver failure, when the hepatocytes are beyond the stage of acute injury. An aspartate aminotransferase–to–alanine aminotransferase ratio of greater than 2 is common in alcoholic hepatitis because alcohol stimulates aspartate aminotransferase production.[1] Incidental findings of transaminase elevations of three to five times normal and alkaline phosphatase of up to twice normal in diabetic or obese patients suggest the presence of NASH in diabetic or obese patients.[21] Alanine aminotransferase is a more specific marker of hepatocyte injury than aspartate aminotransferase. Aspartate aminotransferase is found not only in liver but also in heart, smooth muscle, kidney, and brain. Elevated aspartate aminotransferase can be due to medications, including acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors, nicotinic acid, isoniazid, sulfonamides, erythromycin, griseofulvin, and fluconazole.

γ-Glutamyl transpeptidase production is stimulated by alcohol consumption. It is also elevated by drugs inducing hepatic microsomal enzyme activity, such as phenobarbital and warfarin, and may rise in acute and chronic pancreatitis, acute myocardial infarction, uremia, chronic obstructive pulmonary disease, rheumatoid arthritis, and diabetes mellitus. An elevated γ-glutamyl transpeptidase in the setting of hepatitis suggests an alcoholic cause.

Alkaline phosphatase elevation is associated with biliary obstruction and cholestasis. Mild to moderate elevations accompany virtually all hepatobiliary disease, whereas elevations greater than four times normal strongly suggest cholestasis. Alkaline phosphatase is a nonspecific marker also derived from bone, placenta, intestine, kidneys, and leukocytes. A level of up to double the expected value is normal in pregnancy.

Lactate dehydrogenase is included in most liver test panels, but it is a nonspecific marker, which limits its utility. Moderate elevations are seen in all hepatocellular disorders and cirrhosis, whereas purely cholestatic conditions cause minimal elevations. Hemolysis can produce elevation of lactate dehydrogenase and unconjugated bilirubin. The isoenzyme lactate dehydrogenase-5 is specific to the liver. Tests for lactate dehydrogenase-5 are sometimes useful although not widely available.

Ammonia is generated by hepatic metabolism of nitrogen-containing compounds. The hepatic metabolic failure seen in acute and chronic liver disease can, therefore, cause an elevated serum ammonia level. Very high ammonia levels, seen in fulminant liver failure, contribute to overall toxicity and signify poor prognosis.

Prothrombin time prolongation in liver disease reflects the decreased synthesis of the vitamin K–dependent coagulation factors II, VII, IX, and X and, as such, serves as a true measure of liver function. Prolonged prothrombin time is a common complication of advancing cirrhosis, although it also occurs in acute hepatitis and exacerbations of chronic compensated liver disease. When present in acute viral hepatitis, prolonged prothrombin time often indicates severe disease with widespread hepatocellular necrosis. There is some correlation between the extent of prothrombin time prolongation and clinical outcome in fulminant liver disease. Although prothrombin time is useful as a marker of hepatic function, abnormal values may occur in the presence of a normal liver. Vitamin K deficiency from another entity (i.e., malabsorption of fat and, therefore, of fat-soluble vitamins) can be distinguished from liver synthetic dysfunction by administration of parenteral vitamin K (phytonadione, 10 milligrams IM). A 30% reduction in prothrombin time should occur within 24 hours in vitamin deficiency states.

Albumin also reflects the liver's synthetic function. It may decrease in advancing cirrhosis or severe acute hepatitis and suggests a poor short-term prognosis. Because its half-life is approximately 3 weeks, albumin is less useful than prothrombin time in evaluating fulminant liver disease. Prothrombin time becomes prolonged in a matter of days. Serum albumin levels are also low in malnutrition, so low albumin levels do not necessarily correlate with the degree of hepatic disease in a chronically ill patient.

Viral hepatitis serologies are often grouped into screening panels by hospital laboratories. The diagnosis of specific viral hepatitis entities is complicated by phase of illness, preexisting infections, and likelihood of a given type of infection. The patient who is acutely ill with hepatitis A virus will have positive immunoglobulin M anti–hepatitis A virus antibodies. Acute clinical illness in hepatitis B virus correlates with positive hepatitis B virus surface antigen. Positive immunoglobulin M antibodies correlate to the hepatitis B virus core antigen. Diagnosis of hepatitis C virus is initiated by ordering anti–hepatitis C virus antibodies. This diagnosis is sometimes masked by the 6- to 8-week delay between infection and antibody detection as well as by the acute asymptomatic phase of the hepatitis C virus infection.[22]

Ascitic fluid aspirate is tested for cell count, glucose and protein, Gram stain, and culture to identify bacterial peritonitis. The procedure for obtaining ascitic fluid, paracentesis, is explained in chapter 86, "Gastrointestinal Procedures and Devices." **A total WBC count >1000/mm^3 or a neutrophil count >250/mm^3 diagnoses SBP.** Low glucose or high protein values suggest infection. Gram stains and culture results can be falsely negative 30% to 40% of the time, so empiric antibiotics should be started in the ED based on clinical suspicion. Culture sensitivity increases by using 10 mL of ascitic fluid per blood culture bottle and by transferring the fluid to culture bottles at the patient's bedside. Additional studies of ascites that can help with inpatient evaluation are cytology, albumin, lactate dehydrogenase, and tumor markers.

NONHEPATIC CAUSES OF ABNORMAL LIVER TESTS

Multiple nonhepatic causes may lead to abnormal liver function tests. Abnormal liver test results occur in up to one third of those screened, and only 1% of these indicate clinically significant liver disease. Hypoalbuminemia accompanies protein-wasting enteropathies, malnutrition, and nephrotic syndrome. Alkaline phosphatase elevations occur with a variety of bone diseases, pregnancy, and malignancies. Aspartate aminotransferase elevations accompany acute myocardial infarction and rhabdomyolysis. Bilirubin elevations occur in severe hemolysis, sepsis, and syndromes involving abnormal erythropoiesis. Prothrombin time elevations occur in vitamin K deficiency, chronic antibiotic use, and warfarin therapy.[23,24]

Urine bilirubin and urobilinogen are sometimes used as screening tests for liver disease in the ED. The sensitivity of these urine assays is 70% to 74% for identifying elevated serum bilirubin. For correlation with other liver function tests, their sensitivity is in the 43% to 53% range. Specificity for showing either bilirubin or transaminase abnormality is 77% to 87%. Blood-tinged urine will give a false-positive urobilinogen on a urine dipstick test. Taken together, these statistics do not support screening for liver disease with urine dipstick testing.[25]

IMAGING

US and CT scanning are both useful for initial evaluation of liver disease. Bedside US can identify ascites and guide paracentesis, whereas formal US with duplex Doppler is the test of choice for identifying portal vein and hepatic vein thrombosis. Both sonogram and CT scan of the abdomen can be used to identify cancerous, vascular, or infectious lesions of the liver. CT scanning of the brain is used to identify intracranial hemorrhage in patients with liver disease and altered mental status.

TREATMENT

With the exception of acetaminophen poisoning (see chapter 190), treatment for acute hepatitis is supportive. Pay careful attention to associated conditions such as hyponatremia, alcohol or narcotic withdrawal, alcoholic ketoacidosis, and hypoglycemia. Treating chronic hepatitis in the ED means taking care of its many sequelae such as ascites, encephalopathy, coagulopathy, and variceal bleeding. Chronic hepatitis infection is typically treated by gastroenterologists in an outpatient setting. Liver failure requires critical care in the ED and consultation with a liver transplant center for disposition, including transfer if needed.

ASCITES

Mild- to moderate-volume ascites can be managed with a salt-restricted diet and diuretics, both of which create a negative sodium balance and encourage loss of ascitic fluid. Recommended diuretics include spironolactone, 50 to 200 milligrams per day, and amiloride, 5 to 10 milligrams per day. Furosemide can be problematic because it can lead to overdiuresis.[5] To facilitate monitoring for adverse side effects, diuretics for the cirrhotic patient should be prescribed in collaboration with his or her outpatient physician.

Paracentesis is recommended therapy for large-volume ascites. There are several important considerations when performing paracentesis on a cirrhotic patient. First, the patient's prothrombin time/INR is likely to be elevated. Second, the amount of fluid that can be removed without infusion of albumin to prevent intravascular collapse is controversial. For any tap, guidelines from the American Association for the Study of Liver Diseases state that paracentesis should be considered safe from a bleeding perspective unless there is evidence of fibrinolysis (i.e., three-dimensional bruising, oozing from IV start sites) or overt disseminated intravascular coagulation. For therapeutic paracentesis, American Association for the Study of Liver Diseases guidelines recommend the use of albumin, 6 to 8 milligrams/L of fluid removed, for amounts greater than 4 L.[5] One safe approach is to perform diagnostic paracentesis in the ED and defer large-volume therapeutic taps to the inpatient setting or the ED observation unit.

TABLE 80-4 Diagnosis and Treatment of Spontaneous Bacterial Peritonitis

Diagnosis	Ascitic fluid, obtain 50 cc for cell count, Gram stain, and culture (transfer blood to culture bottles at the bedside for best results)
	WBC count >1000/mm^3
	or
	Polymorphonuclear leukocytes >250/mL
	or
	Bacteria on Gram stain
Empiric treatment	Cefotaxime or other third-generation cephalosporin
	or
	IV fluoroquinolone (ineffective in patients who have received prophylactic quinolone treatment)
	or
	Oral fluoroquinolone in a very mild case with close follow-up

SPONTANEOUS BACTERIAL PERITONITIS

SBP is the most common life-threatening complication of ascites, classically presenting with fever and diffuse abdominal pain and tenderness. However, any or all of these features may be absent. In patients with known ascites, the 1-year incidence of SBP is 29%. Recurrence of SBP is as high as 44%, and survival in patients with a first episode of SBP is low (68.1% at 1 month and 30.8% at 6 months), probably a result of acute infection in the setting of advanced liver disease.[15]

Initial treatment is empiric antibiotic therapy to cover typical enteric flora. The most common isolates in SBP are *Escherichia coli, Klebsiella pneumoniae,* and *Streptococcal pneumoniae*. Empiric antibiotic treatment recommendations from the most recent (2012) guideline from the American Association for the Study of Liver Diseases are shown in **Table 80-4**.[5] Although there is no conclusive evidence proving that cefotaxime is superior to other choices, it is a widely accepted first-line parenteral treatment for SBP. Oral therapy with broad-spectrum quinolones is an option in patients with mild, uncomplicated disease and close follow-up.[26] Patients may have had prior infections with resistant organisms, so review microbiologic sensitivities from prior admissions, if available. The addition of IV albumin (1.5 grams/kg at diagnosis, 1 gram/kg on day 3) to antibiotic therapy may reduce renal failure and hospital mortality in patients with SBP.[27]

HEPATIC ENCEPHALOPATHY

To address hepatic encephalopathy, first consider other entities that could cause altered mental status, such as infection, intracranial hemorrhage, or hyponatremia. Once hepatic encephalopathy is diagnosed, treatment is aimed at reducing the production of nitrogenous wastes by reducing protein intake and suppressing the metabolic activity of intestinal bacteria.

Lactulose is the current mainstay of therapy for hepatic encephalopathy. Lactulose is a synthetic disaccharide containing one molecule of galactose and one of fructose. It is minimally absorbed into the bloodstream. In the colon, it degrades primarily into lactic acid. In the acidified environment, ammonia is trapped and excreted in the stool. Blood ammonia levels can decrease up to 50% using lactulose therapy. Lactulose also inhibits glutamine-dependent ammonia production in the gut wall. Lactulose is given PO or PR. The oral dose is 20 grams diluted in a glass of water, fruit juice, or carbonated drink. For rectal administration, dilute 300 mL of syrup with 700 mL of water or normal saline. The enema should be retained for 30 minutes.

Coagulopathy needs to be treated if the patient has uncontrolled bleeding or is scheduled to undergo a procedure with potential bleeding complications. Vitamin K deficiency can be treated with vitamin K, 10 milligrams IV or PO. Fresh frozen plasma can be given in doses appropriate for the patient's prothrombin level. Finally, decreased or malfunctioning platelets

should be replaced with pooled donor platelets. Specific treatments for variceal bleeding are addressed in chapter 75.

METABOLIC AND RESPIRATORY FAILURE

Treatment of fulminant liver failure in the ED involves care of the patient's respiratory status, blood pressure, and encephalopathy; correction of electrolyte derangements; identification of cerebral edema or intracranial hemorrhage; attention to active bleeding; and careful disposition, ensuring that the patient will be assessed for liver transplant in a timely fashion.

Patients with respiratory failure due to ascites, effusions, or decreased alertness require intubation. Bilevel positive airway pressure is not typically an option in these cases because patients are too somnolent and at risk for aspiration. Blood pressure at this stage of liver disease is typically low due to malnutrition, bleeding, vomiting, diarrhea, and third spacing of fluid. Treat with judicious fluids, blood products, and vasopressors, as needed. Altered mental status at this stage can be from encephalopathy, metabolic abnormalities, intracranial bleeding, or brain edema with increased intracranial pressure. In the case of intracranial hemorrhage, treat coagulopathy. Consult neurosurgery or refer to a facility with neurosurgical services if the patient could benefit from hematoma evacuation or intracranial pressure monitoring. Mannitol is appropriate as a temporizing measure in cases of increased intracranial pressure caused by cerebral edema.[6]

DISPOSITION AND FOLLOW-UP

The disposition of a patient with acute or chronic hepatitis is complex and requires careful planning with the patient and caretakers. Discussion with the primary care physician and gastroenterologist can clarify a vague clinical picture. Patients with acute hepatitis require supportive treatment with pain management, antiemetic medication, and fluid resuscitation. Consider admission for high-risk patients, including the elderly and pregnant women, and patients who do not respond adequately to supportive care. Admit those who have a bilirubin ≥20 milligrams/dL, prothrombin time 50% above normal, hypoglycemia, low albumin, or GI bleeding, which requires further evaluation to determine the presence of varices.[28]

In patients with chronic hepatitis, admission may be indicated for patients with ascites if they have significant respiratory compromise or abdominal pain. In addition, admit the patient with fever, acidosis, or leukocytosis and for evaluation and treatment of SBP.[29] New-onset or worsening hepatic encephalopathy, hepatorenal syndrome, and coagulopathy with bleeding are also strong indications for admission.[30] Patients with severe hyponatremia and severe hyper- or hypovolemia should also be managed in the hospital.[31]

Consider patient safety in the disposition of patients with advanced cirrhosis. Weakness, muscle wasting, and mild encephalopathy are serious risks for falls, and coagulopathy is a risk for cerebral bleed. Patients must be stable on their feet or have supervised assistance for discharge to home.

Discharge planning should include follow-up care by a gastroenterologist or transplant specialist. Patients and family members can be referred to Alcoholics Anonymous, Al-Anon, or support groups for transplant or other special needs. Discharge medications may include antibiotics, diuretics, lactulose, antiemetics, and pain medications.

SPECIAL CONSIDERATIONS

PAIN CONTROL IN PATIENTS WITH HEPATIC DISEASE

It can be difficult to decide on appropriate pain medications and sedatives for patients with compromised liver function. Avoid NSAIDs in patients with chronic hepatitis and cirrhosis due to GI toxicity and possible potentiation of renal dysfunction. Acetaminophen has traditionally been avoided in patients with any type of liver disease, but there are several trials indicating it to be safe for short-term use, at a reduced dose of 2 grams total per day. Gabapentin and pregabalin are safe options for neuropathic pain. Avoid opioids whenever possible, because opioids are metabolized by the liver and their sedative effects can be unpredictable in patients with compromised liver function. Opioids are contraindicated in patients with a history of encephalopathy or substance use. If absolutely necessary, fentanyl and tramadol at reduced doses and increased dosing intervals are possible choices in select patients because they lack the toxic metabolites of traditional opioids.[32] When sedation or pain control is required for the critically ill patient with liver failure, a titratable infusion of a nonbenzodiazepine medication with a short half-life and no toxic metabolites is useful. Propofol has been well studied in the setting of endoscopy and is safe at least in the short term for patients with cirrhosis.[33] Fentanyl provides pain relief and some degree of sedation.

PREGNANCY

Pregnant women can present with various hepatic or cholestatic disorders not specific to pregnancy. HELLP syndrome (hemolysis, elevated liver enzymes, low platelets), however, stands apart as a life-threatening process that must not be missed in the ED. HELLP occurs as part of the pre-eclampsia–eclampsia spectrum in the late third trimester or in the postpartum period. It can present with symptoms resembling viral illness—headache, malaise, nausea, and vomiting. Hypertension, headache, and proteinuria are other associated findings. Eighty percent to 90% of patients present with relative hypertension, and proteinuria is present 85% to 100% of the time. Headache, usually considered a mainstay of the pre-eclampsia diagnosis, is not a sensitive or specific finding.[34]

Perinatal mortality in cases where HELLP complicates a pregnancy before 29 weeks can be as high as 20%. Check liver function studies, CBC, and lactate dehydrogenase in those who present with even vague symptoms of illness in their third trimester and in any third-trimester patient with relative hypertension. Definitive treatment in pregnancies later than 34 weeks is immediate delivery, whereas patients who are mildly ill with HELLP at <34 weeks of gestation may sometimes be managed expectantly. ED disposition of patients with elements of HELLP syndrome is admission to the obstetrics inpatient service.[34] Further discussion of HELLP is provided in chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period."

LIVER TRANSPLANT PATIENT

Liver transplant patients can develop a variety of illnesses, most commonly abdominal, infectious, and metabolic in nature. Febrile patients should be pan cultured, and broad-spectrum antibiotics should be initiated pending further inpatient evaluation. Metabolic derangements can include hyper- or hypoglycemia, sodium imbalance, and hypo- or hyperkalemia. Rejection of the transplant should be a concern even in the absence of abdominal pain and tenderness. Symptoms of rejection can be vague and can include nausea, vomiting, malaise, anorexia, abdominal pain, vomiting, and jaundice. In one series of 290 liver transplant patient visits to the ED, 69% resulted in hospitalization.[35] Further discussion is provided in the section on Special Situations in chapter 297, "The Transplant Patient."

NONALCOHOLIC FATTY LIVER DISEASE

NAFLD deserves particular mention in the discussion of chronic liver disease. It affects up to 30% of the U.S. population by some estimates and is now thought to be the third most common reason for transplantation after hepatitis C virus infection and alcoholic liver disease. Exact figures are unclear because NAFLD often goes undiagnosed through the phases of steatosis (fatty deposits in the liver) and steatohepatitis (fatty deposits with inflammation, also identified by the acronym NASH), and is often categorized as idiopathic cirrhosis by the time of diagnosis and consideration for transplantation. NAFLD is associated with obesity, type 2 diabetes, and hyperlipidemia. Many patients will have fatty liver seen incidentally on abdominal imaging, and few of these patients will go on to develop cirrhosis.[21] There is no specific treatment for NAFLD. The mainstays of treatment are weight loss and exercise, which have been shown to reduce fat deposition and inflammation of the liver parenchyma, but not fibrosis. The efficacy of diabetic medications and statins

has not been well studied, but these are also used in the treatment of NAFLD. Patients with NAFLD found even incidentally during ED evaluation should be advised to avoid further injury by abstaining from alcohol.[21]

TRAVELERS AND GLOBAL CITIZENS

Travelers who have been outside the United States who present with abdominal pain, vomiting, diarrhea, or fever are at risk for having liver disease caused by parasitic infection. **Schistosomiasis** is a waterborne parasite that infects >200 million people worldwide and can cause portal hypertension by invading the portal venules. *Echinococcus* species cause multiple liver cysts. Ascariasis causes hepatobiliary obstruction. *Entamoeba histolytica* infects roughly 10% of the world's population and causes parasitic liver abscesses.[36] For further discussion, see chapter 161, "Global Travelers."

VENO-OCCLUSIVE DISEASE

Veno-occlusive disease of the liver is a potentially fatal adverse effect of herbal remedies, chemotherapy, or bone marrow transplant. It is associated with abdominal pain, the presence of hepatomegaly, ascites, weight gain, and jaundice in a patient with concerning history.[37]

CHAPTER 81

Acute Appendicitis

E. Paul DeKoning

INTRODUCTION AND EPIDEMIOLOGY

Between 250,000 and 300,000 appendectomies for acute appendicitis are performed each year in the United States,[1] with an additional 700,000 patients affected in the European community.[2] The lifetime risk of acute appendicitis in the United States is an estimated 12% for males and 25% for females.[3] Yet, the epidemiology of this common ED diagnosis continues to change. Data suggest a reversal of a previous decline in incidence, with the annual rate increasing from 7.62 to 9.38 per 10,000 between 1993 and 2008,[4] whereas the rate of negative appendectomy has declined.[5] Similarly, between 2001 and 2008 the rate of perforation decreased, but this declining trend has not been consistent.[4,6] Acute appendicitis is most common in patients aged 10 to 19 years,[4] remains the most frequent cause of atraumatic abdominal pain in children >1 year old,[7] and is the most common nonobstetric surgical emergency in pregnancy, complicating up to 1 in 1500 pregnancies.[8,9] Despite advances in lab testing and imaging, accurate diagnosis is a challenge. Both "missed appendicitis" and unnecessary surgery for a false diagnosis are not without consequence. **Thus, consider appendicitis in any patient with acute atraumatic abdominal pain without prior appendectomy.**

PATHOPHYSIOLOGY

Appendicitis is caused by luminal obstruction of the vermiform appendix, typically by a fecalith. Other less frequent causes include obstruction by lymphatic tissue, gallstone, tumor, or parasites. Continued secretion from the luminal mucosa results in increased intraluminal pressure and appendiceal vascular insufficiency, leading ultimately to bacterial proliferation and inflammation. Left unchecked, perforation may occur.

Visceral innervation produces the vague, hard to localize periumbilical or central abdominal discomfort frequently observed early in the clinical course. Progressive inflammation and subsequent irritation of the somatically innervated parietal peritoneum produces the classic migration of pain to the right lower quadrant, to **McBurney's point**, located one third of the distance from the anterior superior iliac spine to the umbilicus. Up to 50% of patients may have an atypical presentation[10] due in part to anatomic variation. For example, a retrocecal appendix produces right flank or pelvic pain, whereas malrotation of the colon results in transposition of the appendix and, subsequently, pain to the left upper quadrant. Abdominal organ displacement from a gravid uterus may lead to right upper quadrant tenderness in pregnancy. Even so, a right lower quadrant location of pain remains the most common location of pain in pregnant women with appendicitis.[9]

CLINICAL FEATURES

The signs and symptoms of acute appendicitis lie along a spectrum that correlates with pathophysiology. Early on, patients classically complain of nonspecific symptoms of general malaise, indigestion, or bowel irregularity. Anorexia is common but not universally present. Alterations in bowel function are highly variable and can include constipation, diarrhea, and even obstruction as a late complication.[11] Periumbilical or central abdominal pain generally develop after nonspecific symptoms. If nausea develops, it typically follows the onset of pain.[12] Vomiting may or may not be present. Subjective or objective fever is frequent.

As the clinical course progresses, discomfort migrates to the right lower quadrant. Flank pain, dysuria, or hematuria can occur, given the typical proximity of the appendix to the urinary tract.[11]

Aggravating and alleviating features can help establish the diagnosis: worsening pain with deep inspiration may be present if there is peritoneal irritation, and individuals may state that the trip to the hospital was painful, particularly when encountering bumps in the road. Such features suggest a peritoneal process is under way. The release of intraluminal obstruction with perforation often results in sudden remittance of pain; consider appendiceal perforation if the patient's pain has suddenly improved.[11]

As the natural course progresses, examination findings likewise evolve. Progressive inflammation and peritoneal irritation yield reproducible tenderness to palpation in the right lower quadrant. The exception to right lower quadrant pain is a retrocecal appendix, which does not contact the anterior parietal peritoneum.[13] Rebound tenderness and involuntary guarding suggest peritonitis. Patients may have costovertebral

tenderness, and percussion of the right heel or shaking of the hospital stretcher may elicit abdominal pain. There is no evidence that the digital rectal exam aids significantly in the diagnosis of acute appendicitis.[10] **Rovsing's sign** reproduces pain over McBurney's point as the clinician palpates the descending colon in the left lower quadrant. A positive psoas sign or obturator test suggests an inflammatory peritoneal process. The **psoas sign** is elicited if abdominal pain is produced with extension of the right leg at the hip while the patient lies on the left side. The **obturator test** elicits pain with internal and external rotation of the flexed right thigh at the hip. The presence of abdominal rigidity, a positive psoas sign, fever, or rebound tenderness increases the likelihood of acute appendicitis. Prior episodes of similar pain, the absence of right lower quadrant pain, and the absence of classic pain migration make appendicitis less likely. The presence or absence of any exam finding in isolation is neither sufficiently sensitive nor specific to rule out or rule in the diagnosis.

In a systematic review of 42 studies investigating appendicitis in patients aged 18 years or younger, fever was the single most useful sign with an LR(+) of 3.4 (95% confidence interval, 2.4 to 4.8), whereas its absence decreased the likelihood of appendicitis (LR(-), 0.32; 95% CI, 0.16 to 0.64). Rebound tenderness and pain migration to the right lower quadrant were also strong predictors.[14] In comparison, a classic study of exam findings in adult patients showed right lower quadrant pain as the single most useful sign (sensitivity, 0.81; specificity, 0.53; LR(+) 7.31-8.46; LR (-) 0-.28) followed by rigidity and migration of pain. Fever in adults had an LR(+) of 1.94 (95% CI, 0=0.28) of 1.94 (95% CI, 1.63 to 2.32) and a LR(-) of 0.58 (95% CI, 0.51 to 0.67).[15] **In both children and adults, however, no historical or physical examination finding is sufficient to rule in or rule out appendicitis.**[14,15]

DIAGNOSIS

Despite the advent of cross-sectional radiographic imaging and high-definition ultrasonography and a more than doubling of their use in recent years, detection rates for appendicitis have essentially remained the same.[16] There are numerous appendicitis mimics, and the differential diagnosis is broad (**Table 81-1**). Perform a complete physical examination, including a pelvic examination in women of childbearing age. Acute appendicitis is largely a clinical diagnosis, and no one adjunctive test is universally indicated.

Consider appendicitis in any patient with atraumatic right-sided abdominal, periumbilical, or flank pain who has not previously undergone appendectomy. Available diagnostic adjuncts include peripheral WBC and other acute inflammatory markers (e.g., C-reactive protein or erythrocyte sedimentation rate), urinalysis, and a pregnancy test. Diagnostic imaging should be considered in atypical presentations or if significant diagnostic uncertainty exists after thorough history and examination.

TABLE 81-1 Differential Diagnosis of Right Lower Quadrant Pain

GI
Cecal/Meckel's diverticulitis
Cecal volvulus
Colitis/terminal ileitis
Constipation/ileus/bowel obstruction
Crohn's/ulcerative colitis flair
Epiploic appendagitis
Functional abdominal pain
Incarcerated inguinal hernia
Intra-abdominal abscess
Intussusception
Malrotation
Mesenteric lymphadenitis
GU
Ectopic/heterotopic pregnancy
Ovarian torsion
Ovarian vein thrombosis
Pyelonephritis
Referred testicular pain
Renal colic
Tubo-ovarian abscess/salpingitis
MUSCULOSKELETAL
Abdominal wall/rectus sheath hematoma
Psoas abscess

SCORING SYSTEMS

Scoring systems, such as the Alvarado and Samuel scores, have been developed to aid in diagnosis. The modified **Alvarado score** for acute appendicitis ranks symptoms (migration, 1 point; anorexia or urinary acetone, 1 point; nausea or vomiting, 1 point), signs (right lower quadrant tenderness, 2 points; rebound, 1 point; fever, 1 point), and WBC count (>10,000/mm^3, 2 points) into low-risk appendicitis (score, 1 to 4) and possible or probable appendicitis (score, 5 to 9). However, the low-risk score (score, 1 to 4) was demonstrated as only 72% sensitive compared to 93% for clinical judgment when appendicitis was either the most likely or second most likely diagnosis.[17] Despite continued technologic advances and development of decision rules, different scoring systems often yield conflicting results and should not replace clinical judgment; the clinical impression of the experienced physician has the highest impact on patient outcome.[18-21]

LABORATORY TESTING

An increase in peripheral WBC may be the earliest marker of inflammation.[22] A study of 722 children identified both prospectively and retrospectively found acute appendicitis to be the most common diagnosis in children >4 years old with nontraumatic abdominal pain and leukocytosis.[23] However, a normal WBC is not uncommon, and leukopenic presentations have been documented.[24] **While numerous studies have evaluated the use of the WBC, there is no clear consensus on its utility.**[22,23,25-27] The WBC does not distinguish between simple and perforated appendicitis.[25] C-reactive protein and the erythrocyte sedimentation rate used alone lack the sensitivity and specificity to rule in or rule out the diagnosis. If the only diagnostic consideration is acute appendicitis (yes or no), the greatest utility of laboratory tests may be in combination: an elevated WBC and/or C-reactive protein may have a combined sensitivity as high as 98%. Normal values of both in patients with a low pretest probability of acute appendicitis make pathologically confirmed appendicitis very unlikely.[27-31] However, WBC and C-reactive protein levels are elevated in a number of other appendicitis mimics, so these markers are not useful if the differential diagnosis of pain is broad.[32,33]

Obtain a urinalysis because isolated microscopic hematuria may support a diagnosis of renal colic, and pyuria may suggest pyelonephritis. However, hematuria or sterile pyuria can be present in acute appendicitis.[11] Document a negative pregnancy test in females of reproductive age to rule out ectopic or heterotopic pregnancy. Other laboratory tests are not routinely indicated but may be beneficial when considering other diagnoses.

IMAGING

Obtain early surgical consultation before imaging in straightforward cases of suspected appendicitis in adults. Imaging is not universally necessary but may be of benefit in certain populations.[34-36] In children, some centers prefer pediatric surgery consultation prior to imaging with ionizing radiation.

When adjunctive imaging is indicated, early surgical consultation may aid guidance in imaging selection. The goal of imaging is to establish the diagnosis of appendicitis, avoid a negative appendectomy, identify perforation, and exclude other causes of abdominal pain with minimal radiation, cost, and time.

Plain radiography is not helpful. Findings are typically nonspecific but may demonstrate a nonspecific bowel gas pattern or adynamic ileus. An appendicolith may be visualized in up to 50% of children with appendicitis.[35]

US **Graded compression US should be the initial imaging modality of choice in both pregnant females[37] and children. It can likewise be considered in young, nonobese adults.** Reports of the effectiveness of US diagnosis of appendicitis in pregnancy are conflicting, with some reporting US as useful[38] and others reporting it as ineffective for diagnosis.[39] Regardless, US is safe, fast, well tolerated, and cost-effective.

The appendix is oval in the axial plane, ends blindly in the longitudinal plane, and should be compressible with a maximal diameter not exceeding 6 mm.[40] The normal appendix is typically differentiated from small bowel on US by the absence of peristalsis and the lack of change in configuration over time; its small size distinguishes it from large bowel. **Typical findings in appendicitis are a thickened, noncompressible appendix >6 mm in diameter (Figure 81-1).** Doppler US may illustrate hyperemia.[35] It is important to image the entire length of the appendix, because inflammation may be more pronounced at or localized to the distal end.[40] Given the highly operator-dependent nature of US, centers treating larger volumes of children may have greater reproducibility of high-quality studies. The diagnostic accuracy of abdominal US in children is better at ruling in acute appendicitis than excluding it.[41] Besides operator skill, other limitations to accuracy include cases of retrocecal appendicitis or perforation, excessive abdominal guarding or bowel gas, a gravid uterus or obese habitus, a decompressed bladder, and lack of patient cooperation. Perforation may lead to disappearance of specific imaging hallmarks and difficult visualization of the appendix on US. Pelvic US may be useful in cases of suspected appendicitis and a nondiagnostic abdominal US or CT,[42] or in the differentiation of appendicitis from pelvic inflammatory disease[43] (see chapter 97, "Abdominal and Pelvic Pain in the Nonpregnant Female").

Abdominopelvic CT In most adult males and nonpregnant females for whom the diagnosis of appendicitis is not sufficiently clear, consider abdominal CT that includes the abdomen and pelvis. Typical CT findings include a dilated appendix >6 mm with a thickened wall, periappendiceal inflammation, and potential visualization of an appendicolith or abscess.[44] Luminal obstruction and dilation may be relieved in cases of perforation, leading to disappearance of specific imaging hallmarks and difficult visualization of the appendix on CT.[11]

The accepted sensitivity of CT (composite studies using oral or IV contrast or no contrast) for the diagnosis of acute appendicitis is typically >94%, with a positive predictive value >95% (**Figure 81-2**).[34,36] In a comparison of CT versus US, the overall sensitivity of CT in patients >2 years old was 96%, with a 96% positive predictive value; graded compression US had an overall sensitivity of 86%, with a 95% positive predictive value.[36] In this same study,[36] women who had preoperative imaging had a statistically significant lower negative appendectomy rate than women who had no imaging, suggesting that women with suspected acute appendicitis derive the greatest benefit from preoperative imaging. **Appendiceal CT**, a less frequently used protocol, uses rectally administered contrast only with acquisition of thin cuts through the right iliac fossa. This avoids the difficulties of oral contrast administration in patients with active emesis and prevents potential adverse reactions of IV contrast. Time to acquisition of images is much shorter, typically around 15 minutes after administration of rectal contrast, but may produce significant patient discomfort.[45,46]

Oral and IV Contrast versus Nonenhanced CT Oral contrast medium has historically been recommended for CT of the abdomen and pelvis when investigating a broad differential of GI or pelvic diagnoses, and many centers continue to recommend CT imaging with both IV and oral contrast. Yet, a growing body of literature calls this practice into question. Multiple studies indicate that nonenhanced CT has excellent performance in the diagnosis of acute appendicitis.[47-53] The imaging evaluation of abdominal pain is time intensive and impacts ED overcrowding. Unenhanced studies can significantly decrease the time to diagnosis and eliminate patient discomfort from oral (especially in vomiting patients) or rectal contrast, and avoids altogether the risk of

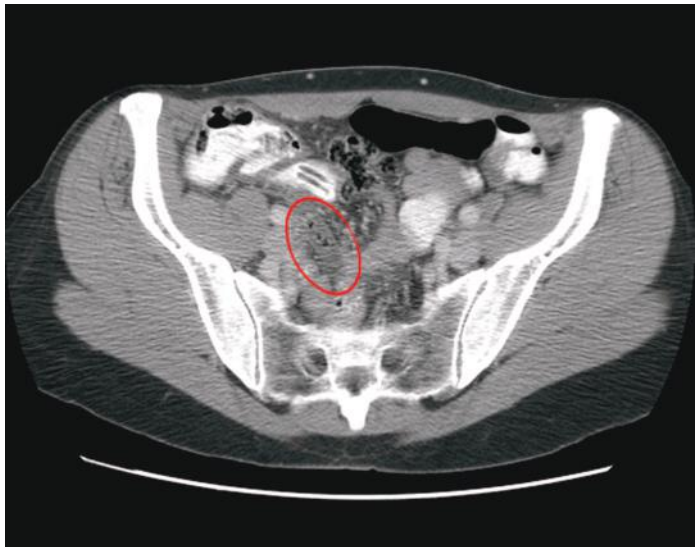

FIGURE 81-2. Acute appendicitis on contrast CT scan as evidenced by dilated and inflamed appendix (*red circle*).

renal injury from IV contrast. More than 52% of 462 patients who underwent CT imaging in at least one study had no oral, IV, or rectal contrast administered, with a combined sensitivity of 93% and a positive predictive value greater than 92%, supporting the suitability of nonenhanced CT imaging for making the diagnosis.[36] A comparison of nonenhanced CT with findings on laparoscopy reported 95% sensitivity with 100% specificity of nonenhanced CT in suspected appendicitis,[2] whereas another systematic review reported a pooled sensitivity of 92.7% (95% CI, 89.5% to 95.0%) and specificity of 96.1% (95% CI, 94.2% to 97.5%).[47] Another systematic review of 23 studies showed equivalent or improved diagnostic performance of nonenhanced CT when compared to oral contrast.[36] Oral contrast frequently does not reach the terminal ileum at the time of imaging, yet in this group of patients, at least one author has shown no diagnostic compromise in the performance of imaging.[52] Several studies attribute disagreement between nonenhanced CT and contrasted studies more to interobserver variability than contrast medium.[51,53] **Noncontrast CT should be considered an acceptable imaging modality in the workup of acute appendicitis.** In patients with renal insufficiency or dye allergy, administration of IV contrast is contraindicated. Body habitus may limit reproduction of noncontrast CT test characteristics; intraperitoneal fat serves as an intrinsic contrast medium in unenhanced CT, and its paucity in very thin patients can affect imaging interpretation.[44,45,54]

MRI Consider MRI as another reliable imaging technology in the evaluation of acute appendicitis, particularly in pregnant women. MRI avoids ionizing radiation and visualizes the entire abdomen in multiple planes. In a survey of U.S. academic medical centers with radiology residency programs, MRI was preferred over CT (39% vs. 32%) for evaluation of appendicitis in the first trimester of pregnancy. This preference reversed in the second and third trimesters.[37] **IV gadolinium crosses the placenta and is not used in pregnancy** given the teratogenic effects seen in animal studies.[55] **Gadolinium is not given to patients with renal insufficiency because it may cause nephrogenic fibrosing dermopathy.** Avoid MRI in the evaluation of the unstable patient given the time necessary for study acquisition. Sedation may be required for small children, rendering it impractical in many pediatric cases.

TREATMENT

Patients with acute appendicitis typically require appendectomy, so immediate surgical consultation is needed. Patients should be maintained as "nothing by mouth" to avoid operative delay. Provide resuscitation and maintenance IV fluids with appropriate antiemetics and analgesia. Initiate perioperative antibiotics upon diagnosis or if the patient exhibits signs of peritonitis. Appropriate choices should broadly cover aerobic and anaerobic gram-negative organisms. Acceptable regimens include ampicillin/sulbactam 3 grams IV (pediatric dose, 75 milligrams/kg IV); piperacillin/tazobactam 4.5 grams IV (100 milligrams/kg IV); cefoxitin 2 grams IV (40 milligrams/kg); or metronidazole 500 milligrams IV plus ciprofloxacin 400 milligrams IV.[56] Given the nonoperative management of uncomplicated diverticulitis, salpingitis, and neonatal enterocolitis with antibiotics, some suggest a similar nonoperative approach to uncomplicated acute appendicitis.[1] However, this is not yet considered the accepted standard of care.

DISPOSITION AND FOLLOW-UP

Surgery is the accepted standard of care for acute appendicitis. If the local surgical services are inadequate or unavailable, transfer the patient to an appropriate institution. For the patient in whom the diagnosis remains elusive despite a rigorous diagnostic evaluation, consider extended observation in the ED or hospital with serial examinations, allowing for evolution of the patient's condition. Alternatively, the stable, reliable patient without significant comorbidities may be a candidate for discharge provided they have a scheduled return visit to the ED or their primary physician (typically within 12 hours) for repeat examination. Patients must have adequate pain control and be able to tolerate oral hydration. Provide clear abdominal pain discharge instructions, including a list of concerning signs or symptoms that should prompt earlier return to the ED.

SPECIAL POPULATIONS

Uninsured/underinsured patients, individuals from low-income communities, and some ethnic minorities may be more likely to develop appendiceal perforation, but previously observed trends have been inconsistent in recent years.[6,57] The elderly are likely to have preexisting comorbidities that alter presentation, management, and outcomes. Institutionalized patients, those with communication difficulties, those with poor access to medical care, and the elderly may have more vague complaints, including diffuse pain, fever, or alteration in mental status. Such individuals commonly present later in the course of the disease and are more likely to have worse outcomes.[58] In such patients, an "atypical" presentation should be considered the norm. A low threshold for prolonged observation or admission can avoid unnecessary morbidity and mortality.

Pregnant women warrant special attention. Acute appendicitis is the most common surgical emergency in pregnancy, and delay in diagnosis is the greatest cause of increased morbidity in the pregnant woman with an acute abdomen.[8,9,59] Ovarian torsion and ectopic or heterotopic pregnancy are additional considerations. If abdominal US is nondiagnostic, consider pelvic US, CT, or MRI. Consult with the radiologist to select the most appropriate imaging study. Many radiologists avoid CT in the first trimester given teratogenic concerns of ionizing radiation.[37] In addition, although iodinated contrast material is safe in pregnancy, avoid IV gadolinium.[55]

Children are a diagnostic challenge, particularly if they cannot adequately verbalize their complaints. In such cases, physical examination, parallel history from the parent or guardian, and a high index of suspicion are the keys to accurate diagnosis. Pediatric imaging should begin with US, but many centers advise early surgical consultation before any imaging if appendicitis is a consideration.

CHAPTER 82

Diverticulitis

Autumn Graham

INTRODUCTION AND EPIDEMIOLOGY

Although uncommon in developing countries, diverticular disease is increasingly prevalent in industrialized nations. Radiographic and autopsy data indicate that the prevalence of diverticulosis increases with age: 5% in patients age <40 years, 30% by age 60, and >70% by age 85.[1,2] One study noted a 26% jump in hospital admissions between 1998 and 2005, particularly in patients less than 45 years of age.[3]

In most patients, diverticular disease is an incidental finding. The natural history of the disease appears to be quite benign. One study followed 2366 Kaiser Permanente patients hospitalized with acute diverticulitis and treated nonoperatively. Of those, 86% required no further inpatient care for diverticulitis during a 9-year follow-up period. Only 4% had a second recurrence. No patient with a second recurrence required an operation.[4]

PATHOPHYSIOLOGY

Diverticula are small herniations at sites where the vasculature, called *vasa recta*, penetrates the circular muscle layer of the colon. Although *true diverticula* involve all layers of the colon wall, most acquired diverticula are considered *false diverticula*, involving only the mucosal and submucosal layers. Diverticula usually range from 5 to 10 mm, but can extend up to 20 mm in length. Diverticulitis occurs when inflammation develops and in complicated diverticulitis, leading to translocation of bacteria, microperforation, and abscess or phlegmon formation.[5]

There are similar chemical and histologic changes seen in inflammatory bowel disease and irritable bowel syndrome, but no unifying mechanism has been demonstrated.[5,6] The most common bacterial pathogens isolated are anaerobes, including *Bacteroides*, *Peptostreptococcus*, *Clostridium*, and *Fusobacterium* as well as gram-negative rods, such as *Escherichia coli*.

Altered bowel motility leads to high intraluminal colonic pressures and diverticula formation. The role of diet remains unclear. Smoking and obesity increase risk for diverticulitis, and an active lifestyle is said to decrease the risk. Nonsteroidal anti-inflammatory drugs, opioids, and steroids increase the risk of perforation.[5]

In the United States, diverticular disease is almost exclusively a left-sided colon disease, specifically the descending and sigmoid colon. Right-sided disease accounts for only 2% to 5% of cases and is found predominantly in Asian populations.[7]

CLINICAL FEATURES

Classically, diverticulitis presents with left lower quadrant abdominal pain, fever, and leukocytosis. Patients with a redundant sigmoid colon, of Asian descent, or with right-sided disease may complain of right lower quadrant or suprapubic pain. The pain may be intermittent or constant and often associated with a change of bowel habits, either diarrhea or constipation. Other associated symptoms include nausea/vomiting, anorexia, and urinary symptoms. On physical examination, patients may exhibit findings ranging from mild abdominal tenderness to moderate tenderness with a tender palpable mass to peritonitis with rebound and guarding.

DIAGNOSIS

In stable patients with a history of confirmed diverticulitis and a similar acute presentation, no further diagnostic evaluation is necessary unless the patient fails to improve with conservative medical treatment. If a prior diagnosis has not been confirmed or the current episode differs from the past episode, diagnostic imaging is required to exclude other intra-abdominal pathology and to evaluate for complications. The differential diagnosis of diverticulitis is extensive, including gynecologic emergencies, cancer, and inflammatory or infectious colitis (**Table 82-1**). Laboratory data are rarely diagnostic for diverticulitis, but liver function panels, CBC, renal panel, lipase, and urinalysis may aid in the exclusion of other disorders.

TABLE 82-1 Differential Diagnosis of Diverticulitis

Acute appendicitis
Colitis—ischemic or infectious
Inflammatory bowel disease (Crohn's disease, ulcerative colitis)
Colon cancer
Irritable bowel syndrome
Pseudomembranous colitis
Epiploic appendagitis
Gallbladder disease
Incarcerated hernia
Mesenteric infarction
Complicated ulcer disease
Peritonitis
Obstruction
Ovarian torsion
Ectopic pregnancy
Ovarian cyst or mass
Pelvic inflammatory disease
Cystitis
Kidney stone
Renal pathology
Pancreatic disease

IMAGING

CT is the preferred imaging modality because of its ability to evaluate the severity of disease and the presence of complications. CT with IV and oral contrast has documented sensitivities of 97% and specificities approaching 100%.[8] CT findings include increased soft tissue density within the pericolic fat, indicating inflammation; presence of diverticula; bowel wall thickening >4 mm; soft tissue masses, representing phlegmon; or pericolic fluid collections, representing abscesses.[8]

Compression US is operator dependent and limited based on the patient's body habitus. Sensitivity and specificity of US for diverticulitis vary but are >80% in experienced hands. CT is preferred to detect complications.[9]

TREATMENT

Treatment varies with disease severity (**Figure 82-1**). Uncomplicated diverticulitis is isolated to inflammation of the diverticula with or without phlegmon or small abscess confined to the bowel wall. Complicated diverticulitis includes diverticular inflammation associated with abscess, stricture, obstruction, fistula, or perforation.

Current treatment recommendations are provided in **Table 82-2**.

Uncomplicated diverticulitis is treated with bowel rest (liquid diet) and oral antibiotics (Table 82-2). Dietary restriction or modification is commonly recommended, but efficacy is not clear.[5] There is no advantage of IV antibiotics over oral antibiotics.[5] Admission is not necessary unless there are serious comorbidities or obstacles to outpatient care. If uncomplicated diverticulitis is confirmed with CT, the success rate of ambulatory treatment is about 98%.[10]

There is growing interest in the treatment of uncomplicated diverticulitis without antibiotics at all, due to questions about antibiotic efficacy and antibiotic adverse effects such as allergy, nausea and vomiting, and *Clostridium difficile* infection.[5,10-12]

One recent randomized controlled study in Sweden evaluated the need for antibiotics in uncomplicated diverticulitis confirmed by CT.

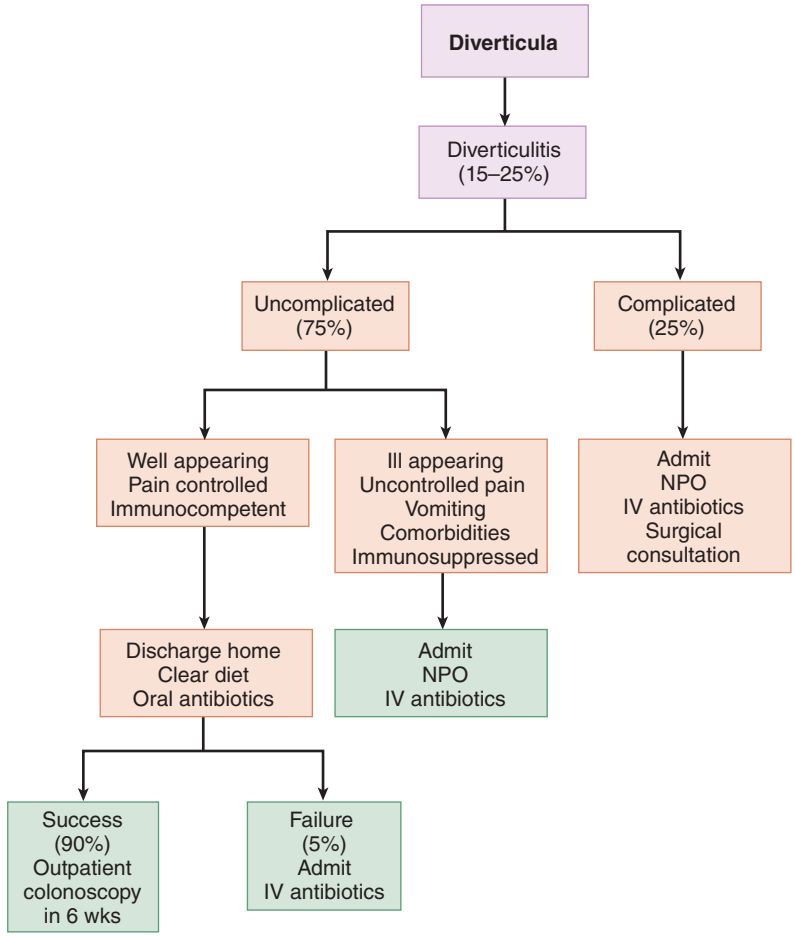

FIGURE 82-1. Algorithm for treatment of diverticulitis. NPO = nothing by mouth.

Of the 669 patients studied, 9 patients experienced complications: three abscesses and three perforations in the nonantibiotic group and three perforations in the antibiotic group. There were no differences in outcomes between the two groups, including symptoms at 30-day follow-up, need for emergency surgery, or median hospital stay.[10] The Infectious Diseases Society of America recommends a 4-day course of treatment.[13] As of this writing, there is no consensus on the omission of antibiotics.

Complicated diverticulitis generally requires admission. In addition to bowel rest and IV antibiotics, specific treatments are directed to complications. Complicated diverticulitis is often referred to by the Hinchey classification scheme[8]: Stage 1 is small, confined pericolic or mesenteric abscesses; stage 2 is larger abscesses, extending to the pelvis; stage 3 is perforated diverticulitis and purulent peritonitis; and stage 4 refers to free perforation with fecal contamination of the peritoneal cavity.

Abscesses and phlegmon are among the most common complications. Phlegmon is inflammation and infection of tissue without abscess. Advances in percutaneous drainage of abscesses have allowed many patients to undergo less invasive treatment. Abscesses that measure <4 cm and phlegmon (Hinchey stage 1) are often admitted for IV antibiotics and do not require percutaneous drainage. Perforation has a high mortality rate, and patients need volume resuscitation, IV antibiotics, and emergent exploratory surgery. For Hinchey stage 3, the mortality rate approaches 13% and increases to 43% for Hinchey stage 4.[8,14]

DISPOSITION AND FOLLOW-UP

ED discharge is appropriate for uncomplicated diverticulitis—that is, for a patient with stable vital signs, who is nontoxic appearing, in whom adequate analgesia can be maintained at home with oral narcotics, and with mild physical examination findings. Advise a clear diet to be advanced as tolerated, oral antibiotics, and instructions to follow up in 2 to 3 days with a primary care provider or return to the ED for recurring pain, high fevers, nausea/vomiting, or abdominal tenderness.

Patients with intractable nausea or vomiting, significant comorbid diseases,[15] poor support at home, high leukocytosis, or high fevers, as well as the elderly, the immunocompromised, and those with persistent pain should be admitted. The immunocompromised and those taking chronic steroids often present atypically and are at risk for morbidity and mortality. Patients with complicated diverticulitis or failed outpatient management should also be admitted. A failure of outpatient therapy is defined as symptoms or worsening radiographic imaging within 6 weeks of the initial episode.

SPECIAL CONSIDERATIONS

YOUNG PATIENTS

Patients <40 years old comprise a small proportion of patients with diverticulitis, but their numbers are growing. This trend may correlate with the growing obesity epidemic in the United States, because young diverticulitis patients tend to be overweight. Their disease is also thought to be more virulent than that of their older counterparts, with higher rates of recurrence, complicated presentation, and surgical intervention compared to patients >50 years old. Younger patients also seem to have higher rates of readmission.[16,17]

MECKEL'S DIVERTICULITIS

Meckel's diverticulum is a true congenital diverticulum that follows "the rule of 2's." It is present in approximately 2% of the population, 2 ft from the ileocecal valve, and symptomatic in 2% of patients. It generally presents with crampy abdominal pain, nausea/vomiting, and bleeding.

TABLE 82-2 Antibiotics for Diverticulitis

Outpatient 4–7 days	First line	Metronidazole 500 milligrams PO q6h PLUS Ciprofloxacin 750 milligrams PO BID OR Levofloxacin 750 milligrams PO q24h OR Trimethoprim–sulfamethoxazole (Bactrim) 1 tab PO BID
	Alternate	Amoxicillin-clavulanate extended release 1000/62.5 milligrams 2 tabs PO BID Moxifloxacin 400 mg PO q24h
Inpatient		
Moderate disease	First line	Metronidazole 500 milligrams IV TID PLUS Ciprofloxacin 400 milligrams IV BID OR Levofloxacin 750 milligrams IV q24h OR Aztreonam 2 grams IV TID OR Ceftriaxone 1 gram IV q24h
	Alternative	Ertapenem 1 gram IV q24h Piperacillin-tazobactam 4.5 grams IV q8h Moxifloxacin 400 milligrams IV q24h
Severe, life-threatening	First line	Imipenem 500 milligrams IV q6h Meropenem 1 gram IV q8h Piperacillin-tazobactam 4.5 milligrams IV q8h
	Alternative	Ampicillin 2 grams IV q6h PLUS Metronidazole 500 milligrams IV q6h PLUS Ciprofloxacin 400 milligrams IV q12h OR Amikacin, gentamicin, or tobramycin (Penicillin allergy: Aztreonam 2 grams IV q6h PLUS metronidazole 500 milligrams IV q6h)

Definitive diagnosis is often difficult, but radionucleotide imaging or CT may be helpful. Due to overlapping signs and symptoms, Meckel's diverticulitis is often confused with acute appendicitis. Treatment is surgical.

EPIPLOIC APPENDAGITIS

Epiploic appendages are small fat-filled sacs situated near the lining of the colon that can become inflamed as a result of torsion or venous thrombosis. The typical presentation is sharp abdominal pain, nausea, and vomiting. The symptoms can be confused with acute appendicitis, diverticulitis, or cholecystitis. Epiploic appendagitis is usually an incidental finding on CT and follows a benign, self-limiting course. The treatment consists of pain management and follow-up in 1 week.

CHAPTER 83

Bowel Obstruction

Timothy G. Price
Raymond J. Orthober

INTRODUCTION AND EPIDEMIOLOGY

Intestinal obstruction is the inability of the intestinal tract to allow for regular passage of food and bowel contents secondary to mechanical obstruction or adynamic ileus. Intestinal obstruction accounts for approximately 15% of all ED visits for acute abdominal pain.[1]

Mechanical obstruction can be caused by either intrinsic or extrinsic factors and generally requires definitive intervention in a relatively short period of time to determine the cause and minimize subsequent morbidity and mortality (**Tables 83-1 and 83-2**). Adynamic ileus (paralytic ileus) is more common but is usually self-limiting and does not require surgical intervention.

Both large and small intestines may be obstructed by various pathologic processes (Table 83-1). Extrinsic, intrinsic, or intraluminal processes precipitate mechanical obstruction. Differentiating small bowel obstruction from large bowel obstruction is important, because the incidence, clinical presentation, evaluation, and treatment vary depending on the anatomic site of obstruction. Intestinal pseudo-obstruction (Ogilvie's syndrome) may mimic bowel obstruction.

PATHOPHYSIOLOGY

Normal bowel contains gas as well as gastric secretions and food. Intraluminal accumulation of gastric, biliary, and pancreatic secretions continues even if there is no oral intake. As obstruction develops, the bowel becomes congested and intestinal contents fail to be absorbed. Vomiting and decreased oral intake follow. The combination of decreased absorption, vomiting, and reduced intake leads to volume depletion with hemoconcentration and electrolyte imbalance, and may lead to renal failure or shock.

Bowel distention often accompanies mechanical obstruction. Distention is due to the accumulation of fluids in the bowel lumen, an increase in intraluminal pressure with enhanced peristaltic contractions, and air swallowing. When intraluminal pressure exceeds capillary and venous pressure in the bowel wall, absorption and lymphatic drainage decrease, the bowel becomes ischemic, and septicemia and bowel necrosis can develop. Shock ensues rapidly. Mortality approaches 70% if bowel obstruction has progressed to this degree. This sequence of events may occur more rapidly in a closed-loop obstruction with no proximal escape for bowel contents. Examples of closed-loop obstruction include an incarcerated hernia and complete colon obstruction in the presence of a closed ileocecal valve.

SMALL BOWEL OBSTRUCTION

Small bowel obstruction is approximately four times more common than large bowel obstruction. The most common cause of small bowel obstruction is adhesions after abdominal surgery. Although in most

TABLE 83-1 Common Causes of Intestinal Obstruction

Duodenum	Small Bowel	Colon
Stenosis	Adhesions	Carcinoma
Foreign body (bezoars)	Hernia	Fecal impaction
Stricture	Intussusception	Ulcerative colitis
Superior mesenteric artery syndrome	Lymphoma	Volvulus
	Stricture	Diverticulitis (stricture, abscess)
		Intussusception
		Pseudo-obstruction

TABLE 83-2 Key Features of Ileus and Mechanical Bowel Obstruction

	Ileus	Bowel Obstruction
Pain	Mild to moderate	Moderate to severe
Location	Diffuse	May localize
Physical examination	Mild distention, ± tenderness, decreased bowel sounds	Mild distention, tenderness, high-pitched bowel sounds
Laboratory	Possible dehydration	Leukocytosis
Imaging	May be normal	Abnormal
Treatment	Observation, hydration	Nasogastric tube, surgery

cases several months to years have passed from the time of the previous surgery, small bowel obstruction may occur within the first few weeks after surgery. The second most common cause of small bowel obstruction is incarceration of a groin hernia (see chapter 84, "Hernias"). Other sites that occasionally are responsible for small bowel obstruction secondary to hernia include the umbilicus, femoral canal, and, rarely, the obturator foramen. Umbilical hernias are more readily apparent and occur in any age group. Obturator or femoral hernias are much less common. Elderly females are particularly susceptible to these hernias, which may present with femoral or medial thigh pain. Finally, a defect in the mesentery itself may cause intestinal obstruction. In the elderly population, adhesions and hernias are still common causes of small bowel obstruction, whereas carcinoma is the most likely cause of large bowel obstruction because of the increased likelihood of cancer as people age. Patients >60 years old are more likely to succumb secondary to complications of bowel obstruction.

Bariatric surgery may be complicated by internal hernias after Roux-en-Y gastric bypass.[2,3] Other causes of small bowel obstruction are much less common and generally are the result of intraluminal or intramural processes. Primary small bowel lesions include polyps, lymphoma, or adenocarcinoma. Hamartomatous polyps are common in Peutz-Jeghers syndrome; polyps occur in patients between the ages of 10 and 30 years and cause obstruction in about 40% of patients.[4] An unusual cause of intraluminal obstruction is gallstone ileus. In this situation, a gallstone has eroded from the gallbladder through the bowel wall and can cause obstruction at the ileocecal valve. Signs of gallstone ileus include bowel obstruction and air in the biliary tree. Lymphomas may be the leading point of intussusception and present as small bowel obstruction. Bezoars are most commonly composed of vegetable matter or pulp from persimmons. Patients who have undergone GI pyloroplasty or pyloric resection are most susceptible to intraluminal obstruction by bezoars.

Inflammatory bowel disease and infectious processes, including abscesses, may obstruct the small bowel at various sites. Radiation enteritis should be considered as a possible cause of small bowel obstruction in patients who have undergone radiation therapy. Blunt abdominal trauma may cause a duodenal hematoma. This condition is seen in children as a result of lap belt use and may present as intra-abdominal pain and vomiting similar to other causes of small bowel obstruction.

Visualization of the entire small bowel can be accomplished by capsule endoscopy. An important complication is capsule retention, with literature-reported frequencies of 1% to 20%.[5] Capsule retention can lead to obstruction and perforation, so patients with abdominal pain after capsule introduction should be carefully evaluated for these complications.[5]

LARGE BOWEL OBSTRUCTION

Neoplasms are by far the most common cause of large bowel obstruction. Colonic obstruction is almost never caused by hernia or surgical adhesions and should prompt an evaluation for a neoplasm. Diverticulitis may create significant mesenteric edema and secondary obstruction. Stricture formation may occur with chronic inflammation and scarring. Fecal impaction is a common problem in the elderly or debilitated and may present with symptoms of colonic obstruction.

The next most frequent cause of large bowel obstruction after cancer and diverticulitis is sigmoid volvulus. Elderly, bedridden, or psychiatric patients who are taking anticholinergic medication are most at risk for volvulus. A history of constipation may precede the development of volvulus. Radiographic appearance is usually classic (**Figure 83-1**). Cecal volvulus may cause large bowel obstruction. There is a higher incidence of cecal volvulus in gravid patients.[6]

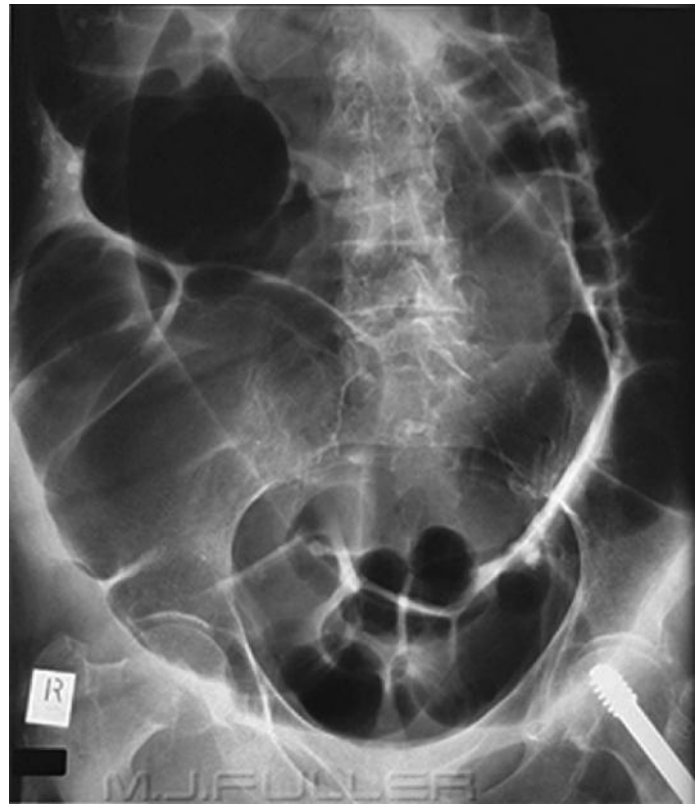

FIGURE 83-1. Sigmoid volvulus. Extends into the T10 area or higher. [Reproduced with permission from Wikiradiography.com.]

CLINICAL FEATURES

HISTORY

The site and nature of the obstruction and the preexisting condition of the patient will determine the clinical presentation. Although some generalizations are possible, there are no components of the history able to reliably predict small bowel obstruction.[7] Almost all patients will have abdominal pain. Pain generally is crampy and intermittent. Pain of mechanical small bowel obstruction is often episodic, lasting for a few minutes at a time, and may be periumbilical or diffuse. Pain tends to be less intense and more constant in adynamic ileus. Proximal obstruction usually causes vomiting. Vomitus is usually bilious in proximal obstruction but is feculent in distal ileal or large bowel obstruction. The pain of large bowel obstruction is usually hypogastric.

Other features that are consistently present with obstruction of small bowel or colon include the inability to have a bowel movement or pass flatus. "Constipation" is a common symptom of bowel obstruction. Partial bowel obstruction, however, is often associated with regular passage of stool and flatus. Additional risk factors are advanced age and anticholinergic or tricyclic antidepressants, which depress bowel motility.

PHYSICAL EXAMINATION

Physical findings vary depending on the site, duration, and etiology of the pathologic process. In small bowel obstruction, distention is the most reliable sign, and some distention is usually present early in the disease process.[7] Abdominal tenderness may be minimal to severe and localized or diffused. Peritonitis causes severe pain. The abdomen may

be tympanitic to percussion. Mechanical obstruction produces active, high-pitched bowel sounds with occasional "rushes." If obstruction has been present for several hours, peristaltic waves and bowel sounds may be diminished. Patients with an adynamic ileus may have some abdominal distention associated with diminished or absent bowel sounds. Localized or rebound tenderness may be a sign of gangrenous or perforated bowel, which requires immediate surgical intervention.

Careful examination coupled with radiographic investigation will often distinguish bowel obstruction from ileus. Emptiness of the left iliac fossa has been reported to be a reliable sign of sigmoid volvulus. Organomegaly or masses may suggest a cause of the obstruction. The *absence* of stool or air in the rectal vault supports a diagnosis of obstruction and may aid in the diagnosis of bowel obstruction, but its *presence* does not eliminate a more proximal obstruction. A rectal examination may identify fecal impaction, rectal carcinoma, occult blood, or stricture. Consider a pelvic examination in women to identify gynecologic pathology causing obstruction (see chapter 97, "Abdominal and Pelvic Pain in the Nonpregnant Female"). A vaginal pessary can cause colonic obstruction due to extrinsic compression of the colon.[8] See Table 83-2 for the key causes of ileus and mechanical bowel obstruction.

DIAGNOSIS

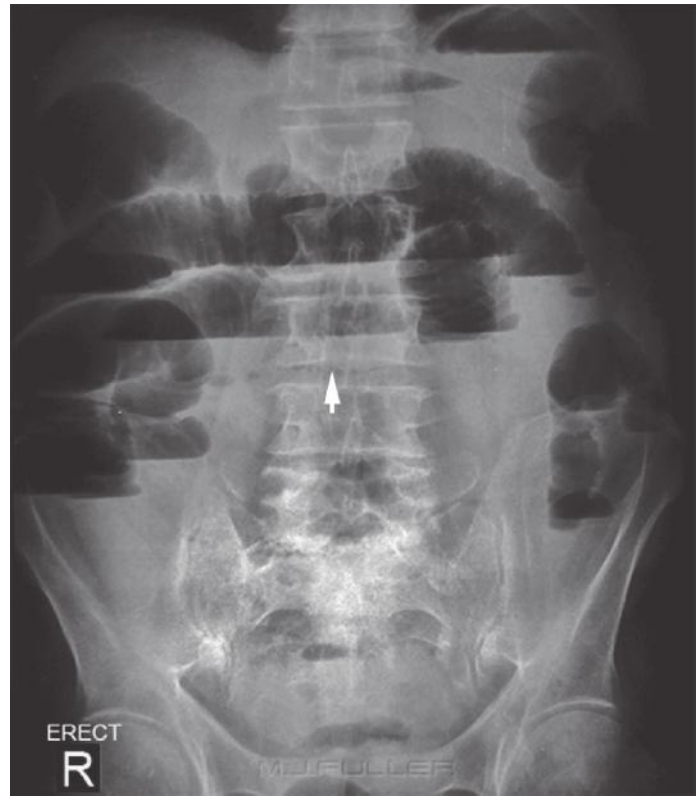
Consider bowel obstruction or ileus in any patient with abdominal pain and distention. Numerous other pathologic processes may also cause these symptoms, but additional evaluation guided by the history and physical examination may be necessary to confirm or rule out obstruction or ileus. Although any segment of bowel may be affected, low colonic obstruction is the most common clinical presentation. Radiographs may demonstrate a massively dilated colon with well-defined septa and haustral markings and very little fluid, without air-fluid levels. A CT scan is the most reliable diagnostic modality and offers the advantage of detecting mucosal inflammation and evaluating mucosal viability.[9] Avoid barium studies because the patient may be unable to evacuate the barium.

LABORATORY TESTING

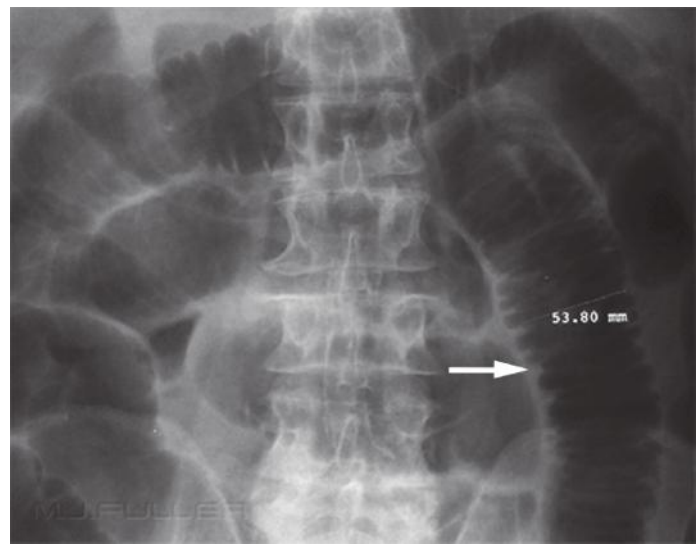
Laboratory studies usually include a CBC and electrolyte levels, the results of which may vary widely depending on the duration and site of obstruction and the presence of bowel necrosis. A leukocytosis of >20,000/mm^3 or left shift should make one suspect bowel gangrene, intra-abdominal abscess, or peritonitis. Extreme leukocytosis (>40,000/mm^3) suggests mesenteric vascular occlusion. The serum amylase and lipase levels may be mildly elevated. Increases in hematocrit, BUN, and creatinine are consistent with volume depletion and dehydration. Other indications of the severity of obstruction or secondary complications include increased urine specific gravity, ketonuria, elevated lactate levels, and metabolic acidosis. Small studies suggest that procalcitonin may predict bowel ischemia or failure of conservative management.[10]

IMAGING

In the ED, flat and upright abdominal radiographs with an upright chest x-ray or a lateral decubitus view can be used to confirm diagnostic suspicion for bowel obstruction, severe constipation, or free air. Plain x-rays can also localize the site of obstruction to large or small bowel (**Figure 83-2**). However, if clinical suspicion for obstruction is strong, CT scan with oral and IV contrast is the imaging method of choice in the ED. The CT scan is extremely sensitive in high-grade obstruction, providing information not only about the presence or absence of an obstruction but often its location, severity, and cause.[1] In the presence of renal insufficiency or contrast allergy, oral contrast alone may provide sufficient diagnostic information.



A



B

FIGURE 83-2. Small bowel obstruction. A. Multiple air-fluid levels. B. Coiled spring sign. [Reproduced with permission from Wikiradiography.com.]

TREATMENT

Most patients with small bowel obstruction may be successfully managed nonoperatively, whereas most patients with large bowel obstruction will require surgery.[1] For colonic obstruction due to malignancy, resection of the tumor has been the gold standard treatment. Self-expanding endoluminal stents can be used to relieve the obstruction and avoid emergent operation.[11] Use of a nasogastric tube is often unnecessary and is associated with potential benefit and potential risks. It should be considered in the presence of severe distention and vomiting. Local surgeon preference continues to dictate local practice with regard to nasogastric tube use. Vigorous IV fluid replacement is needed because of loss of absorptive capacity, decreased oral intake, and vomiting. Monitor adequacy of fluid resuscitation by the response of blood pressure, heart rate, and urine output. **Closed-loop obstruction, bowel necrosis, and cecal volvulus are surgical emergencies.** Administer preoperative broad-spectrum antibiotics in the ED. There are many possible regimens. Monotherapy

could be tazobactam-piperacillin, 3.375 grams IV every 6 hours, ticarcillin-clavulanate, 3.1 grams IV every 6 hours, or a carbapenem.

If adynamic ileus is suspected or the diagnosis is uncertain, conservative inpatient management, including IV fluids and observation, generally is effective in allowing the bowel to resume normal activity and function. Any medication that inhibits bowel mobility should be discontinued.

DISPOSITION AND FOLLOW-UP

Admit patients with bowel obstruction to the hospital. Surgical consultation should generally be obtained in the ED or at the time of admission. Adynamic ileus should also be admitted for the treatment of the underlying cause and until resolution of the ileus.

CHAPTER 84

Hernias

Donald Byars
Turan Kayagil

INTRODUCTION

With nearly 10% of the population developing some sort of hernia during their lifetime, this is among the most common of surgical problems.[1] Hernias are classified by anatomic location, hernia contents, and the status of those contents (e.g., reducible, strangulated, or incarcerated).[2]

A hernia is called **reducible** when the hernia sac itself is soft and easy to replace back through the hernia neck defect. A hernia is **incarcerated** when it is firm, often painful, and nonreducible by direct manual pressure. **Strangulation** develops as a consequence of incarceration and implies impairment of blood flow (arterial, venous, or both). A strangulated hernia presents as severe, exquisite pain at the hernia site, often with signs and symptoms of intestinal obstruction, toxic appearance, and, possibly, skin changes overlying the hernia sac. A strangulated hernia is an acute surgical emergency. This chapter discusses hernias in adults. Hernias in children are discussed in chapter 130, "Acute Abdominal Pain in Infants and Children."

ANATOMY OF COMMON HERNIAS

INGUINAL HERNIA

Seventy-five percent of all hernias occur in the inguinal region, making it the most common form of hernia, with two thirds of these being of the indirect type (**Figure 84-1**). Although there is a clear male predilection, inguinal hernias are also the most common hernias in women. Inguinal hernias present as a groin mass. Typically the mass has been present for some time, but may have recently become larger or the patient may have begun to develop symptoms of incarceration or strangulation. The differential diagnosis for a groin mass is somewhat broad and includes, in addition to hernia, hidradenitis, other abscess, sebaceous cyst, lymphoma, hydrocele, varicocele, femoral hernia, and femoral aneurysm. Thankfully, the physical examination for most hernias is fairly straightforward. Bedside US can be very helpful in the identification of an inguinal hernia if the diagnosis remains in question (**Figure 84-2**). One study reported 100% sensitivity and 100% specificity of bedside emergency US for the diagnosis of groin hernia.[3]

A **direct inguinal hernia** passes directly through a weakness in the transversalis fascia in the Hesselbach triangle. Hesselbach triangle is constructed with the lateral border of the inferior epigastric arteries, a medial border with the rectus sheath, and an inferior border of the inguinal ligament (**Figure 84-3**).[4]

The hernia sac from an **indirect inguinal hernia** passes from the internal to the external inguinal ring through the patent process vaginalis, and then to the scrotum (**Figure 84-4**).

VENTRAL AND INCISIONAL HERNIAS

Ventral hernias develop as a result of a defect in the anterior abdominal wall and can be either spontaneous or acquired. They are typically characterized by their anatomic location as epigastric, umbilical, incisional, or hypogastric (rare; **Figure 84-5**).[5]

Incisional hernias account for up to 20% of all abdominal wall hernias. They are often the result of excess wall tension or inadequate wound

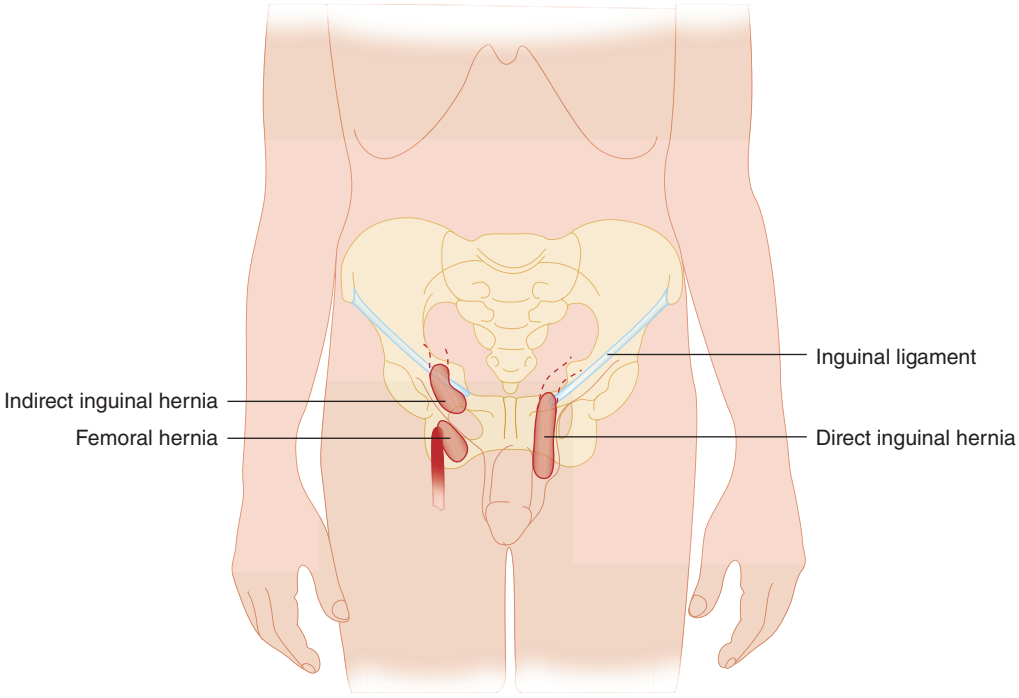

FIGURE 84-1. Groin hernia.

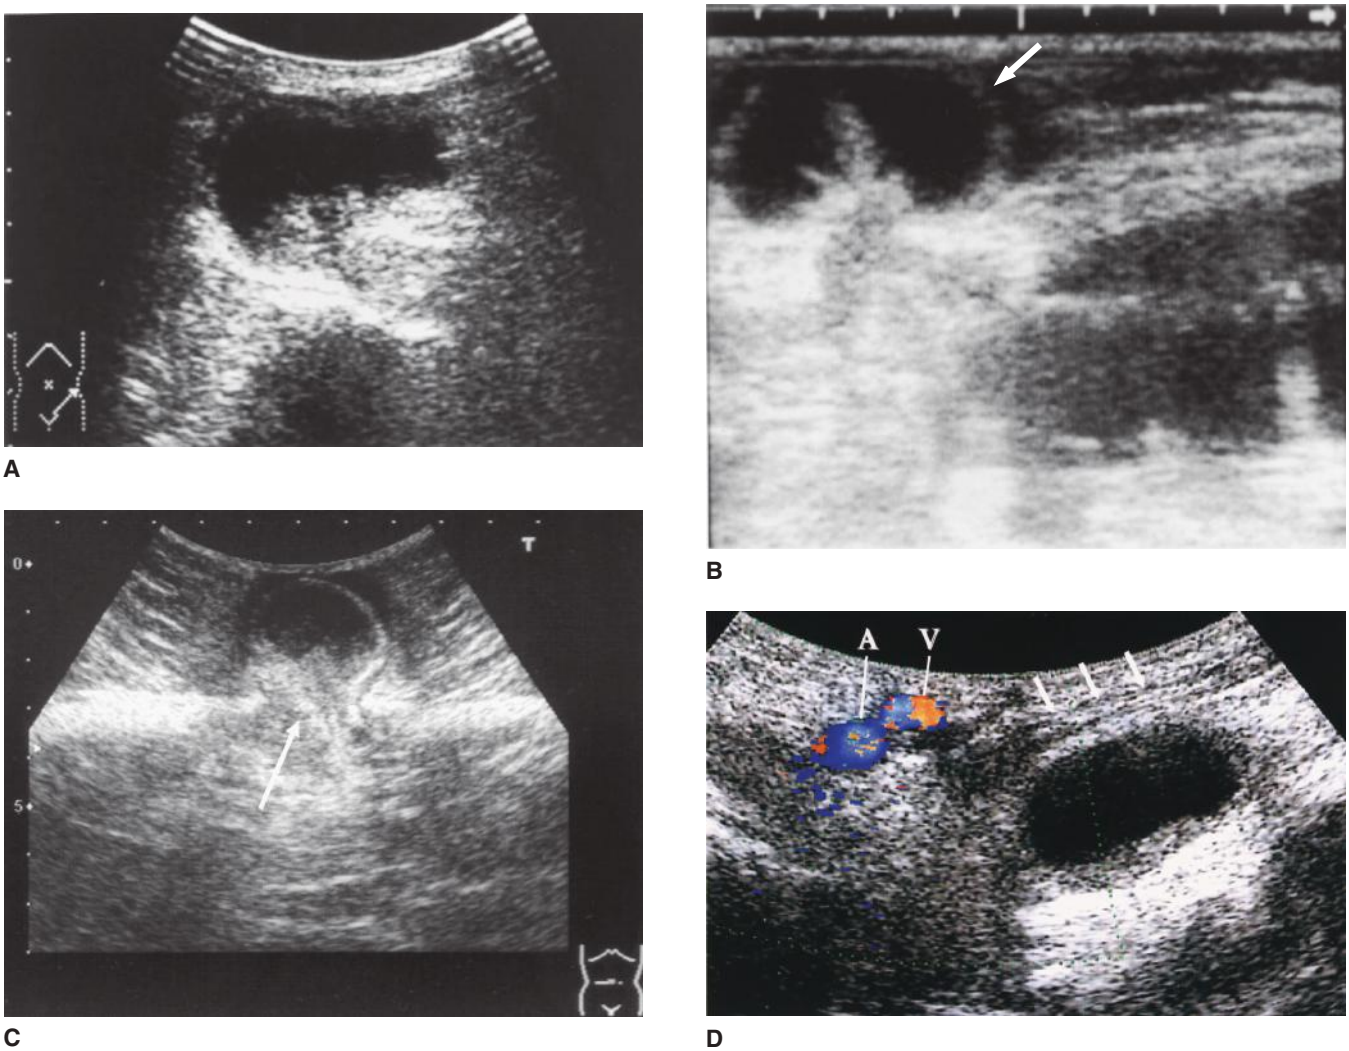

FIGURE 84-2. Incarcerated hernia. **A.** An incarcerated femoral hernia is demonstrated as a small-bowel segment herniated through the femoral canal. **B.** In an incarcerated incisional hernia, a small-bowel segment (*arrow*) is demonstrated as herniated through a small orifice in the abdominal wall. Dilated small-bowel loops are evident proximal to the incarceration. **C.** In an umbilical hernia, a herniated small-bowel segment is demonstrated within the fluid space in the hernia sac. The segment was softly strangulated at the hernia orifice (*arrow*) formed by a defect of the fascia and was easily reduced by manipulation in this case. **D.** An incarcerated obturator hernia is demonstrated deep in the femoral region. It locates posterior to the pectineus muscle (*arrows*) and medial to the femoral artery (A) and vein (V). FIGURE 84-3. Direct inguinal hernia.

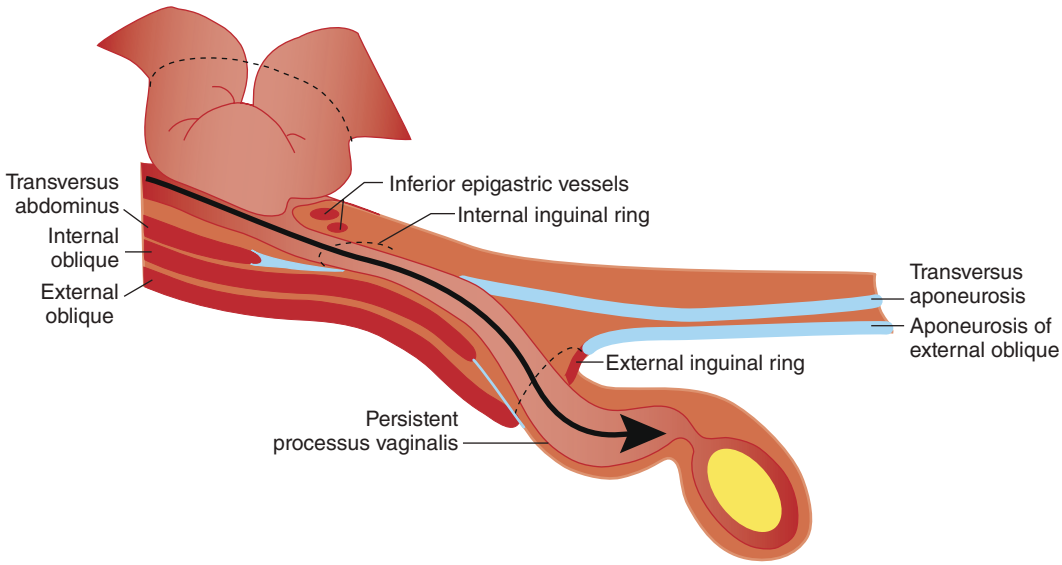

FIGURE 84-4. Indirect inguinal hernia.

healing. They are also associated with surgical wound infections. Risk factors for the development of incisional hernias include obesity, age, wound infection, and medical conditions (i.e., chronic obstructive pulmonary disease) that increase intra-abdominal pressure.[6] Incisional hernias can become quite large and produce symptoms varying from discomfort to extrusion of abdominal contents to incarceration and strangulation. Despite primary repair, the recurrence rate can be as high as 50%.

UMBILICAL HERNIA

The adult form of umbilical hernia is largely acquired and due to medical conditions that increase intra-abdominal pressure, including ascites, pregnancy, and obesity. Although strangulation is unusual in most patients, those with chronic ascites (i.e., cirrhotics) are at risk for umbilical hernia strangulation, rupture, and death from peritonitis.[7]

ANATOMY OF UNCOMMON HERNIAS

FEMORAL HERNIA

Femoral hernia (Figure 84-1) is so named because the hernia sac protrudes through the femoral canal and produces a mass that is typically below the inguinal ring. Femoral hernias are more common in women, with a 10 to 1 female predilection. The femoral hernia is particularly prone to complications, such as incarceration and strangulation. One study reported a 40% emergency surgery rate due to such complications in patients with a known femoral hernia.[8] All femoral hernias should be urgently referred for elective repair. Delays in femoral hernia repair lead to increasing rates of strangulation, reaching 45% at 21 months.[9] A small study by Malek et al[10] reported worrisome complication rates (31%) and surprising high mortality (13%) from delayed repair of femoral hernias.

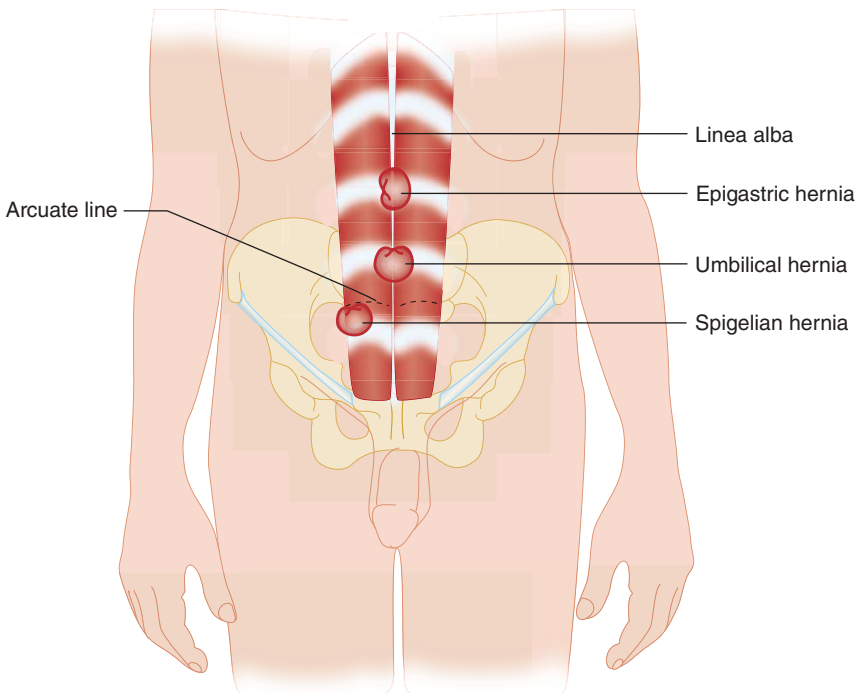

FIGURE 84-5. Anterior abdominal wall hernia.

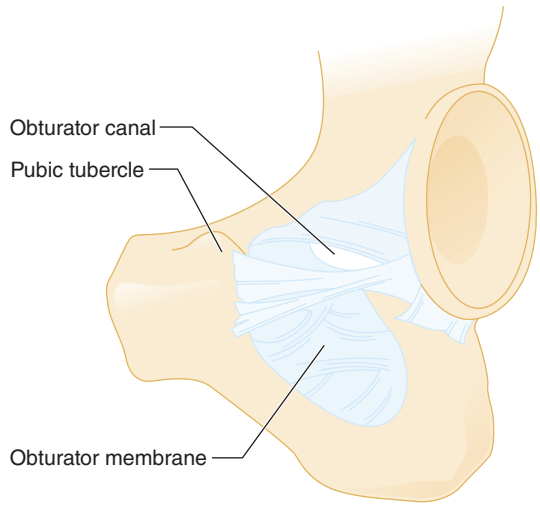

FIGURE 84-6. Obturator foramen. [Reproduced with permission from Pansky B: *Review of Gross Anatomy*, 6th ed, © 1995, The McGraw-Hill Companies, 1995, p. 511.]

SPIGELIAN HERNIA

Spigelian hernia (Figure 84-5), also known as a *lateral ventral hernia*, arises at the lateral edge of the rectus muscle and the arcuate (semilunar) line. Spigelian hernias are nearly always acquired conditions due to comorbidities that increase intra-abdominal pressure. These hernias are very difficult to diagnose, especially given the variability in presentation. The classic presentation is abdominal pain associated with an anterior lateral abdominal wall mass or bulge. Physical examination is unreliable,[11] and accurate diagnosis often requires diagnostic imaging. Bedside emergency US can accurately and quickly make the diagnosis.[12] CT scan remains the best radiologic test available but has the limitations of time, cost, and radiation exposure. Spigelian hernias should be surgically corrected given their high rates of incarceration.

OBTURATOR HERNIA

Obturator hernia is bowel herniation through the obturator canal (**Figure 84-6**) and nearly always presents as either a partial or complete bowel obstruction. The typical patient is an elderly frail female with signs and symptoms of intestinal obstruction. Although physical examination findings, such as the Howship-Romberg sign (pain in medial portion of the thigh due to obturator nerve compression), are well documented in the literature, the sign is not as useful in routine practice. Diagnosis is made by CT scanning of the abdomen and pelvis. It is important to properly diagnose this hernia given its high complication rate reported as perforation in >50% of cases and mortality approaching 20%.[13]

RICHTER HERNIA

Richter hernia involves only the antimesenteric border of the intestine and only involves a portion of the wall circumference. The Richter hernia presents differentially from a traditional incarcerated/strangulated hernia, as it often presents without vomiting or intestinal obstruction due to the incomplete involvement of the circumference of the intestine. Thus, the Richter hernia more often leads to strangulation and gangrene than other more standard hernias. Surgical repair is indicated when diagnosed.[14]

DIAGNOSIS

Traditional laboratory studies, such as a CBC, serum chemistries, and urinalysis, are routinely ordered but are of minimal value in the evaluation unless seeking an alternative diagnosis or for preoperative clearance.

IMAGING

Plain films are not required in hernia patients without significant symptoms. The acute abdominal series can reveal the presence of free air and signs of intestinal obstruction, but otherwise, plain films are usually indeterminate or nondiagnostic.

US has many advantages including low cost, no ionizing radiation, ready availability, no contrast agents used, and ability to be performed at the bedside. However, US is both operator and body habitus dependent. The primary role of US is the identification of the hernia itself. The **dynamic abdominal sonography for hernia** examination has good results in the hands of surgeons as compared to CT for the diagnosis of hernia.[15] When a hernia is identified by US, note hernia size, contents, reducibility, location of the facial defect, and tenderness.[16] In addition to determining whether bowel is present in a hernia sac, US can sometimes identify signs of incarceration and strangulation.[16-18] Strangulated bowel, by definition, has vascular compromise. In the natural history of an incarcerated hernia, the thin-walled veins and lymphatics become compressed and compromised before the thick-walled arterial supply. Doppler US can detect the arterial flow to the loop of bowel but is usually not sensitive enough to detect venous flow and cannot detect lymphatic flow. Thus, Doppler US can be insensitive for strangulation.[16-18] However, preservation of arterial inflow with obstruction of venous outflow causes increased intravascular pressure and extravasation of fluid into the extracellular space. This manifests itself as free fluid in the hernia sac on B-mode US, which is a sensitive finding for incarceration and strangulation. The specificity of free fluid in the hernia sac is good per se, but may be confounded by patients with ascites. Other US findings associated with incarceration and strangulation include hyperechoic fat, isoechoic thickening of the hernia sac, thickening of the wall of the herniated bowel, and free fluid within the herniated bowel loop.[16,18] Absence of peristalsis in a herniated bowel loop is suggestive of incarceration, and the presence of peristalsis implies that bowel resection is less likely to be necessary when the patient undergoes operative intervention.[18] US is most useful for diagnosis in children and pregnant women given its lack of ionizing radiation.[12]

It can be clinically difficult to differentiate hernia from hydrocele when assessing a scrotal mass. Obtaining a scrotal US in the standing position, with and without Valsalva maneuver, is a good way to demonstrate hernia.

CT is the best-performing radiographic test for hernia diagnosis and can identify uncommon hernia types (e.g., Spigelian or obturator) as well as demonstrate incarceration and strangulation.[19]

TREATMENT

If the hernia is easily reducible on physical examination, then refer the patient for elective outpatient surgical repair.

If the hernia is exquisitely tender and is associated with systemic signs and symptoms, such as intestinal obstruction, toxic appearance, peritonitis, or sepsis, then assume hernia strangulation. Consult general surgery immediately.[20] Administer broad-spectrum IV antibiotics, such as cefoxitin, provide fluid resuscitation and adequate narcotic analgesia, and obtain preoperative laboratory studies.

If the hernia is incarcerated but the patient does not yet show signs of strangulation, then make one or two attempts at reduction in the ED. Steps for hernia reduction[21] are listed in **Table 84-1**.

TABLE 84-1 Steps for Hernia Reduction

NPO status in case reduction attempts are unsuccessful.
Adequate IV narcotic analgesia.
Apply cold packs to the hernia site to reduce swelling and make reduction attempts easier.
Grasp and elongate the hernia neck with one hand, and with the other hand, apply firm, steady pressure to the proximal part of the hernia at the neck at the site of the fascial defect. US can aid in the identification of the fascial defect if it is not clinically obvious. Applying pressure on the most distal part of the hernia can cause bulging (or ballooning) at the hernia neck and prevent reduction.
Consult surgery if the reduction is unsuccessful after one or two attempts.

After ED reduction of an incarcerated hernia, it is reasonable to observe the patient in the ED for a period of time for serial abdominal examinations. Persistent significant abdominal pain must raise clinical concern for "**reduction en mass**."[22] Although a rare complication of reduction attempts, it has been reported in the literature from the early 1900s to the present day.[23,24] A reduction en mass occurs when an incarcerated hernia is reduced back into the peritoneal cavity but a loop of bowel remains inside the hernia sac even after reduction, so that the retained bowel remains incarcerated.[22,24] In cases of reduction en masse, the patient will continue to exhibit signs and symptoms of incarceration despite apparent clinical reduction. Imaging can assist in the detection of this distinctly uncommon but serious diagnosis.

If there is any concern for strangulation, do not attempt hernia reduction. The reintroduction of ischemic, necrotic bowel back into the peritoneal cavity can result in subsequent perforation and sepsis.[25] Bedside US using a linear high-frequency probe with color or power Doppler of the hernia sac can be useful in borderline cases to establish the presence or absence of arterial blood flow.[12]

CHAPTER 85

Anorectal Disorders

Brian E. Burgess

INTRODUCTION

Anorectal disorders range from simple to complex and can manifest signs and symptoms of underlying serious local or systemic disorders that may be life threatening. Precise causes may be difficult to determine; thus a focused history and careful examination can narrow the differential diagnosis and aid timely and appropriate management.

ANATOMY

The rectum begins at the S3 vertebral body and descends for about 13 to 15 cm becoming the anus, comprised of the anal canal, anal verge, and anal margin. The rectum narrows and traverses through the muscular pelvic floor, at the level of the levator ani and coccygeal muscles, and becomes the anal canal, 4 cm in length, surrounded by the anal sphincter muscle (**Figure 85-1**).

The dentate line marks the junction of these two structures as the anal canal continues more distally joining the perianal skin at the anal verge (**Figure 85-2**). The anal canal mucosa consists of stratified squamous epithelium and contains no hair follicles or sweat glands. At the anal verge, the anoderm thickens and includes hair follicles and other cutaneous appendages. Proximal to the dentate line, the rectal ampulla narrows to conform to the opening of the anal canal. In doing so, its mucosa takes on a pleated appearance, forming 8 to 14 convoluted longitudinal folds: the columns of Morgagni. Each adjacent column is connected at the dentate line by a flap of mucosa that forms a small anal crypt, normally 1 to 3 mm deep. Anal sepsis, cryptitis, perianal abscesses, and fistulas result from inflammation, obstruction, and infection of the crypts and glands. The anal wall is a continuation of the usual layers of the wall of the colon and rectum, and the innermost mucosal lining continues to the anal verge. Just proximal to the dentate line, the mucosa transitions

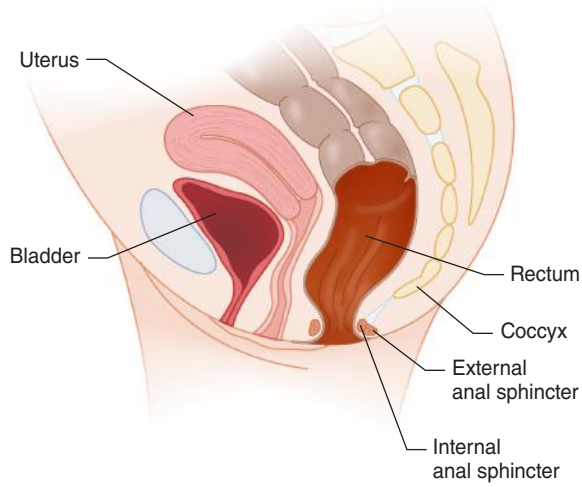

FIGURE 85-1. Midsagittal section, anorectum.

from rectal columnar to cuboidal to squamous epithelium. The submucosa, which normally contains the bulk of the bowel's blood vessels and autonomic nerves, thickens considerably proximal to the dentate line. The superior hemorrhoidal artery, from the internal mesenteric artery, supplies the proximal two thirds of the rectum, whereas the middle hemorrhoidal artery, from the internal iliac artery, supplies the distal one third of the rectum. The inferior hemorrhoidal artery supplies the anus but also supplies the rectum by a submucosal network. The venous and lymphatic system mirrors the arterial supply. The superior rectal vein drains into the portal system, whereas the middle rectal vein drains into the inferior vena cava. The inner circular muscle layer of the rectum thickens considerably as it terminates distally in the anorectum to form the involuntary internal sphincter muscles. The more attenuated longitudinal muscles of the rectum extend caudally, blending with fibers of voluntary skeletal muscles from the levator ani and external sphincter groups, to form the intersphincteric space (Figure 85-2).

The external sphincters are voluntary skeletal muscles and are actually a caudal extension of the puborectalis muscle, which interacts with the levator ani muscle, forming the pelvic floor. The puborectalis, the proximal external sphincters, and the internal sphincters form the ring of muscles that one palpates when performing a digital examination of the anorectum.

Lateral to the external sphincters is the ischiorectal space, and superior to the levator ani is the supralevator (pelvirectal) space, where deep, life-threatening infections can occur. Inferior mesenteric and paraaortic nodes drain the proximal two thirds of the rectum, whereas the lower one third of the rectum and proximal anal canal are drained by both the inferior mesenteric nodes and the internal iliac nodes. The inguinal nodes usually drain lymphatics distal to the dentate line. Proximal to the dentate line, the anus is supplied by the sympathetic and parasympathetic nerves, yet is devoid of somatic pain fibers, unlike distal to the dentate line, where somatic fibers are present. Parasympathetic nervous stimulation (S2 to S4) contracts the rectal wall and relaxes the internal anal sphincter, whereas sympathetic stimulation (L1 to L3) maintains continence through rectal wall inhibition and contraction of the internal anal sphincter.

PHYSICAL EXAMINATION

No matter how much historical information is obtained, no definitive diagnosis can be made without a careful examination of the anus and rectum. Patient education before and during the examination will be helpful in obtaining maximal cooperation. The lateral or Sims position is the most common position for routine digital rectal examination and anoscopy. This position is preferred for the elderly or pregnant women. Elevating the upper buttock provides better exposure of the perianal area. In debilitated patients, one may have to perform the examination

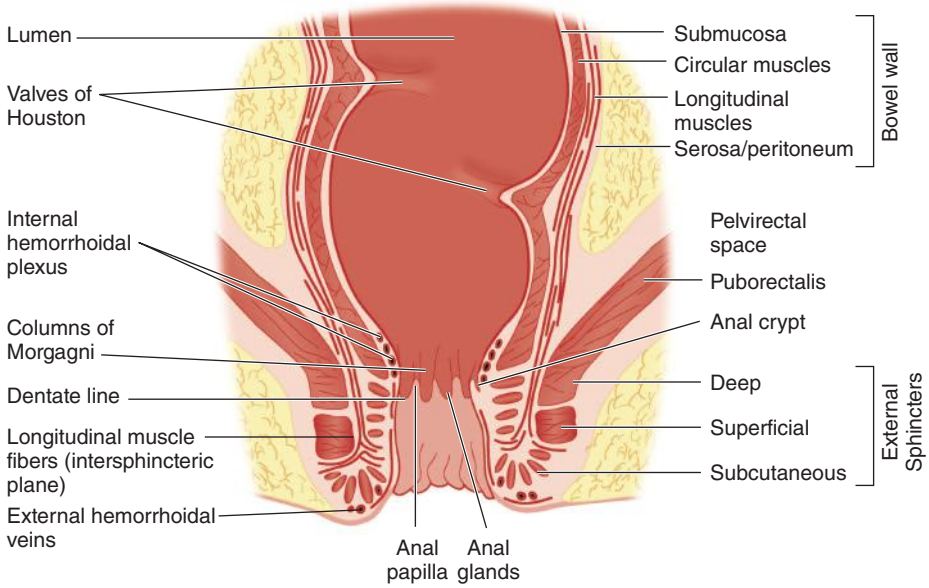

FIGURE 85-2. Coronal section, anorectum.

with the patient in a supine, lithotomy position. Examining a patient placed in the knee-chest position requires a cooperative patient who is not too ill or in too much distress.

A digital examination of the entire inner wall with a lubricated index finger should always be performed before doing any endoscopic procedure. In men, palpate the prostate to determine its size, texture, and tenderness or if masses are present. In women, palpate the posterior vaginal wall for a mass, rectocele, or rectovaginal fistula. Note anal tone and sensation. The anal mucosa, dentate line, both external and internal hemorrhoids, fistulas and fissures, condyloma, and distal rectal mucosa can be evaluated with the use of an anoscope (**Figure 85-3A**). No bowel preparation is needed for anoscopy, and cultures can be obtained. Suction and a good light source should be available. After performing a digital examination and determining that the patient will tolerate passage of an anoscope, introduce a well-lubricated, lighted anoscope with the obturator in place. Next, remove the obturator, and gently rotate as needed to view the anorectum circumferentially while withdrawing the anoscope (**Figure 85-3B**). After visual inspection, ask the patient to bear down to detect any rectal mucosal prolapse.

ANAL TAGS

Skin tags are minor projections of skin at the anal verge and are sometimes residuals of prior hemorrhoids (**Figure 85-4**).

CLINICAL FEATURES

Skin tags are usually asymptomatic, but inflammation may cause itching and pain. Skin tags covering anal crypts, fistulas, and fissures are called "sentinel tags." **Surgical referral for excision and/or biopsy is warranted because inflammatory bowel disease may be associated with sentinel tags.**

HEMORRHOIDS

ANATOMY

Hemorrhoids are vascular cushions that become enlarged and distally displaced within the anal canal. Current theory suggests that there is anal canal sliding and that hemorrhoidal formation occurs when the supporting tissues of these cushions deteriorate.[1] Consequently, the downward displacement of these cushions causes the internal and external hemorrhoidal plexuses to become excessively engorged, referred to as *hemorrhoids*—one of the most common problems afflicting human beings (**Figure 85-5**).

Hemorrhoids may become inflamed, thrombosed, prolapsed, ulcerated, or ischemic. Internal hemorrhoids originate proximal to the dentate line, from terminal branches of the superior rectal artery. They are constant in their location, coursing longitudinally at the right posterolateral, right anterolateral, and left lateral positions; 2-, 5-, and 9-o'clock positions, when the patient is viewed prone (**Figure 85-6A**). Commonly, they are single and are located at the 5-o'clock position. Internal hemorrhoids are not readily palpable and can best be visualized through an anoscope. Their appearance is consistent with the columnar epithelial surface of the surrounding anal canal (**Figure 85-6B**). **External hemorrhoids**, distal to the dentate line, are located anywhere along the anoderm, form as a result of dilatation of veins at the anal verge, and can be seen at external inspection. Their appearance is consistent with the stratified squamous epithelium of the surrounding anoderm, which has exquisite sensory innervation.

CLINICAL FEATURES

Enlarged hemorrhoids are associated with constipation and prolonged straining at stool, frequent diarrhea, and older age. Increased abdominal pressure may cause obstruction of venous return and engorgement of the hemorrhoidal plexus. Consider inflammatory bowel disease in patients with frequent diarrhea and hemorrhoids. Hemorrhoidal veins can have high resting pressures and are devoid of valves, and as patients age, the supportive connective tissue surrounding the vasculature diminishes. Hemorrhoids can develop during pregnancy and may be the result of sustained increased pressure on the venous drainage of the rectum. Increased portal pressure, from chronic liver disease, may produce marked dilatation and varix formation, distinct from true hemorrhoids, resulting in bleeding that can be extremely difficult to control. Tumors of the rectum and sigmoid colon, often associated with constipation, tenesmus, and incomplete evacuation, may cause hemorrhoids. **Although the most common cause of bright red rectal bleeding is hemorrhoids, tumors must be ruled out as a cause of rectal bleeding in patients >40 years of age.** Ascites, ovarian tumors, distended bladders, and excessive fibrosis from radiation therapy may contribute to the formation of external hemorrhoids. **Hemorrhoidal bleeding is usually limited, with the bright red blood on the surface of the stool, on the toilet tissue, or noted at the end of defecation, dripping into the toilet bowl. When patients describe the passage of blood clots, one should suspect colonic lesions. Chronic slow blood loss detected on fecal occult blood testing resulting in anemia requires further investigation.** Hemorrhoids themselves generally do not cause pain unless they are

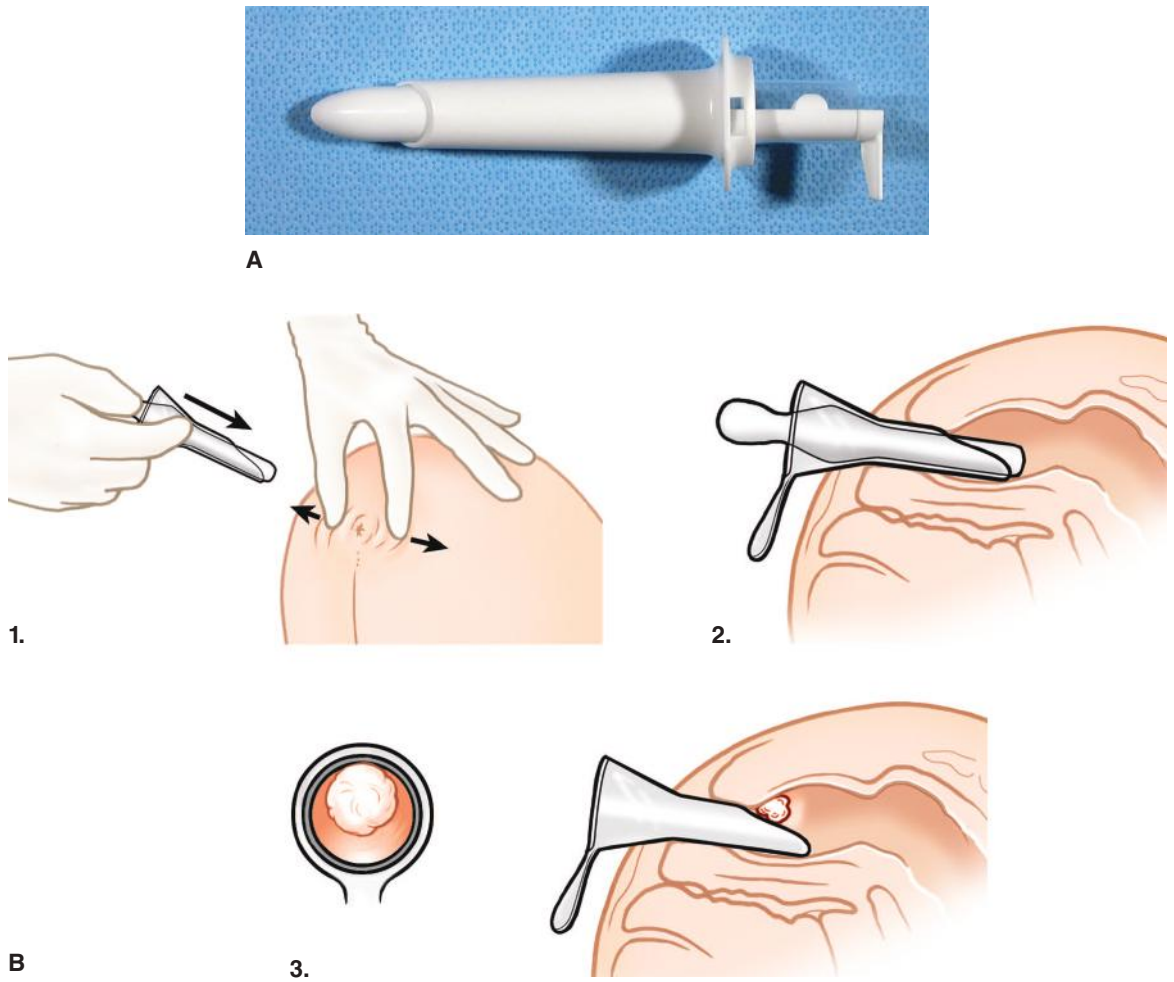

FIGURE 85-3. A. Anoscope. B. Anoscope insertion technique (1, 2, and 3). [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures,* 2nd ed. McGraw-Hill, Inc., 2013. Figure 70-5A-C.]

thrombosed or are strangulated fourth-degree internal hemorrhoids. If the patient complains of pain, but on examination the hemorrhoids are not thrombosed, suspect perianal or intersphincteric abscesses or anal fissures. Thrombosed external hemorrhoids are painful and are often described as a burning perianal lump, and they usually exhibit a bluish-purple discoloration (**Figure 85-7**). Hemorrhoids may become more prominent with a Valsalva maneuver. As hemorrhoids increase in size, they may prolapse, requiring periodic reduction by the patient. Pain can be quite severe at the time of defecation and usually subsides with time.

Uncomplicated internal hemorrhoids are painless due to visceral innervation and lack of sensory innervation. Anoscopy reveals bulging, purple-colored veins at the distal rectum or anal canal (**Figure 85-8**). Often a chief complaint is painless, bright red rectal bleeding with defecation. Internal hemorrhoids may be palpable on digital examination

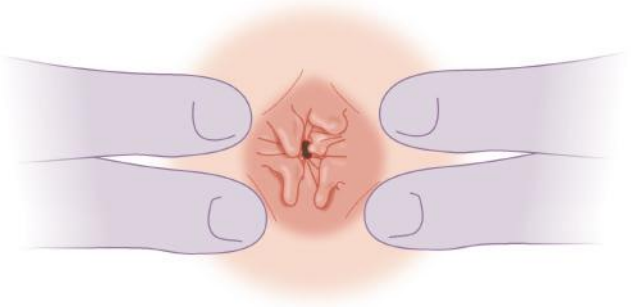

FIGURE 85-4. Anal skin tag.

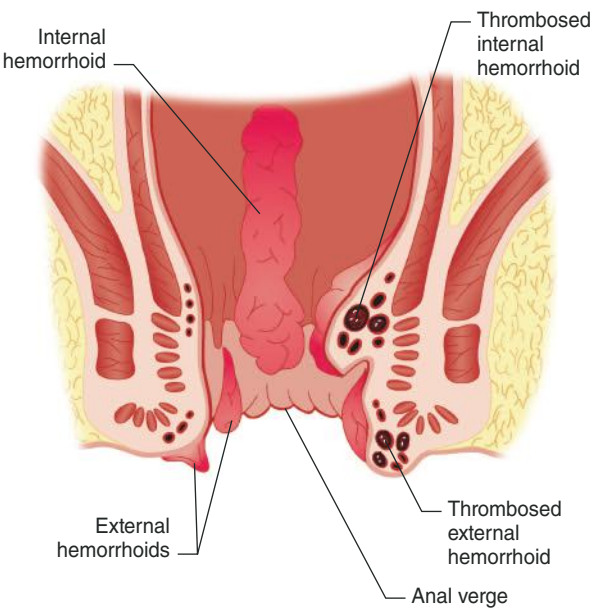

FIGURE 85-5. Coronal section of anorectum.

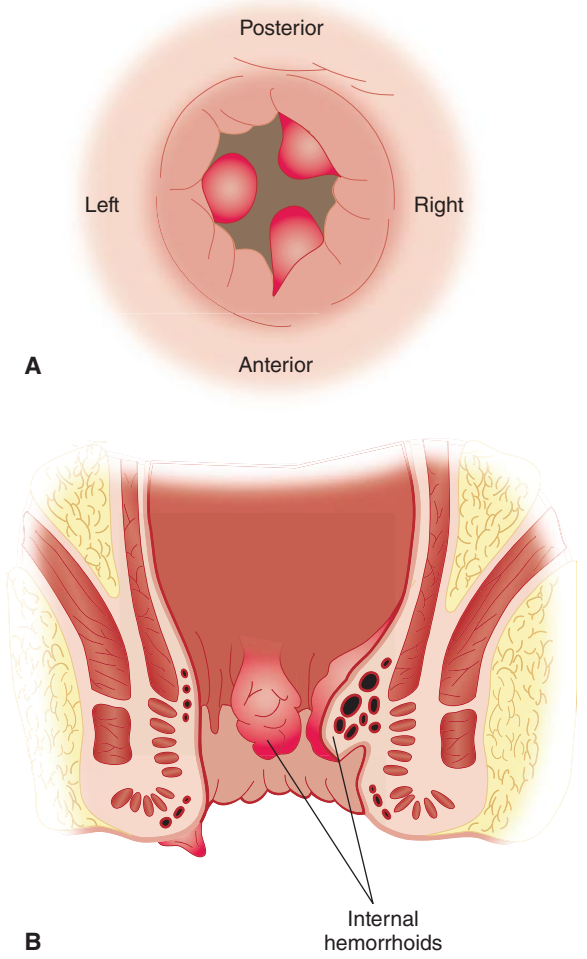

FIGURE 85-6. A. Internal hemorrhoids at 2, 5, and 9 o'clock. B. Protrusion of internal hemorrhoids.

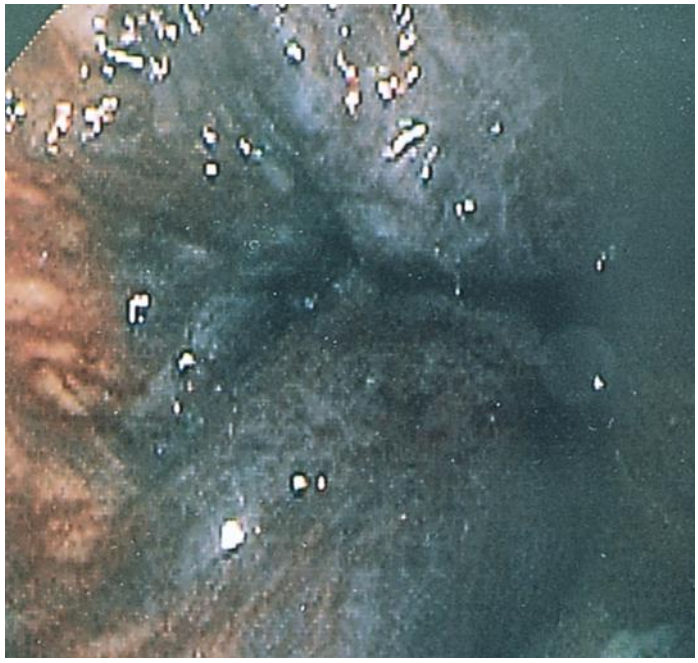

FIGURE 85-8. Grade I internal hemorrhoids. [Photo contributor: Virender K. Sharman, MD; reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

when thrombosed or prolapsed.[2] Nonreducible, prolapsed, internal hemorrhoids may become thrombosed and strangulated. They appear dark red, exhibit rectal bleeding, and cause exquisite pain and possibly urine retention. Ulceration, necrosis, gangrene, sepsis, and hepatic abscess formation may ensue. Internal hemorrhoids are classified by the amount of prolapse into the anal canal (**Table 85-1**).

Mucous discharge and pruritus ani may be seen with luminal prolapse[2] (Figure 85-8).

TREATMENT

Conservative therapy with warm baths is often successful for mild to moderate symptomatic grade I and II internal hemorrhoids. Manual reduction of grade III internal hemorrhoids and warm baths (which decrease sphincter pressures) for at least 15 minutes three times a day and after each bowel movement are the most effective ways to relieve symptoms. After the bath, the anus must be dried gently but thoroughly to avoid maceration of the perianal skin. Topical analgesics and steroid-containing ointments may provide relief. The patient should not sit on the commode for a prolonged period. Bulk laxatives and stool softeners should be used after the acute phase is treated. Avoid the use of laxatives causing liquid stool, because cryptitis and anal sepsis can result. A high-fiber, low-fat diet, with increased water consumption, regular exercise, and avoidance of constipating medications, should help prevent future problems. Recommend surgical referral for symptomatic hemorrhoids, because a variety of procedures (sclerosing injections, rubberband ligation, photocoagulation, cryotherapy, electrocautery, laser treatments, radiofrequency ablation, staple repair, or excision) can provide definitive treatment. A rare complication of hemorrhoidal banding is pelvic sepsis.[2]

TABLE 85-1 Grades of Internal Hemorrhoids

Grade I: Luminal protrusion above dentate line	Do not extend below dentate line and do not prolapse, cause painless bleeding
Grade II: Prolapse with spontaneous reduction	Prolapse during straining
Grade III: Prolapse requires manual reduction	Prolapse during straining
Grade IV: Prolapse-nonreducible	Can result in edema and strangulation

Obtain surgical evaluation in the ED for continued and severe bleeding, pain, incarceration, and/or strangulation (grade IV internal hemorrhoids). External hemorrhoidal thrombosis is usually self-limiting, with resolution in 1 week. Therapy for thrombosed external hemorrhoids depends on the severity of symptoms. If the thrombosis has been present for more than 48 hours, the swelling has started to shrink, the hemorrhoid is not tense, and the pain is tolerable, the patient may be treated with warm baths and bulk laxatives. Suppositories, which are placed proximal to the anorectal ring, are of no help. If, on the other hand, the thrombosis is acute, has lasted less than 48 hours, and is extremely painful, significant relief can be provided by clot excision.

Excision of Thrombosed External Hemorrhoid **Excision of thrombosed external hemorrhoids should not be performed in the ED on immunocompromised patients, children, pregnant women, patients with portal hypertension, and those who are anticoagulated or have a coagulopathy.** Obtain optimal exposure by placing the patient in the side-lying or prone position. The area of the overlying skin to be incised is infiltrated using a 30-gauge needle with a local anesthetic such as bupivacaine 0.5%, with epinephrine (1:200,000), and bicarbonate buffering. An elliptical incision distal to the anal verge in the overlying skin will expose the thrombosis. Remove the clot through the incision site. Because multiloculated clots can be present, the technique of unroofing a thrombosed hemorrhoid with an elliptical incision and removing the overlying skin gives far better results than the simple incision and evacuation of a clot (**Figure 85-9, A–C**).

Control the bleeding by tucking the corner of a small piece of gauze into the wound and leaving it in place for a few hours. A small pressure dressing may be applied external to the gauze and removed when the patient takes the first warm bath in 6 to 12 hours. Narcotics may be prescribed, but they cause constipation and may produce more problems. Complications, such as continued bleeding, recurrence, infection, fistula, and abscess formation, may occur; thus follow-up in 24 to 48 hours is recommended. Referral for definitive hemorrhoidectomy is prudent. Recently, small studies suggest that patients with acutely thrombosed internal or external hemorrhoids can be treated with topical nifedipine and 1.5% lidocaine ointment or isosorbide dinitrate ointment with surgical follow-up.[2,3]

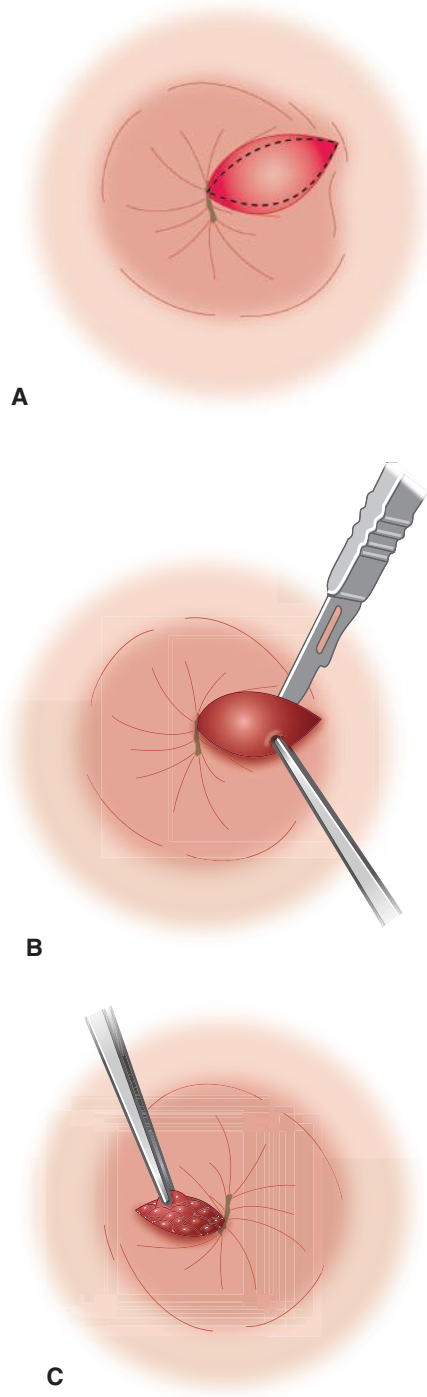

FIGURE 85-9. Excision of a thrombosed external hemorrhoid. **A.** Elliptical incision. **B.** Unroofing of thrombosed external hemorrhoid. **C.** Evacuation of clot.

ANAL FISSURES

ANATOMY

An anal fissure is the result of a superficial linear tear of the anal canal below the dentate line and extending distally to the anal verge (**Figure 85-10**). Acute fissures are present for less than 6 weeks; fissures are chronic if they persist longer. The mucosa of the anal canal has a rich supply of somatic sensory nerve fibers. Chronic anal fissures are pale in color with edema of the surrounding tissues. Fissures persist because of the severe, chronic, internal sphincter spasm that may occur along with development of a secondary infection at its base. The fissure edges become fibrotic and raised, possibly exposing sphincter fibers, hypertrophic papillae proximally, and the characteristic sentinel tag distally. The latter is frequently misdiagnosed as an external hemorrhoid when, in actuality, it is the result of edema and fibrosis secondary to the ulcerating fissure. The fissure may become inflamed and form a perianal or intersphincteric abscess that may drain into the anal canal or in the posterior midline externally.

CLINICAL FEATURES

Anal fissures are usually single and occur in the midline posteriorly in 80% to 90% of cases.[4] The posterior location of anal fissures may be because of the posterior angulation of the rectum on the anus where the posterior midline of the anorectal canal becomes the "lesser curvature" for the passage of stool. Anterior anal fissures are associated with younger age (33 years versus 41 years for posterior fissures), female sex, obstetric trauma, and occult external anal sphincter injury.[5] A chronic nonhealing fissure, lasting more than 6 weeks, or one not located in the midline should arouse suspicion that another, potentially serious cause may be involved. Such diagnostic possibilities include Crohn's disease, chronic ulcerative colitis, squamous cell carcinoma of the anus, adenocarcinoma of the rectum invading the anal canal, localized anal cancers such as Bowen's disease and extramammary Paget's disease, leukemia, lymphoma, syphilitic fissures, chlamydia, gonorrhea, human immunodeficiency virus, and a tuberculous ulcer. Consideration of these diagnoses requires referral for diagnostic biopsy of the ulcer edge, culture of the anal canal, and a systemic evaluation. Fissures due to Crohn's disease are multiple, off midline, and asymptomatic more commonly than the general population.[6] Most often, the traditional midline anal fissure is caused by the trauma produced by the passage of a particularly hard and large fecal mass, but it also may be seen after frequent acute episodes of diarrhea. Children with constipation will commonly complain of painful defecation only to find an anal fissure upon closer inspection (Figure 85-10A). Child abuse should be considered as a possible cause (Figure 85-10B).

A

B

FIGURE 85-10. Anal mucosal fissures. A. Constipation. B. Sexual assault. [A: Photo contributor: Paul J. Kovalcik, MD. Anal fissures are characterized by tearing pain with defecation and rectal bleeding. The pain may persist as a dull ache and burning sensation for a few hours after each bowel movement. Invariably it subsides between movements, which is a feature that distinguishes fissures from other forms of painful anorectal disease. The bleeding is bright red and small in quantity, usually being noticed only on the toilet paper. In infants, the presence of small amounts of bright red blood on the stool or toilet paper is usually the presenting complaint from an anal fissure. Sphincter spasm and pain may be severe enough to make the patient retain stool and avoid defecation. The diagnosis of an anal fissure is usually suggested by the history, but the anal area must be examined in all cases. Fissures may often become more noticeable if the patient bears down as if having a bowel movement. With the patient relaxed, gentle separation of the buttocks will often expose the fissure. The mere retraction of the buttocks and the anal skin may cause considerable spasm and discomfort and may not permit digital examination. Topical 2% lidocaine jelly may provide some relief for examination, but severe pain may require sedation. If the fissure can be visualized and is present in the posterior midline, rectal examination can be deferred until the patient is having less spasm and pain.

TREATMENT

Healing is by the development of granulation tissue and the re-epithelialization of the ulcerated area. Most uncomplicated acute fissures will heal in a few weeks, but relapse can be as high as 50%. If healing does not occur within 6 weeks or relapses are frequent, surgical referral is recommended. Treatment is aimed at providing symptomatic relief, extinguishing the anal sphincter spasm, and preventing stricture formation. Warm baths for at least 15 minutes three to four times a day and after each bowel movement along with stool softeners may suffice. The addition of fiber to the diet will serve to prevent stricture formation by providing a bulky stool. Warm baths and increased fiber will result in healing in about half of all anal fissures.[6] Topical lidocaine ointments and 1% hydrocortisone creams may provide symptomatic relief. Medical therapies for anal fissure are generally no more effective than placebo, and for chronic fissures, all medical therapies are less effective than surgery.[7,8]

ANAL STENOSIS

Anal stenosis occurs when the pliable tissue is replaced by scarred fibrotic tissue. Congenital and primary causes may occur, yet secondary causes are more common. Stenosis most commonly occurs after surgical hemorrhoidectomy.[4] Other causes include radiation, fistulectomy, trauma, inflammatory bowel disease, chronic laxative use, sexually transmitted diseases, and chronic diarrhea.

CLINICAL FEATURES

Typical complaints include constipation, bleeding, pain with stool evacuation, and narrow-caliber stools. As stenosis progresses, performing a digital exam with the little finger is met with severe resistance. Incontinence secondary to overflow constipation may occur. Careful specialist examination, often with sedation, may be necessary.

TREATMENT

Treatment involves stool softeners, fiber supplementation, and daily gradual anal dilatation after initial dilatation in the operating room. Stricturotomy and stricturoplasty are used when conservative management has failed.

CRYPTITIS

Anal crypts are superficial mucosal pockets that lie between the columns of Morgagni. Formed by the puckering action of the sphincter muscles, crypts normally flatten out during the passage of a stool. Sphincter spasm and superficial trauma caused by repeated bouts of diarrhea or chronic constipation may cause breakdown in the mucosal lining of the crypts, leading to cryptitis. Infecting organisms enter crypt pockets, and inflammation extends into the lymphoid tissue of both the crypts and anal glands. Cryptitis could well be the common denominator for the development of fissure-in-ano, fistula-in-ano, and perirectal abscesses (**Figure 85-11, A and B**).

Visualized by anoscopy, the anal papillae appear as slight projections of pink epithelium that produce the serrated appearance of the dentate line. Initially, the locally inflamed crypts are asymptomatic, producing a bead-like spot of pus. Inflammation of the crypts extends to the adjacent papillae. Hypertrophied anal papillae may be palpated as small, hard nodules and are associated with cryptitis.

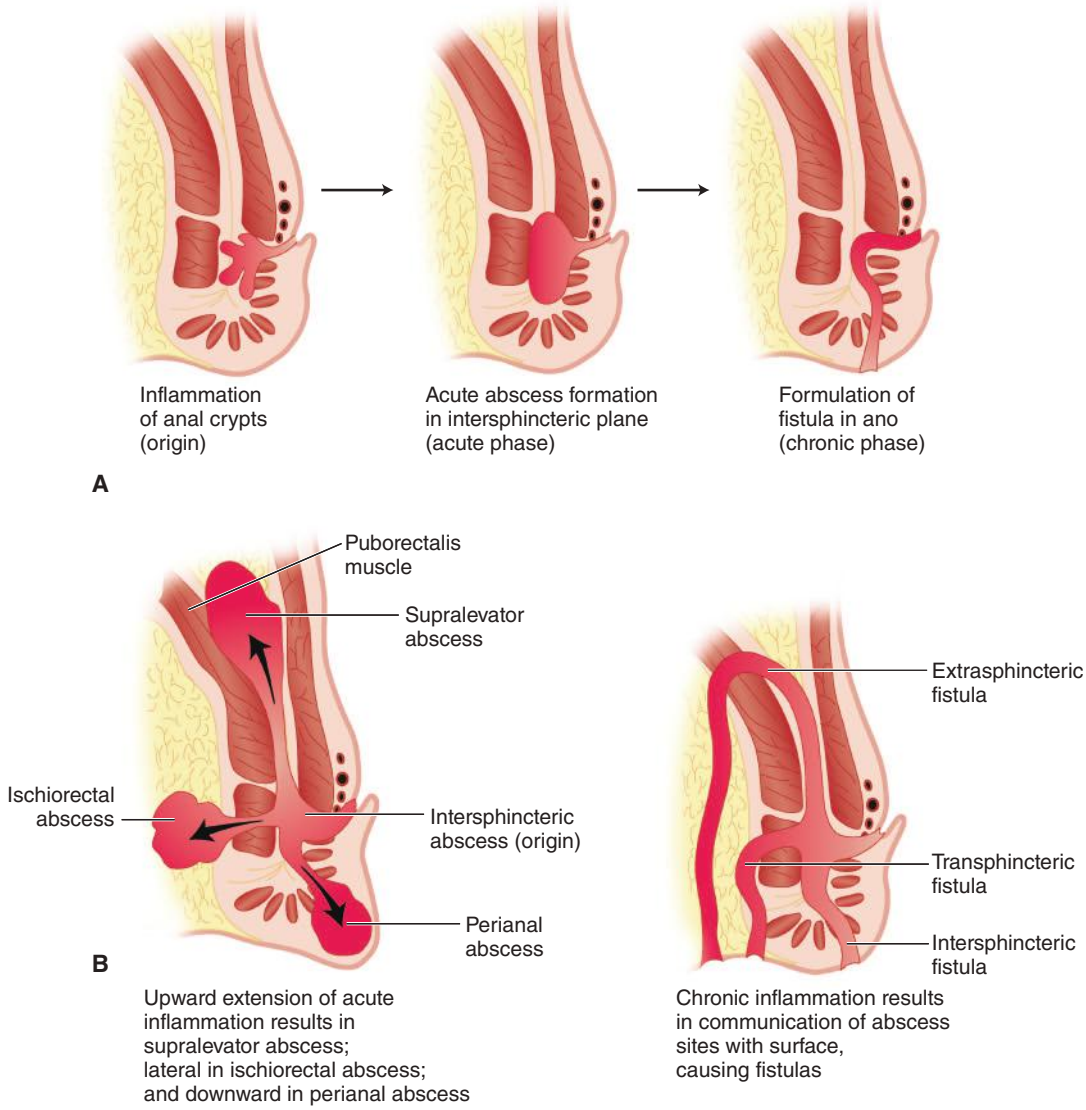

FIGURE 85-11. A, B. Illustration of the mechanism for anorectal abscess and fistula formation.

CLINICAL FEATURES

Anal pain, spasm, and itching with or without bleeding are the cardinal signs and symptoms of cryptitis. Rarely, papillae may hypertrophy and present as a prolapsing polypoid tumor. **The crypts most commonly involved are in the posterior half of the anal ring and, in most cases, in the posterior midline, the same location where anal fissures occur.** The definitive diagnosis of cryptitis is made by visualization of the erythema, inflammation, and pus during anoscopic examination.

TREATMENT

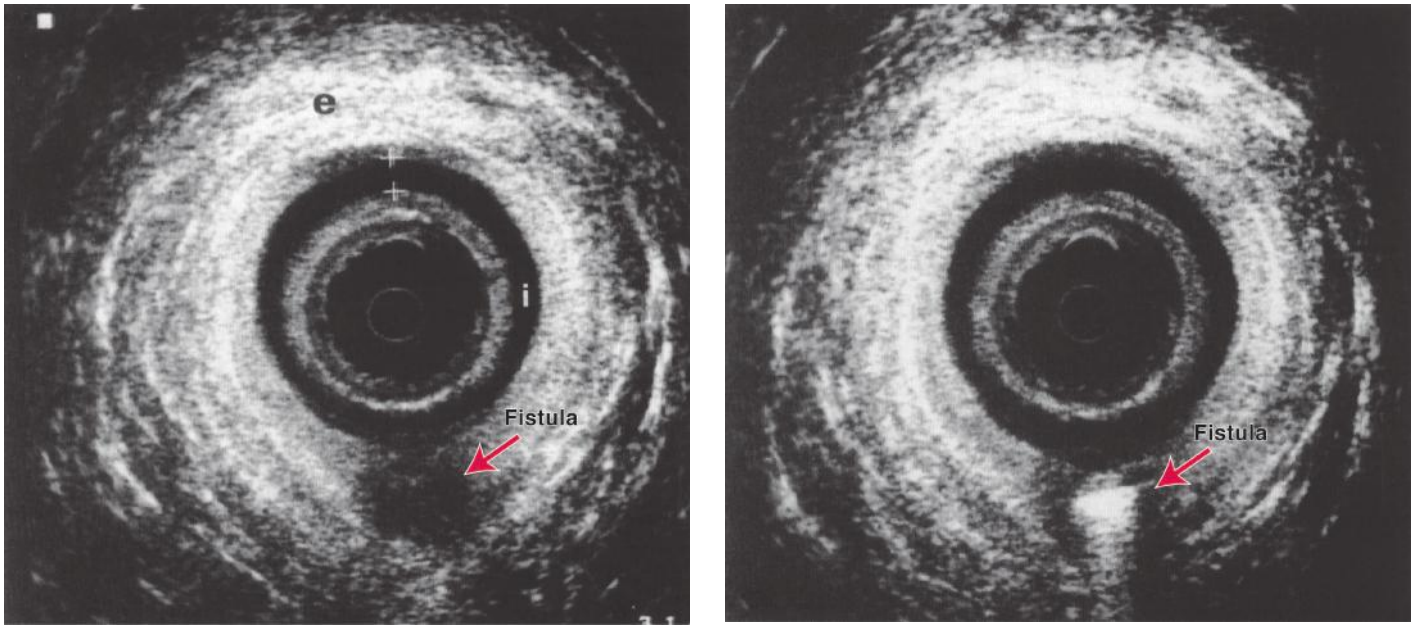
Treatment when the patient is symptomatic includes bulk laxatives and additional roughage added to the diet to produce formed, soft stools. Warm baths enhance healing by keeping the anus clean and the crypts empty. Refer to a surgeon for drainage when the infection has progressed and there is a deep, redundant crypt that will not drain adequately on its own. Cryptitis may be associated with underlying infections from parasites, inflammatory disorders, and localized trauma.

FISTULA-IN-ANO

Fistula-in-ano may result after drainage of an anorectal abscess. Fistulas may also be associated with ulcerative colitis, Crohn's disease, colonic malignancies, radiation, leukemia, sexually transmitted disease, actinomycosis, anal fissures, foreign bodies, or tuberculosis. Fistula-in-ano originates from an infected crypt and tracks to the skin. Fistulas are characterized according to the relationship to the anal sphincter: submucosal, intersphincteric, suprasphincteric, transsphincteric, or extrasphincteric (Figure 85-11). Goodsall's rule is used to help determine the location of the internal opening. Although anterior-opening fistulas tend to follow a simple, direct course to the anal canal, posterior-opening fistulas may follow a devious, curving path, including some that are horseshoe-shaped, opening in the posterior midline.

CLINICAL FEATURES

Open fistulous tracts may produce painless, blood-stained mucus, perianal itching, and malodorous discharge. If the tract becomes blocked, inflammation may be followed by spontaneous rupture or abscess formation. Abscess formation is associated with throbbing pain that is constant and worsened by sitting, moving, and defecation. Induration or a fibrous cord (more chronic fistula) may be palpated. A fistulous opening adjacent to the anal margin suggests a more superficial connection from the intersphincteric region. An opening more proximal to the anal margin suggests a deeper, more superior abscess. US using a 7.0-MHz endoprobe and enhanced with a hydrogen peroxide solution has been used to identify fistulas more easily.[9] In one study, endoscopic US was more accurate than CT scan (82% vs 24%) in the evaluation of perirectal fistulas, although it was comparable to MRI (91% vs 87%)[9] (**Figure 85-12, A and B**).



A B

FIGURE 85-12. A. Transanal US, simple transsphincteric fistula. The dark hypoechoic area (*arrow*) is visible dorsally in the external anal sphincter. B. Transanal US after infusion of hydrogen peroxide revealing a hyperechoic fistula (*arrow*). e = external sphincter; i = internal sphincter.

TREATMENT

Give analgesics, IV fluids, antibiotics (ciprofloxacin and metronidazole), and antipyretics, and obtain surgical consultation to determine need for admission or to arrange surgical follow-up. Definitive treatment may involve placement of a drain through the fistula, fibrin glue (fibrinogen, thrombin, and calcium), fistulotomy, fistulectomy, or more complex procedures. Improperly excised fistulas may result in permanent fecal incontinence. Monoclonal antibody use may be considered in patients with Crohn's disease.

ANORECTAL ABSCESSES

Almost all abscesses begin with involvement of an anal crypt and its gland. Abscesses are typically polymicrobial with both aerobic and anaerobic bacteria. Infection with *Staphylococcus aureus, Streptococcus* and *Enterococcus* species, *Escherichia coli, Proteus,* and *Bacteroides* can progress to involve any of the potential spaces that are normally filled with fatty areolar tissue with little inherent resistance to the progression of infection. These spaces include the perianal, submucosal, intersphincteric, ischiorectal, and postanal (connecting the ischiorectal space on each side posteriorly), and the supralevator (pelvirectal) (**Figure 85-13, A and B**).

A variety of diseases and other conditions are less commonly associated with the development of abscesses, including Crohn's disease, carcinoma of the anorectum and adjacent organs, trauma, ulcerative colitis, radiation fibrosis, Hodgkin's disease, tuberculosis, gonococcal proctitis, *Chlamydia*, *Actinomyces*, herpes, lymphogranuloma venereum, and immunocompromised states. The perianal abscess occurs most commonly, and the supralevator abscess is the least common (**Figure 85-13, C and D**).

CLINICAL FEATURES

Located close to the anal verge, often posterior midline, the perianal abscess is a superficial tender mass, which may or may not be fluctuant (Figure 85-13, C and D). Ischiorectal abscesses, which are the second most common, traverse the external anal sphincter; tend to be larger, indurated, and well circumscribed; and are located more laterally on the medial aspect of the buttocks (Figure 85-13C). The patient may exhibit edema, fever, and anorexia. The deeper postanal abscess may not manifest cutaneous signs, but rectal pain and tenderness are invariably present (**Figure 85-14**). Anorectal abscesses are more common in early middle-aged males.

Isolated perianal abscesses are generally the only type of anorectal abscess that can be adequately treated in the ED (Figure 85-13, C and D). Surgical referral after drainage is suggested because fistula formation is not uncommon. Clinical evaluation of a perianal abscess is usually sufficient, but US localization may be helpful. If pain is out of proportion to physical findings or if the extent of the abscess is uncertain, CT or MRI is recommended. Ischiorectal abscesses can be problematic and complicated as the ischiorectal fossa forms a large potential space on either side of the rectum, communicating behind it through the deep postanal space. These abscesses may be palpable through the rectal wall or on the overlying skin. Intersphincteric, submucosal, postanal, and supralevator abscesses may not demonstrate edema but are often associated with constitutional symptoms. Infections in this area are insidious and extensive and can spread to an area some distance from the anal verge. If a complicated abscess is suspected, obtain CT or MRI (**Figure 85-15, A–D**). US may be useful to diagnose intersphincteric and submucosal abscesses, whereas CT and/or MRI are capable of detecting those as well as deeper abscess formations such as supralevator and ischiorectal rectal abscesses.

Perianal abscesses are easily palpable at the anal verge, whereas deeper perirectal abscesses may be palpated through the rectal wall or more lateral to the anal verge, on the buttocks. Initially, the patient notices a dull, aching, throbbing pain that becomes worse immediately before defecation, is lessened after defecation, but persists between bowel movements. Pain is exacerbated by movement and sitting. Perianal abscesses, unlike more complicated perirectal abscesses, are usually not accompanied by fever, leukocytosis, and sepsis in the immunocompetent patient. Pain is aggravated by straining or coughing, particularly when due to intersphincteric abscesses. **Ischiorectal abscesses** are often painful on rectal examination and are lateral to the anal verge. **Intersphincteric abscesses**, painful with defecation, may be associated with rectal discharge and fever, and a tender mass may be palpable on digital examination of the rectal canal, often in the posterior midline. **Supralevator abscesses**, often an extension of an intersphincteric abscess, frequently present with few outward signs. Generalized, nondistinct perirectal pain with fever, malaise, leukocytosis, and urinary retention may occur. Tender inguinal adenopathy is often a clue to these deeper abscesses. Supralevator abscesses may be palpable on vaginal examination.

FIGURE 85-14. CT scan, postanal abscess (*arrow*).

TREATMENT

All perirectal abscesses (ischiorectal, submucosal, intersphincteric, and supralevator) should be drained in the operating room (Figure 85-13E). Simple, isolated, fluctuant perianal abscesses may be drained in the ED using local anesthetics and, occasionally, procedural sedation. Adequate patient positioning, preparation, and good exposure are necessary. Lidocaine with epinephrine should be administered with a small-gauge needle. Needle aspiration (18-gauge) over the painful region may be done to localize the purulent pocket. US can delineate the size and depth of the abscess. Drainage can be accomplished with a linear or cruciate incision. If using a linear incision, loosely pack the abscess cavity with strips of gauze to prevent premature closure of the skin edges. To ensure adequate drainage, a cruciate incision can be made over the fluctuant

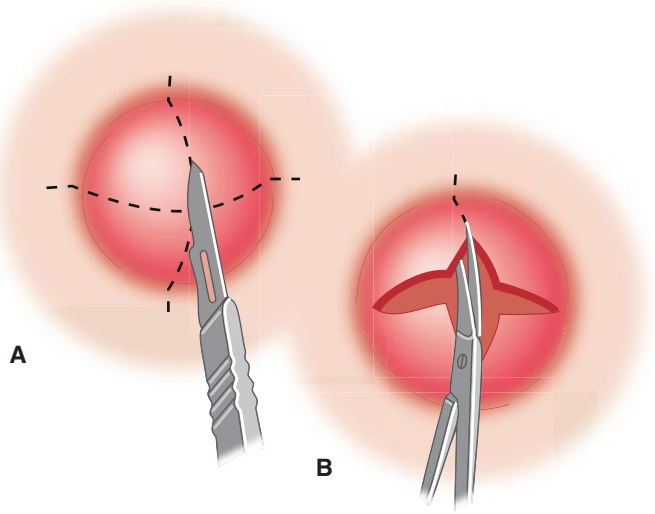

FIGURE 85-16. A and B. Technique to drain a perianal abscess.

part of the abscess. Trimming the flaps is suggested to prevent closure, and packing is not required (**Figure 85-16, A and B**).

Cover the wound with a bulky dressing, and have the patient take frequent warm baths starting the next day. Antibiotics are not necessary after adequate drainage in healthy patients. Provide ED follow-up in 24 hours, regardless of which type of incision is made, and consider surgical referral for definitive care. For the elderly or those with fever or leukocytosis, diabetes, valvular heart disease, cellulitis, or immunosuppression, give broad-spectrum antibiotics (piperacillin-tazobactam, 3.37 grams IV every 6 hours; or ampicillin-sulbactam, 3 grams IV every 6 hours), obtain surgical consultation, provide tetanus prophylaxis as needed, and admit to the hospital.

PROCTITIS

Proctitis is inflammation of the rectal mucosa. Clinical manifestations often include anorectal pain, itching, discharge, ulcers, diarrhea, bleeding, or lower abdominal cramping. Anoscopic examination may reveal mucosal inflammation, erythema, bleeding, ulcerations, and/or discharge. Proctitis may develop from prior radiation treatments, autoimmune disorders, vasculitis, ischemia, and infectious diseases (enteric pathogens and sexually transmitted infections (**Table 85-2**).

If the patient has an anorectal infection caused by one of the sexually transmitted infection organisms, assume that another may be present. Screen for other sexually transmitted infections; obtain appropriate blood tests, specimens from anoscopy for Gram stain, and viral and bacterial cultures; and start empiric therapy. For detailed discussion of sexually transmitted infections, see chapters 149, "Sexually Transmitted Infections" and 252, "Skin Disorders: Groin and Skinfolds."

CONDYLOMATA ACUMINATA

Condylomata acuminata, commonly known as *anal warts*, are often caused by human papillomavirus types 6 and 11.[10] Lesions begin as discrete, soft, fleshy growths on the perianal skin and the squamous epithelium of the anal canal. They may vary from dot-like to larger papilliform, cauliflower-like lesions. With time, pain, itching, bleeding, and anal discharge become part of the symptom complex. Perianal involvement is often associated with vulvovaginal and penile lesions. Optimal treatment is referral to an appropriate specialist for laser ablation, cryotherapy, electrocautery, immunotherapy, or surgical excision. **Anorectal carcinoma and cervical and orogenital cancer are associated with human papillomavirus types 16 and 18.**

*Treponema pallidum**	Human papillomavirus

**Most common sexually transmitted pathogens*

GONORRHEA

Surprisingly most women and about 50% of men with anorectal gonorrhea are asymptomatic.[10] Classically, patients experience tenesmus with profuse yellow, bloody discharge, which usually begins about 1 week after exposure. Patients in the acute phase generally have mild burning and/or pruritus with some purulent seepage. Anoscopic examination during this phase of the disease reveals marked hyperemia and edema of the rectal mucosa and diffuse inflammation with purulent discharge from the anal crypts. Unlike nonvenereal cryptitis, infection is not confined to the posterior crypt. Diagnosis is made by Gram stain, cultures, and nucleic acid amplification tests. Dissemination involving the heart, liver, CNS, and joints should be considered. Treatment is with ceftriaxone, 250 mg IM, and azithromycin, 1 gram PO once, or doxycycline, 100 milligrams PO twice a day for 7 days.

CHLAMYDIA

Chlamydia trachomatis causes both urogenital and anorectal infections. The lymphogranulomatous variety, serovars L1, L2, and L3, occurs mainly in the tropics. Infection can involve the rectum by perirectal lymphatic invasion from vaginal seeding or from direct anorectal mucosal infections. The nonlymphogranulomatous variety, serovars D to K, may infect the rectal mucosa, although it does not cause the extensive rectal scarring and stricturing that its lymph gland–invading cousin from the tropics does. A patient with chlamydial proctitis may be asymptomatic or may present with anal pruritus, pain, bleeding, tenesmus, and purulent discharge. The more severe form of proctitis occurring with this infection is usually due to the lymphogranulomatous type of chlamydia. Signs include fever, flulike symptoms, and prominent unilateral lymph node enlargement. Perirectal abscesses and chronic fistulas may develop. Red, friable mucosa and acutely painful anal ulcerations may be seen on anoscopy. Testing is not commonly available, and treatment is based on clinical findings. Treatment for nonlymphogranulomatous chlamydial proctitis includes azithromycin, 1 gram PO once, or doxycycline, 100 milligrams PO twice a day for 7 days. Treatment for lymphogranulomatous chlamydial infections includes doxycycline, 100 milligrams PO twice a day for 21 days, or erythromycin, 500 milligrams PO four times a day for 21 days.

SYPHILIS

The causative agent of syphilis is the spirochete *Treponema pallidum*. Chancres that form a few weeks after infection are the characteristic lesion of primary syphilis and usually manifest themselves at the anal verge or in the anal canal. Rectal mucosal involvement is uncommon, and at times, the chancre may be absent. **Syphilitic chancres may be misdiagnosed as a simple fissure because anal chancres are often very painful.** A symmetric lesion on the opposite side of the anal margin and inguinal adenopathy may be present. Condyloma lata are large, raised, flat, grey or white lesions. They appear in the perianal region as a manifestation of the secondary stage of syphilis. The rapid plasma reagin and the Venereal Disease Research Laboratory tests are commonly used for screening, with confirmation with a *T. pallidum*–specific immunoassay. Current treatments include benzathine penicillin G (Bicillin L-A), 2.4 million units IM for one dose, or doxycycline, 100 milligrams PO twice a day, or tetracycline, 500 milligrams PO four times a day for 14 days.

HERPES SIMPLEX VIRUS

Anorectal herpes is more commonly caused by the type 2 herpes simplex virus. Symptoms occur within a few weeks after exposure and consist of itching and soreness in the perianal area, progressing to severe anorectal

TABLE 85-3 Anorectal Acquired Immunodeficiency Syndrome–Related Infections

Herpes simplex virus types 1 and 2	*Campylobacter*

Shigella	*Giardia*

pain. Early lesions are small, discrete vesicles on an erythematous base. Vesicles then enlarge, coalesce, and rupture, forming exquisitely tender ulcers on the perianal skin, the anoderm, and rectal mucosa. The pain and tenesmus from these lesions may be so intense that the patient develops severe constipation and difficulty urinating. The patient may develop a flulike illness with inguinal adenopathy noted on examination during the initial course of the illness. Symptoms persist for 1 to 2 weeks and are frequently recurrent, although less pronounced, during the ensuing year. Topical analgesia may be needed for adequate examination. Viral cultures, polymerase chain reaction, and immunofluorescent testing are helpful for diagnosis. Treatment consists of adequate pain medication, stool softeners, and acyclovir, 400 milligrams PO five times a day for 10 days for the initial episode, and 400 milligrams PO three times a day for 5 days for recurrent episodes. Suppression consists of acyclovir 400 milligrams PO twice a day. **Consider herpes simplex virus, syphilis, human immunodeficiency virus, chancroid, and donovanosis when anal ulcers are present.**

ANORECTAL ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED INFECTIONS

Patients rendered immunodeficient by human immunodeficiency virus are subject to a variety of opportunistic infections that affect the intestinal, anorectal, and other body systems (**Table 85-3**). Severe rectal pain, diarrhea, and hematochezia are common presenting symptoms. Anoscopy confirms anal canal ulcers and acute proctitis. Obtain serology for syphilis, and start antibiotic therapy.

Stool softeners, sitz baths, careful anal hygiene, and pain medications will provide some relief. Enteric pathogens may require antibiotics such as trimethoprim and sulfamethoxazole (*Isospora*), metronidazole (*Entamoeba*, *Giardia*), azithromycin (*Campylobacter*), acyclovir (herpes), or fluoroquinolones (*Salmonella, Shigella*). Provide empiric therapy against gonorrhea, nonlymphogranulomatous chlamydia, and incubating syphilis for human immunodeficiency virus–associated acute proctitis. Refer for appropriate follow-up, further evaluation, and definitive treatment.

RECTAL PROLAPSE

Rectal prolapse is the circumferential protrusion of part or all layers of the rectum through the anal canal. Basically, there are three types of rectal prolapse: (1) prolapse involving the rectal mucosa only, (2) prolapse involving all layers of the rectum (complete), and (3) intussusception of the upper rectum into and through the lower rectum so that the mucosal apex of the intussusception nearly extends to the anus (incomplete) (**Figure 85-17**).

Rectal prolapse in children is generally mucosal and occurs more commonly in males less than 3 years old. The prolapse may appear as a painless, maroon-colored, protruding mass with possible mucus and blood. The mucosal prolapse rarely protrudes more than 5 cm beyond the anal verge.[11] With children, parents often mistakenly believe that the prolapsed mucosa is a hemorrhoid. Mucosal prolapse is believed to occur due to a lack of the natural sacral curve reducing the anorectal angulation. With increased intra-abdominal pressure from coughing, diarrhea, vomiting, and straining, mucosal prolapse can develop. Incomplete and full-thickness prolapses occur because of the laxity of the pelvic fascia and muscles in addition to a generalized weakening of the anal sphincters.

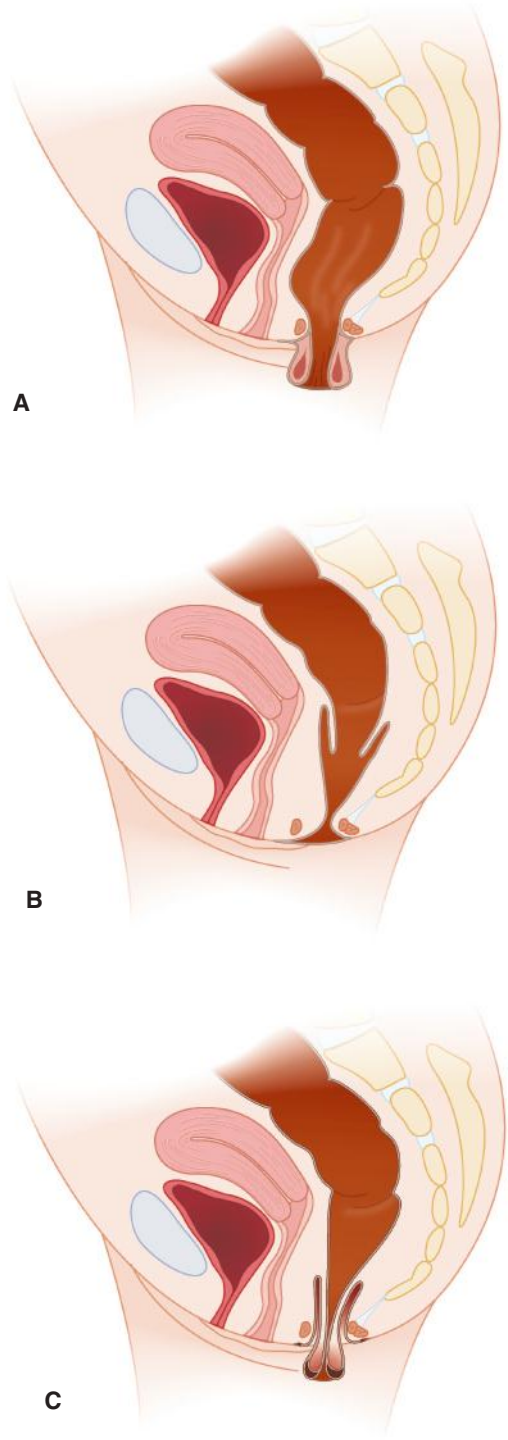

FIGURE 85-17. Rectal prolapse. A. Mucosal prolapse. B. Partial (incomplete) prolapse. C. Full-thickness prolapse.

CLINICAL FEATURES

Patients with partial prolapse may experience stool seepage or constipation. With more advanced cases, patients are able to detect the presence of a mass, especially after defecation or strenuous activity, or even with standing or walking. Irritation to the rectal mucosa caused by recurrent prolapse results in a mucous discharge along with bleeding. Associated anal sphincter weakness may result in fecal incontinence. With complete prolapse, the anus appears normal in contrast to a mucosal prolapse in which the anal edges appear everted. **Pain is not a significant feature with complete prolapse, but abdominal or pelvic discomfort may**

be present.[11] Digital rectal examination reveals a thick muscular wall with decreased tone, in contrast to a much thinner wall from a mucosal prolapse. Complete prolapse appears as a red, ball-like mass, with concentric folds in the protruding mucosa (**Figure 85-18, B and C**). Prolapsing internal hemorrhoids may be confused with mucosal or rectal prolapse. A distinguishing feature of prolapsed hemorrhoids are the radially directed folds (**Figure 85-18A**). With complete prolapse, a sulcus may be palpated between the extruded bowel and anus, compared to no sulcus with a mucosal prolapse.

TREATMENT

In young children, after appropriate analgesia and sedation, the prolapse can be reduced manually by first gently spreading the buttocks and then replacing the protruding mucosa, proximal to the anorectal ring of sphincter muscles, with a slow, steady pressure applied to the prolapsed segment. Digital rectal examination should then be performed. Every effort should be made to prevent constipation. **Refer the child for further evaluation due to a possible underlying condition such as cystic fibrosis, polyps, pelvic floor weakness, diarrhea, and malnutrition.**

In adults, a complete prolapsed rectum can sometimes be reduced with gentle continuous pressure, which may take several minutes. The buttocks may be taped apart while the prolapsed segment is grasped in such a way that the thumbs are placed over the luminal surfaces medially while the fingers grasp the outer walls laterally. Continuous pressure, starting with the thumbs followed by an internal rolling force of the fingers, will aid in reduction (**Figure 85-19**).

After reduction, perform a digital rectal examination to ensure that reduction is complete and to evaluate for a rectal mass or polyp. Obtain surgical consultation for repair, or refer for colonoscopy and dietary changes depending on the clinical circumstances.

Once the rectal walls become edematous, reduction is difficult. Prolonged prolapse may lead to venous engorgement, thrombosis, superficial ulcerations, rectal incarceration, strangulation, and ischemia. **An effective technique is the early application of generous amounts of granulated sugar over the entire prolapsed segment. Synthetic sweeteners are not effective. After 15 minutes or so of sugar application, the edema reduces, allowing for easier prolapse reduction.**[12] Gauze with lubricant can be placed over the anal verge after reduction and taped in place for a few hours. If the prolapse cannot be reduced, is severe, or recurs after reduction, or if ischemia or gangrene of the prolapsed segment is suspected, emergency surgical consultation and hospitalization are needed for reduction or surgical treatment (rectopexy).

ANORECTAL TUMORS

Carcinoma of the anal area is uncommon. Factors such as smoking, anal intercourse, human immunodeficiency virus, and human papillomavirus, particularly types 16 and 18, resulting in genital warts, have been associated with the development of anorectal cancer (**Figure 85-20**).

At the level of the dentate line and extending approximately 1 cm proximal is a transitional zone of epithelium connecting the squamous cell epithelium of the anoderm with the columnar epithelium of the rectum. This transition zone includes columnar, cuboidal, transitional, and squamous epithelial cells that represent the source for a variety of malignancies that arise in the anal canal. Anorectal malignancies can generally be divided into two regions: (1) malignancies of the portion proximal to the dentate line and including the transitional zone, which are referred to as *anal canal neoplasms*, and (2) tumors arising in the anoderm distal to the dentate line, which are referred to as *anal margin neoplasms* (**Table 85-4**).

Anal margin neoplasms have a low-grade malignant potential and are slow to metastasize, with the exception of melanoma. Anal canal neoplasms are far more virulent, metastasize early, and have a poor prognosis. Squamous cell carcinoma of the anal canal has a much poorer prognosis than its anal margin counterpart. Anal margin neoplasms generally metastasize to femoral and inguinal lymph nodes, whereas anal canal malignancies metastasize to the perirectal, mesenteric, and paravertebral lymph nodes via the portal circulation. **The anal canal is the third**

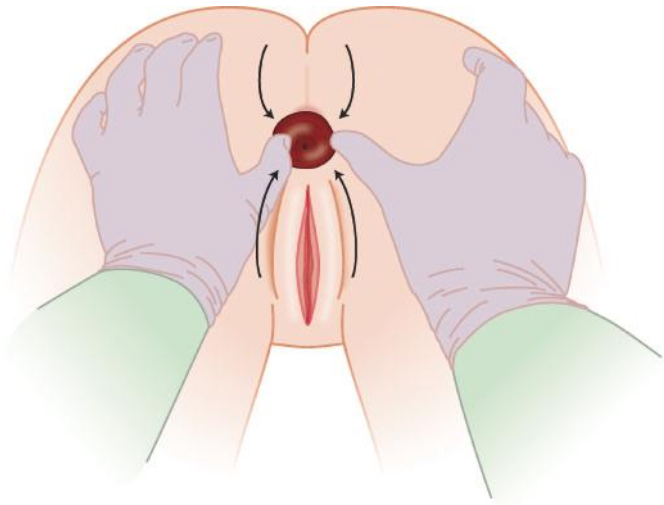

FIGURE 85-19. Reduction of complete rectal prolapse.

most common site of malignant melanoma (after the skin and the eye), which, when it occurs there, may not be pigmented and is frequently missed.

CLINICAL FEATURES

Early anal canal malignancies usually cause nonspecific symptoms, such as pruritus, pain, and bleeding admixed with stool, but may be asymptomatic. Rectal pain may also be referred from retrorectal tumors and pelvic vessel aneurysms. As the tumor progresses, rectal fullness develops. The sensation and presence of a lump in the anal canal may be erroneously diagnosed as a hemorrhoid. As the neoplasm progresses, the patient experiences anorexia, bloating, weight loss, diarrhea, constipation, narrowing of the caliber of the stool, and, eventually, tenesmus with or without a bowel movement. Anal canal tumors may produce partial rectal prolapse and hemorrhoidal dilatation. More advanced

TABLE 85-4 Anorectal Tumors

Anal Canal Neoplasms	Anal Margin Neoplasms
Adenocarcinoma of glands and ducts	Bowen's disease
Transitional cell carcinoma	Squamous cell carcinoma (SCC)
Melanoma, SCC	Basal cell carcinoma
Kaposi's sarcoma	Melanoma
Villous adenoma	Paget's disease

malignancies may present as perirectal abscesses, fistulas, and bloody mucous discharge. Villous adenomas, which arise from the rectal columnar epithelium, frequently produce clear, watery diarrhea and a profuse rectal discharge, with secondary excoriation of skin and pruritus. Watery diarrhea may cause hypokalemia or hyponatremia. Anal margin neoplasms tend to be circumferential and may present with bleeding, persistent ulcers, or chronic dermatologic conditions such as eczema or mycotic infections. Any ulcer that fails to heal within 30 days or any discrete skin lesion that fails to improve with appropriate therapy must be biopsied to rule out the presence of malignancy. **Virtually all anorectal tumors can be detected by careful visual examination of the perianal area, digital palpation of the distal rectum and anal canal, and proctoscopic or sigmoidoscopic examination.**

Specific diagnosis and treatment require surgical consultation and referral.

RECTAL FOREIGN BODIES

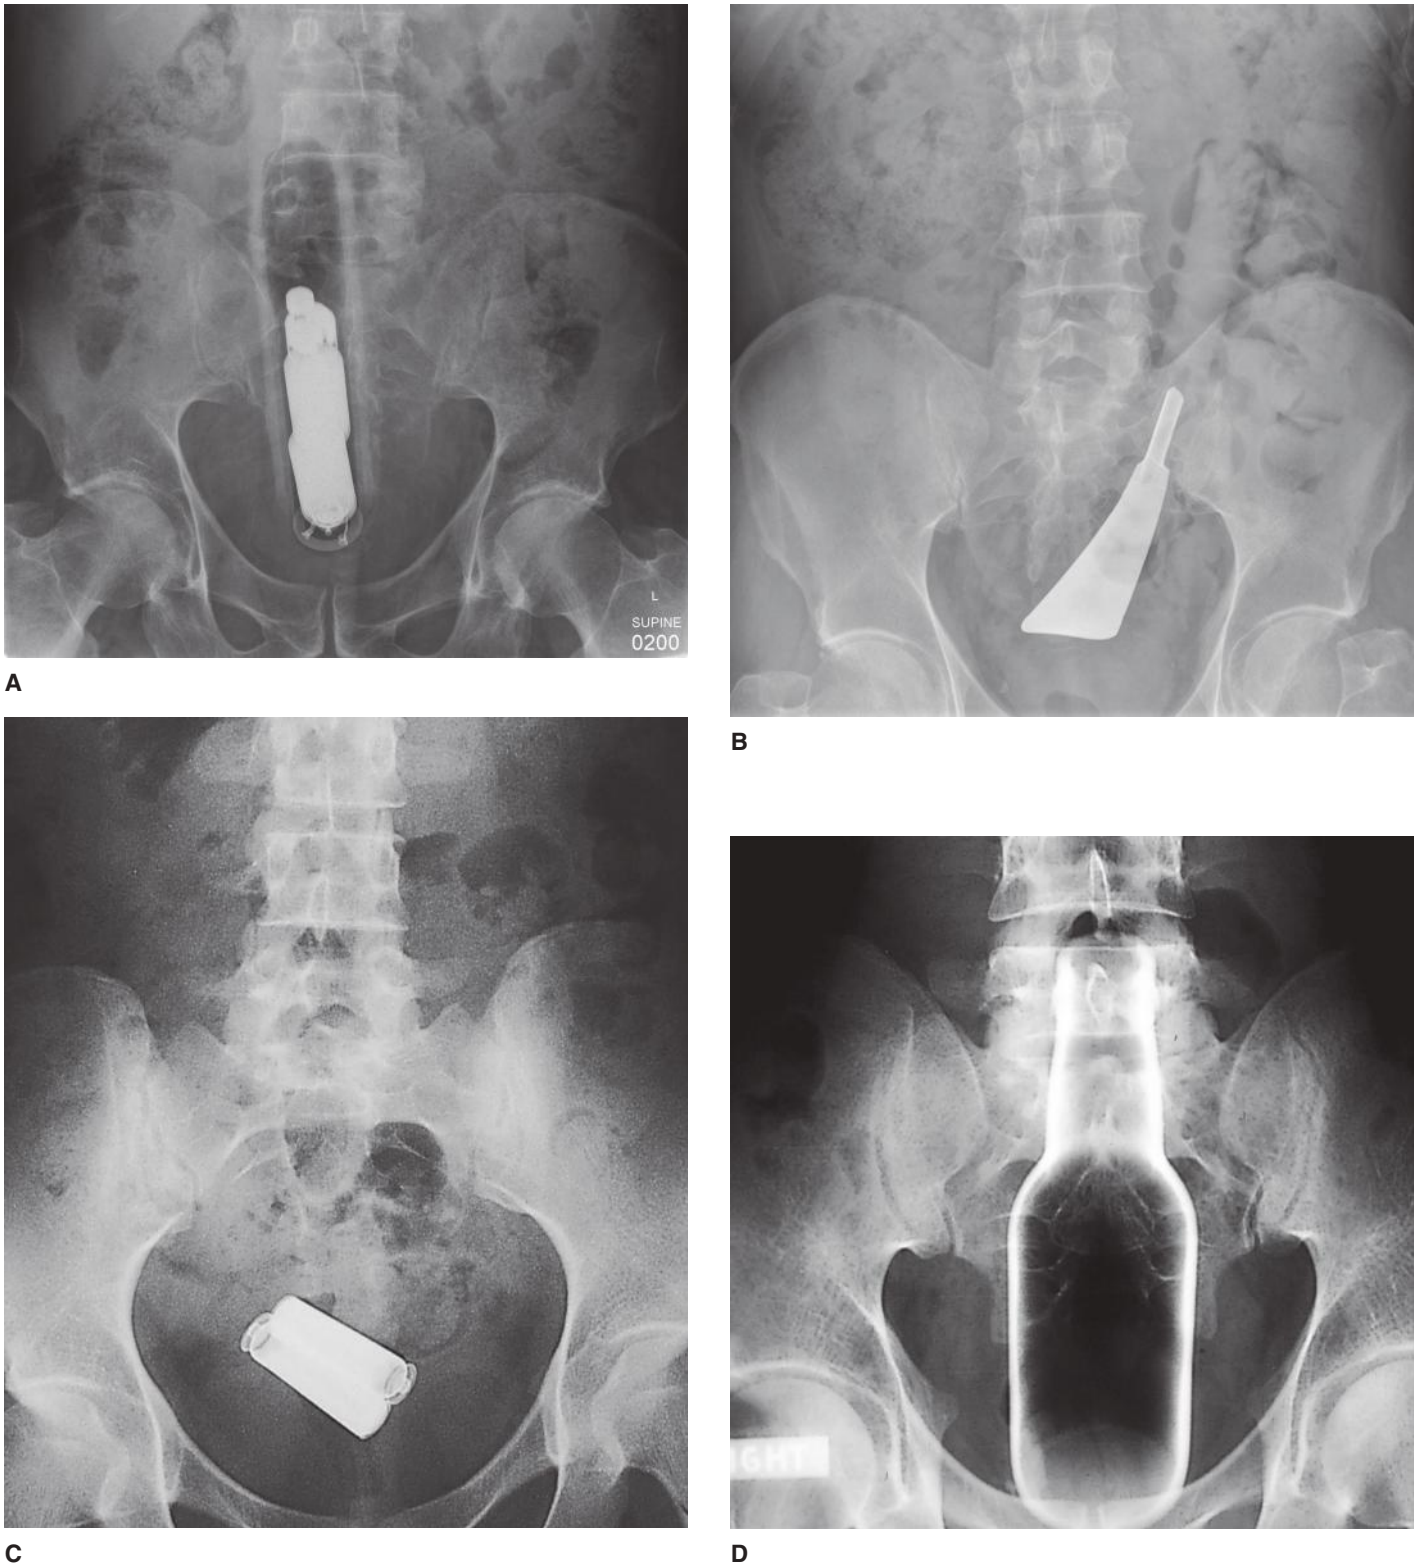
The medical literature is replete with the variety of foreign bodies that have been reported to have been inserted into the rectum (**Figure 85-21, A–D**).

CLINICAL FEATURES

Patients may complain of abdominal pain and cramping, anorectal bleeding, discharge, and discomfort and may not initially be forthcoming with an accurate history. Most foreign bodies are in the rectal ampulla and are therefore palpable through careful digital examination. Anoscopy may detect signs of trauma and should replace the digital exam when sharp objects are suspected. Foreign bodies lodged above the rectosigmoid junction are usually not palpable. Injuries may consist of hematoma formation, various lacerations with potential perforation, and ischemic segments (particularly a delayed presentation). X-rays of the abdomen may demonstrate not only the position, shapes, and number of foreign bodies, but also the possible presence of free air. Perforation of the rectum or colon, although uncommon, is a serious complication. Perforation of the rectum below the peritoneal reflection often causes retroperitoneal injuries, and plain radiographs may demonstrate extraperitoneal air along the psoas muscles. Perforation above the peritoneal reflection usually reveals intraperitoneal free air under the diaphragm noted on an upright chest x-ray. **CT scan is useful when the foreign body is radiolucent and for the detection of free air. Fever, leukocytosis, abdominal pain, rectal bleeding, and peritoneal signs are clinical manifestations suggestive of perforation.** Both can result in life-threatening sepsis, although perforation below the peritoneal reflection may be managed with more conservative therapy.

TREATMENT

Although some distal rectal foreign bodies can be removed by the emergency physician, many objects require surgical intervention, particularly if they are made of glass, have sharp edges, or show signs of perforation. Foreign bodies with greater success of being removed in the ED are those that are located in the mid to lower rectum. When assessing the likelihood of removal in the ED, determine the type of object inserted and likelihood of injury to the GI tract or sphincter from removal. Sims, lithotomy, or knee-chest position with application of suprapubic pressure while the examiner digitally grasps the foreign body may help expulse the foreign body. After anal lubrication and with the aid of obstetric forceps, ask the patient to assist extraction by bearing down



A

B

C

D

FIGURE 85-21. A–D. Rectal foreign bodies. [C and D: Photo contributor: Kevin J. Knoop, MD. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

(**Figure 85-22A**). If the foreign body is removed in the ED and is of a size or shape that could cause perforation or laceration, proctoscopic examination and x-ray studies must be performed. In questionable cases, observation for at least 12 hours should be done to ensure that perforation has not occurred. Rectal and anal lacerations may be present and require repair. For removal of large foreign bodies, surgical consultation or emergency colonoscopy by a gastroenterologist is usually required. Large bulbar objects create a vacuum-like effect in the rectal ampulla, making it difficult to retrieve the object by simple traction. The vacuum can be overcome by passing a 20- to 26-French, three-way catheter beyond the object and injecting up to 30 mL of air. Inserting Foley catheters around the foreign body may then be used as traction devices to deliver the foreign body or manipulate it into a more accessible position (**Figure 85-22B**). If there is a risk of sphincter injury,

ischemia, or perforation, or if excess manipulation will be needed to remove the foreign body (potential for bacteremia), obtain emergent surgical evaluation and appropriate laboratory studies, initiate IV therapy with crystalloid solution, and administer a broad-spectrum antibiotic (i.e., piperacillin-tazobactam, 3.37 grams IV every 6 hours).

PRURITUS ANI

Pruritus ani is a symptom complex that occurs secondary to a variety of anal and systemic problems (**Table 85-5**). Primary or idiopathic disease occurs when no cause is identified. **Pruritus ani is the second most common anorectal condition after hemorrhoids.**[13] It affects 1% to 5% of the population; men are affected four times more often than women; and it most commonly occurs in the fourth to sixth decades of life.[14]

CLINICAL FEATURES

Symptoms are often worse at night. The skin becomes macerated by constant mucous and purulent discharge. Bacterial infections, such as staphylococci and streptococci, in addition to all sexually transmitted organisms, can cause pruritus.

Pinworms (*Enterobius vermicularis*) are a common cause of anal pruritus in children. Institutionalized adults may also develop pinworms.[13] *Candida albicans*, particularly in diabetic patients, is commonly found on the perianal skin but is not usually associated with pruritus; the *Trichophyton* species, on the other hand, are associated with pruritus. **Fecal contamination resulting from loose bowel movements, diarrhea, and poor anal hygiene is a frequent irritant to the perianal skin.** Excessive anal cleansing and wearing of synthetic, tight-fitting underwear that retains moisture can cause pruritus. Any of the anal margin neoplasms may initially cause pruritus. Systemic conditions, such as diabetes mellitus, psoriasis, pemphigus, leukemia, lymphoma, thyroid disorders, hepatic diseases, renal failure, iron deficiency anemia, and certain vitamin deficiencies (vitamins A and D and niacin), because of their secondary effect on the perianal skin, can cause pruritus. Lumbosacral radiculopathy has been associated with idiopathic pruritus ani.[13] The skin appears normal with early, mild cases. Superficial cracks seen on examination do not extend to the dentate line, as do fissures. With acute, more severe exacerbations, the perianal skin will appear reddened, edematous, excoriated, and moist. In chronic cases, the perianal skin takes on a thickened, almost leathery, depigmented appearance. The normal radiating folds of skin thicken into rugae and may produce factitiously induced superficial fissures.

TREATMENT

Diagnose and treat the underlying cause. Perianal streptococcal dermatitis (**Figure 85-23**) is well known in children, where it can cause

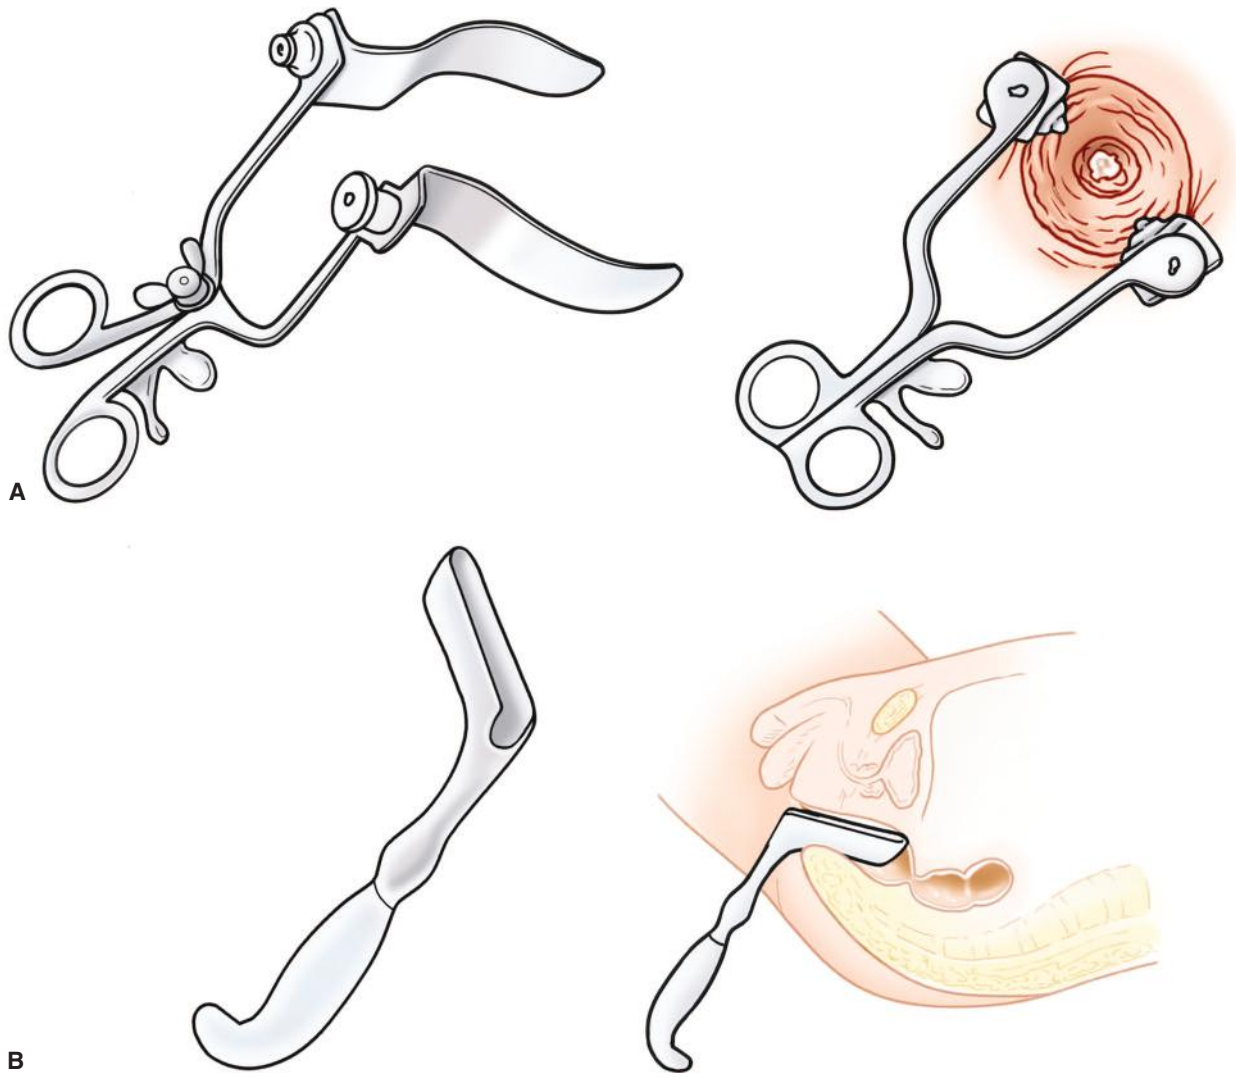


FIGURE 85-22. A. Foreign body exposure. B. Removal techniques. [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures,* 2nd ed. McGraw-Hill, Inc., 2013. Figures 72-3, 72-4.]

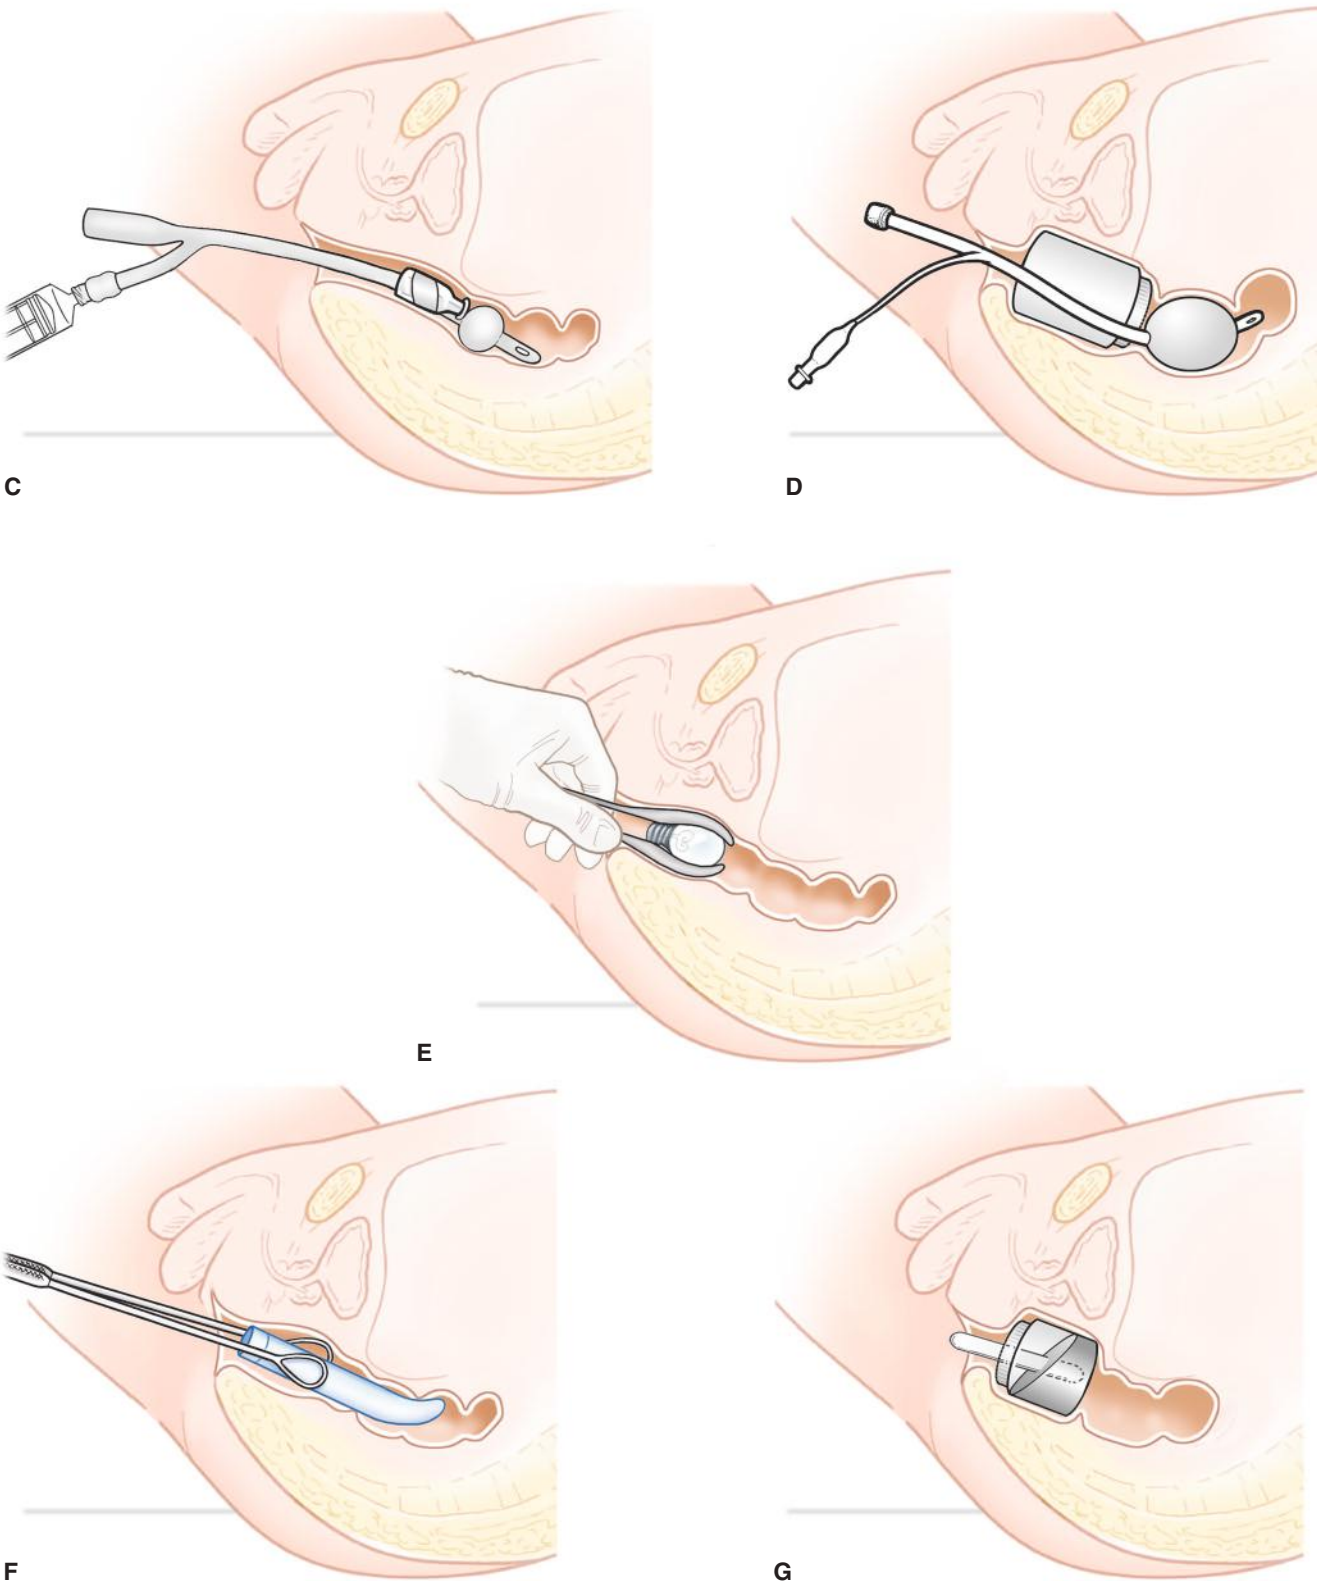

FIGURE 85-22. (*Continued*)

systemic infection, but is also recognized and can cause serious infection in adults. Obtain cultures and treat empirically with penicillin or erythromycin.[15] Pinworms can be identified by touching the perianal skin with transparent tape to collect the worm and then viewing under a microscope. Idiopathic causes may be treated by adding fiber to the diet, which can bulk the stools and help prevent persistent soiling and irritation when the patient is plagued by frequent loose stools. To avoid scratching at night, the patient can wear gloves at bedtime. Warm baths are recommended for at least 15 minutes two to three times a day for hygiene, instead of soap, followed by thorough drying. Zinc oxide ointment can provide a protective covering for the perianal skin and may promote healing, while athlete's foot powder may enhance drying.

TABLE 85-5 Some Secondary Causes of Pruritus Ani

Anorectal disease: Draining perirectal abscess, fissures, hemorrhoids, rectal prolapse, fistulas
Dietary factors: Caffeine, cola, calcium, chocolate, citrus, alcohol, tomatoes, spices, peanuts
Local infection: Bacteria, viruses, fungi, worms, lice, scabies, bed bugs, hidradenitis
Local irritants: Perfumed toilet tissue, soaps, detergents, hygiene sprays
Dermatologic: Atopic dermatitis, lichen planus, psoriasis, seborrheic dermatitis
Systemic illness: Diabetes, various malignancies, Crohn's disease, acanthosis
Psychogenic: Stress, obsessive compulsive disorder

One percent hydrocortisone cream is effective for the allergic component of the inflammation. Fungicidal creams, antibiotics, and antiviral and antiparasitic medications should be prescribed for patients with infectious causes. Hydroxyzine hydrochloride may be used as an effective bedtime sedative. Refer to a proctologist or dermatologist for resistant symptoms.

PILONIDAL SINUS

Pilonidal sinus is an acquired problem formed by the penetration of the skin by an ingrown hair, which causes a foreign body granuloma reaction. The sinus is perpetuated by the presence of the hair and repeated bouts of infection.

CLINICAL FEATURES

Pilonidal sinuses or cysts occur in the midline in the upper part of the natal cleft, which overlies the lower sacrum and coccyx. Because of their proximity to the anus, infected pilonidal cysts (abscesses) are sometimes mistakenly diagnosed as perirectal abscesses (**Figure 85-24, A–C**).

Occasionally, an inflamed cyst may refer pain to the coccygeal region. **An abscessed pilonidal sinus is almost always located in the posterior midline over the sacrum and coccyx.** Although there may be secondary fistulous openings on either side of the midline, they do not communicate with the anorectum. On the other hand, long, horseshoe-type fistulas emanating from a perirectal abscess may drain close to the location of a pilonidal sinus but not in the midline. Fistulous tracts most commonly ascend superiorly. Pilonidal disease may present as a painless cyst, an acute abscess, or chronic recurring cysts with draining sinuses. Alternate causes for draining fistulas should be considered, such as anal fistulas, syphilitic and tuberculous granulomas, simple furuncles, fungal infections, and sacral osteomyelitis. Carcinoma is a rare complication of

chronic, recurring pilonidal sinus disease. It is more frequent in men and is usually a well-differentiated, dermal-type squamous cell carcinoma.

TREATMENT

Treatment is incision and drainage, and antibiotics are needed only if cellulitis is present. Ultrasonography can delineate the extent of the abscess. Following incision and drainage in the ED, refer to a surgeon for definitive care.

HIDRADENITIS SUPPURATIVA

In postpubertal males and females (the second to fourth decades of life), the perianal surface containing hair follicles and apocrine sweat glands may become blocked, which generally occurs in the perineal, groin, axillary, or inframammary regions. Perineal disease is more common in males, whereas axillary disease is more common in females.[16]

CLINICAL FEATURES

Fistulas with a malodorous discharge may develop but do not extend to the intersphincteric plane, and the abscesses are quite superficial and do not originate at the dentate line. Fistulas that extend above the dentate line may suggest coexisting cryptoglandular or Crohn's disease.[16] Chronic inflammation, edema, tissue induration, fibrosis, and significant pitted scarring may occur (**Figure 85-25**).

TREATMENT

Recurrence is common, particularly in the perineal region, resulting in scarring, edema, painful nodules, induration, and draining sinus tracts, all of which are difficult to treat. Small abscesses can be drained in the ED, but extensive lesions require surgical or dermatologic referral. Topical clindamycin or oral clindamycin with rifampin can be helpful.[16] Other treatments include erythromycin, tetracycline, and doxycycline as well as retinoids, hormones, and immunosuppressive and anti-inflammatory agents. Some success is seen with radiation, cryosurgery, and laser treatments. With advanced disease characterized by recurrent abscesses, multiple interconnecting fistulas, and scarring, resection of the skin and subcutaneous fat down to the fascia yields the lowest recurrence rate.[16]

FIGURE 85-25. Perianal hidradenitis suppurativa in a 27-year-old man. Abscesses, draining sinuses, and scars are seen in the sacral region. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th ed. McGraw-Hill, New York, 2009.]

Gynecologic or surgical trauma or foreign body	Gynecologic malignancies
Pelvic irradiation	Leukemia
Local infection	Inflammatory bowel disease
Congenital	

RECTOVAGINAL FISTULA

The lower rectum and anal canal abut the posterior wall of the vagina, so the fistula may be located anywhere along this region.

CLINICAL FEATURES

The presenting complaint of patients with a rectovaginal fistula is usually flatulence and/or malodorous vaginal discharge or gross stool emanating from the vagina. They may note air or stool in the urine, or rectal urine. **Table 85-6** lists various causes. A rectovaginal fistula can arise from the rectum or small or large bowel. Usually, stool is seen during the pelvic examination. CT scan or MRI confirms the diagnosis. Surgical consultation is required.

CHAPTER 86

Gastrointestinal Procedures and Devices

Michael D. Witting

NASOGASTRIC ASPIRATION

Nasogastric (NG) aspiration is used to remove liquid contents from the stomach and decompress the stomach and small bowel. The need for NG aspiration often varies with the clinical presentation (**Table 86-1**). Gastric decompression is useful in small bowel obstruction, although some studies have shown that medical therapy with octreotide or somatostatin has allowed safe treatment of bowel obstruction associated with malignancy.[1,2] NG aspiration and decompression are no longer considered routine for the treatment of adynamic ileus.[3,4] **Removal of liquid contents is useful**

TABLE 86-1 Selection of Patients for Nasogastric Aspiration

Clinical Situation	Best Uses	Consider Withholding
GI bleeding with hematemesis	Rapid bleeding (large hematemesis, refractory hemodynamic instability)	Slow or mild bleeding (coffee grounds, blood-streaked emesis)
GI bleeding without hematemesis	Massive rectal bleeding with hemodynamic instability	Clinical picture suggests lower GI source (bright red blood per rectum, age >50 y, blood urea nitrogen/creatinine <30)[5]
Small bowel dilation	Small bowel obstruction	Ileus

TABLE 86-2 Complications of Placement of Nasogastric and Nasoenteric Tubes

Epistaxis

Vocal cord paralysis
Pneumomediastinum
Laryngeal injuries
Knotting (preventing removal)

in cases of GI bleeding, but not all patients with GI bleeding require NG aspiration.

In GI bleeding, a common and controversial situation for NG aspiration,[6] aspiration of stomach contents can localize the source of bleeding, indicate the rate of bleeding, and clear the stomach for endoscopy. Patients with hematemesis virtually always have an upper GI source, and NG aspiration is helpful to assess the rate of hemorrhage rather than identify the source. In significant upper GI bleeding, such as suggested by refractory hemodynamic instability or large quantities of bright red bloody emesis, the rate of bleeding can determine the success of medical interventions and the need for emergent endoscopy. When the clinical picture suggests a slower rate of bleeding, such as with coffee-ground emesis or blood-streaked emesis, the need for NG aspiration is less clear because less sensitive methods of assessing the rate of hemorrhage, such as observation of spontaneous bleeding, hemodynamic assessment, and serial hematocrit measurement, are often adequate.

In patients without hematemesis, NG aspiration lacks sensitivity to detect an upper GI source.[7,8] Although it has been reported that 10% of patients with hematochezia have an upper GI source, many of these are from a duodenal source and are beyond the reach of the NG tube.[9] Most patients with melena have an upper GI source and require upper endoscopy regardless of the results of NG aspiration. In severe, ongoing rectal bleeding with hemodynamic instability, NG aspiration is relatively useful because severe upper GI bleeding is generally easier to stop than severe lower GI bleeding.

The literature is riddled with case reports of bizarre mishaps resulting from the use of NG tubes, some of which are listed in **Table 86-2**. However, the rate of adverse effects has not been systematically addressed. The main morbidity from the procedure is probably related to pain, followed by epistaxis, both of which can be minimized by good technique.

The equipment required for NG tube insertion is listed in **Table 86-3**. The optimal positioning is with the patient seated upright with the neck slightly flexed. Topical application of anesthetic can reduce the pain of the procedure, and a vasoconstrictor can shrink the turbinates, creating a larger nasal opening, but use a vasoconstrictor with caution in hypertensive patients. One option is to mix 4% lidocaine with oxymetazoline and instill this solution using a nasal atomizer.[10] Nebulized lidocaine also provides effective analgesia.[11] Although it is tempting to use viscous lidocaine on the tip of the tube instead of premedication, this maneuver does not allow time for the lidocaine to be effective. A right-handed operator may choose the right side or the side of patient preference. Premedication with IV metoclopramide, in adults, or lingual 24% sucrose, in infants, may also decrease pain.[12,13]

TABLE 86-3 Equipment for Nasogastric Tube Insertion

Absorbent pad (blue Chux®)
Kidney basin

TABLE 86-4 Techniques for Identifying Nasogastric and Nasointestinal Feeding Tube Placement

Indicates gastric placement
Epigastric auscultation of air insufflated through the tube
Aspiration of visually recognizable GI secretions
pH testing of aspirates (pH <6 indicates gastric placement)
Indicates tracheobronchial placement
Coughing or choking
Inability to speak
Air bubbles when proximal end of tube is placed in water

Describing the procedure to the patient in advance and talking to the patient during the procedure minimize anxiety. Insert the lubricated tube into the selected nostril. Direct the tube posteriorly, not superiorly, and it should naturally bend inferiorly toward the glottis. Resistance is expected at the level of the glottis. At this point, have the patient take a drink of water, and advance the tube at the time of swallowing. This step minimizes the potential for false passage at the level of the glottis. Warming the distal tip of the tube will make it more pliable and may further decrease the pain of the procedure. Once the tube is past the glottis, quickly advance the tube and aspirate stomach contents. If the patient coughs during the procedure, stop and make sure that the patient can speak clearly. Failure to aspirate stomach contents should prompt visualization of the pharynx to ensure the tube is not coiled in the posterior pharynx. If the appearance of the gastric aspirate is inconclusive, its pH can be tested, or air can be insufflated during auscultation over the stomach (**Table 86-4**). A chest x-ray can also be obtained to confirm tube placement. If the NG tube is to remain in place, it can be taped to the patient's nose and connected to low-intermittent suction.

Some situations make NG tube insertion more difficult, such as obstructed nares, lack of patient cooperation, or endotracheal intubation. In patients with obstructed nares, the orogastric route may be used, although this is often less comfortable than the NG route. In obtunded patients with a poor gag reflex, endotracheal intubation may prevent aspiration. In patients with endotracheal intubation, flexing the neck or cooling the tube in ice water to stiffen it may facilitate passage.

ANOSCOPY

Anoscopy can identify an anorectal cause of bleeding in patients with hematochezia. Although an uncomfortable test, it is safe if performed properly. Contraindications include rectal foreign bodies and suspected rectal perforation. Anoscopy requires only an anoscope (a hollow plastic tube with a blunt obturator), lubricant, 4 × 4 gauze pads, blue absorbent pads (Chux®), and a light source. Because both hands contact contaminated areas during anoscopy, an assistant can hold a hand-held light source, or the operator can use a forehead-mounted light.

Usually, the lateral decubitus position is least uncomfortable, although the knee-chest position is an alternative. The equipment can be assembled onto the blue absorbent pad on the bed. After a careful external visual inspection of the anus with retraction of the buttocks, the generously lubricated anoscope is gently inserted into the anus. Step-by-step verbal communication is essential. If resistance or pain is encountered, slowing the rate of insertion or redirecting can allow more comfortable passage. After insertion is completed, remove the obturator, obtain stool from the

tip, and perform guaiac testing. Then peer through the anoscope as it is withdrawn, looking for potential sources of bleeding. Internal hemorrhoids are common sources of anorectal bleeding that are visible through the anoscope. After the procedure, the patient or operator may wipe off the lubricant with gauze and dispose of it in the blue absorbent pad.

OROGASTRIC LAVAGE

Orogastric lavage is used to remove pills and fragments from the stomach. It is only appropriate for patients presenting well within 1 hour after a potentially lethal ingestion.[14] Because an NG tube is too small to retrieve pill fragments, gastric lavage for solids is done orally with a large-bore tube. Gagging and vomiting during the procedure are common, and aspiration is a significant risk, particularly when airway protection is in doubt. Many other complications are possible, including tube misplacement into the bronchi, pharyngeal injury, and viscus perforation. Endotracheal intubation before this procedure can minimize these risks when a patient is or may become obtunded.

Equipment for the procedure includes a large-bore tube, such as the Ewald tube® or the Tum-E-Vac® (Ethox Corp, Buffalo, NY); lubricant; suction; emesis basin; blue absorbent pad; a catheter-tip syringe; irrigation fluid; and a bite block or oral airway to prevent patients from biting down on the tube. Patient positioning, tube advancement, and confirmation of placement are similar to NG tube insertion, but be especially sure to aim the proximal end away from others. After inserting a bite block in uncooperative patients, insert the gastric tube to the level of the glottis, and encourage the patient to swallow. Then pass the tube quickly into the stomach. Coughing or airflow from the tube raises concern for tracheal malpositioning. Have the patient vocalize to exclude tracheal placement. After suction and irrigation of gastric contents, charcoal and sorbitol can be instilled before withdrawal of the tube.

ESOPHAGEAL BALLOON (SENGSTAKEN-BLAKEMORE) TAMPONADE

The Sengstaken-Blakemore tube is designed to tamponade bleeding from esophageal varices (**Figure 86-1**). With the increasing availability of endoscopy and success of medical therapy with octreotide, somatostatin, and vasopressin, its use has declined. Nevertheless, it still has a role in cases in which endoscopy is unavailable or hemorrhage is refractory to endoscopic techniques. It is only useful in patients with esophageal varices that are known or suspected from the clinical picture, such as in patients with severe hematemesis and signs of cirrhosis. The procedure frequently provokes emesis, and aspiration can be minimized by endotracheal intubation. Other risks include gastric or esophageal rupture. Insert the tube orally after the same procedure described in the section "Orogastric Lavage." After confirming tube placement as described earlier, expand the distal balloon with water or normal saline and apply gentle traction to the tube. Because varices are often at the gastroesophageal junction, this often stops the bleeding. If not, expand the proximal balloon. To maintain traction, tape the proximal end of the tube to the face guard of a football or lacrosse helmet that the patient wears. The patient will not be able to swallow secretions with this in place, so proximal suction, whether from a proximal port in the device or an NG tube inserted proximally, will further minimize the risk of aspiration.

Once the tube is in place, maintain traction to the minimum amount necessary to stop the bleeding to minimize the risk of tissue ischemia. Maintain balloon tamponade until more definitive measures can be taken.

PARACENTESIS

In paracentesis, ascitic fluid is removed for diagnostic or therapeutic purposes. Patients with ascites and abdominal pain or other GI symptoms may have peritonitis, requiring diagnostic paracentesis. This may be true even if the abdominal pain is mild and unaccompanied by signs of systemic infection.[15] Patients with respiratory compromise or severe pain due to tense ascites require therapeutic paracentesis, in which a large quantity of fluid is removed. Large-volume therapeutic paracentesis is a lengthy procedure associated with complications such as hyponatremia,

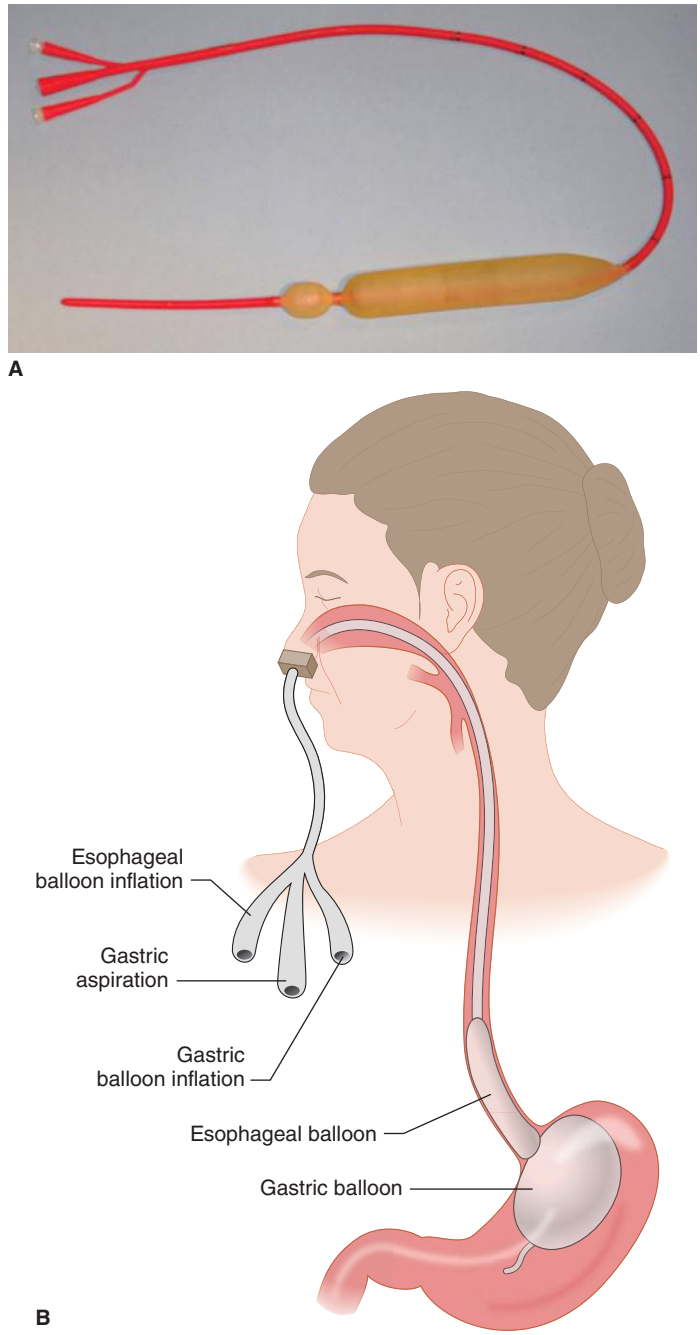

FIGURE 86-1. **A.** Sengstaken-Blakemore tube. **B.** Insertion of Sengstaken-Blakemore tube.

renal impairment, and encephalopathy, and many of these patients require other treatment.[16] Therefore, it is generally best reserved for the admitting team or ED observation unit, except in rare cases in which pain or respiratory compromise cannot be controlled in the ED with medications or supplemental oxygen. Other risks of paracentesis in general, whether diagnostic or therapeutic, include bowel perforation, ascitic fluid leak, hemorrhage, and introduction of infection.

Equipment for diagnostic paracentesis includes sterile drapes (both fenestrated and nonfenestrated), sterilizing solution (povidone-iodine or chlorhexidine), gauze, assorted syringes (3, 10, or 30 mL), a small-bore (27-gauge or smaller) needle, three medium-bore (21-gauge) needles, local anesthetic (lidocaine), and containers for cell count and culture for the laboratory. If paracentesis is also to be therapeutic, a three-way stopcock, sterile tubing, and a source of suction—either vacuum bottles or a setup for wall suction—are necessary, and a large-bore needle or plastic catheter (18- or 16-gauge) will speed the procedure. Ultrasonography can

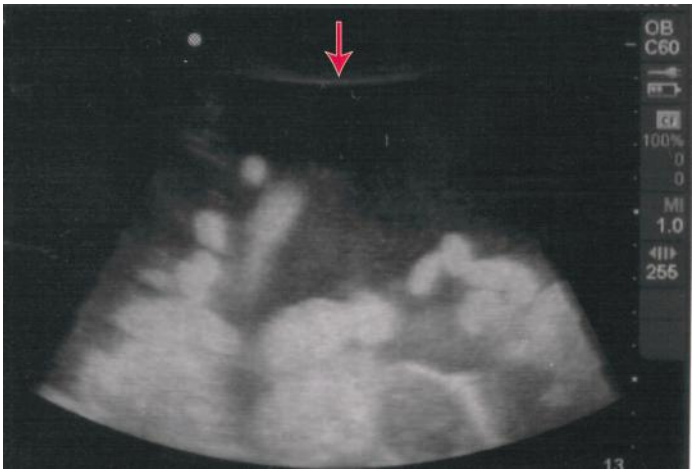

FIGURE 86-2. US view of a desirable puncture site for paracentesis (*arrow*).

confirm ascites and identify a target fluid collection to minimize the potential for bowel perforation (**Figure 86-2**). US guidance can also assist the operator in avoiding subcutaneous vessels dilated by portal hypertension, and it decreases the risk of bleeding.[17]

If the patient has coagulopathy or thrombocytopenia, correct deficiencies before paracentesis. Place the patient in a comfortable supine position, and cleanse and sterilely prepare the site of expected needle insertion. The left lower quadrant is generally a good area because this minimizes the potential for liver injury, but the right lower quadrant may also be used if the left lower quadrant has distorted anatomy, such as with prior scarring or ostomy surgery (**Figure 86-3**). Anesthetize the skin over the target area by raising a wheal, and then switch to a larger-bore needle to infiltrate to the level of the peritoneum. A Z-track technique, in which traction on the skin is used to create a displaced track to the peritoneum, can minimize the potential for infection and persistent leakage.[16] At a depth expected to be near the peritoneum, apply suction to the syringe and infiltrate lidocaine while advancing until peritoneal fluid is aspirated. Once the fluid is aspirated, change the syringe with the needle still in place, and then aspirate at least 50 cc of fluid into the fresh syringe for laboratory analysis. In therapeutic paracentesis, attach tubing to the needle, catheter, or stopcock, and connect to suction. Even if the goal is diagnosis, up to 1 L is unlikely to cause complications and may provide significant symptomatic relief. Then withdraw the needle or catheter and cover the insertion site with a dressing. A purse-string suture can be placed to minimize leakage. Recheck the patient in 30 minutes to identify persistent leakage or an increase in symptoms to suggest a complication. Patients with large-volume paracentesis should be monitored for hypotension for several hours after the procedure. Cover the puncture site with a dry dressing for 48 hours.

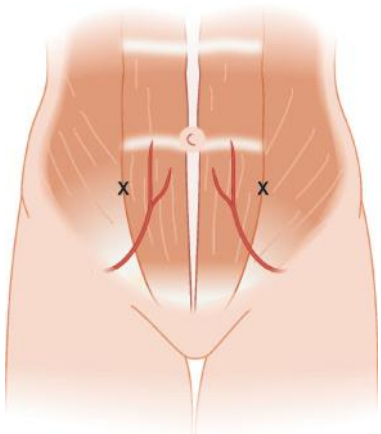

FIGURE 86-3. Sites for needle introduction in the left or right lower quadrant (x) for abdominal paracentesis.

TRANSABDOMINAL FEEDING TUBES

Although the techniques for the initial placement of transabdominal feeding tubes (gastrostomy [G-tube], jejunostomy [J-tube], and gastrojejunostomy) are beyond the scope of emergency physicians, complications related to these tubes need to be recognized (**Table 86-5**). These tubes can be placed by a surgeon using open technique, by a gastroenterologist using endoscopic technique (percutaneous endoscopic gastrostomy), or by a radiologist with percutaneous techniques. The radiographic technique has been associated with fewer complications than has open or endoscopically assisted placement.[18]

Frequent minor complications are associated with the use of these tubes, including purulent drainage and leakage around the stomal site, clogging, dislodgement, and vomiting and diarrhea.

Drainage from the stomal site is a common finding and represents a foreign-body reaction due to the catheter. As long as there is no evidence of cellulitis or necrotizing fasciitis, local skin care with hydrogen peroxide and warm water usually will clear up the problem. If there is granuloma

TABLE 86-5 Complications Seen with Transabdominal Feeding Tubes

Complication	Initial Considerations
Purulent drainage from stoma	Local care with hydrogen peroxide unless cellulitis is present.
Leakage from stoma	Carefully replace with larger tube.
Tube occlusion	Attempt irrigation; most often, just replace.
Dislodged tubes	Gently replace; confirm placement with x-rays.
Pneumothorax	High index of suspicion; consider needle aspiration.
Bacteremia	Consider as potential source in septic patient.
Bleeding from tract	If recently inserted, consider local injection, consult.
Bleeding from granuloma buildup	Local therapy with silver nitrate.
Infection of surrounding skin	Consultation, pull tube, IV antibiotics.
Necrotizing fasciitis	Consider MRI to help confirm; surgical debridement.
Peritonitis	Determine if fistula exists; consultation, IV antibiotics.
Pulmonary aspiration of feedings	Reduce flow rate, half-strength feeds, consider J-tube.
Vomiting or diarrhea	Reduce flow rate, half-strength feeds, stop feeds.
Gastroesophageal reflux	Reduce flow rate, half-strength feeds, consider J-tube.
Intestinal obstruction	Step feedings, NPO, admit, and observe.
Gastric outlet obstruction	Reposition tube.
Gastric volvulus	Surgical consult.
Gastric perforation	Surgical consult.
Esophageal perforation	Surgical consult.
Colonic perforation	Surgical consult.
Colocutaneous fistula	Surgical consult.
Electrolyte abnormalities	Change feedings or increase free water.
GI bleeding	Endoscopy and therapy directed at cause.
Bolster buried in abdominal wall	Surgical consult.

Abbreviations: J-tube = jejunostomy tube; NPO = nothing by mouth.

formation with localized bleeding from friable skin, local treatment with silver nitrate usually will help.

Leakage of gastric contents can become a problem. This is managed by careful insertion of a larger tube. Care should be used not to force too large a tube into the stoma, because this can cause separation of the stomach wall from the abdominal wall.

Prevention is the best treatment for clogging of gastrostomy and jejunostomy tubes. Frequent flushing with water and careful crushing of pills usually can prevent this problem. Vomiting and diarrhea can be relieved by decreasing the amount of the feedings and/or diluting the feedings. To unclog the tube, instill warm water or carbonated beverage (cola is most often used) and let it remain for 20 minutes. Then attempt flushing.[19] Alkalinized pancreatic enzymes (12,000 lipase units dissolved in 650 mL bicarbonate) have also proven effective in about 50% of cases.[20]

TUBE REPLACEMENT

If the tube cannot be unclogged or if it has fallen out, replacement will be necessary. If the tube was placed by a surgeon or gastroenterologist and has not been replaced, it probably will have a bolster (also called a *mushroom* or *bumper*) holding the tube in place (**Figure 86-4**). This will prevent the tube from being removed. The bolster must be removed endoscopically, or the tube may be cut off and the bolster allowed to pass through the GI tract.[21] The latter technique is generally safe in adults, but passage in children has complications,[22] and tube removal should be done by the endoscopist or surgeon. Tube removal should be done by the endoscopist or surgeon. Endoscopic removal in adults is advisable when there is suspected or potential obstructive disease of the GI tract, such as pyloric stenosis, intestinal pseudo-obstruction, and intestinal stricture (e.g., due to radiation, ischemia, or inflammatory bowel disease). If the tube is cut, an abdominal radiograph should be obtained 1 week later to confirm passage of the internal component. Most reported complications from a retained internal bolster have occurred when the bolster did not pass within 1 to 2 weeks.[23] If the bolster or bumper becomes buried in the abdominal wall, consult with the endoscopist or surgeon who placed the device. Do not attempt removal by traction. Some specially designed tubes have internal bumpers that can be removed by external traction, but consultation with the endoscopist or surgeon who placed the device is necessary before any traction is applied to verify the type of tube and the appropriate method of removal[24] (Figure 86-4).

If the tube has become dislodged or has fallen out, **replace it as quickly as possible (within a few hours) to prevent closure of the tract. Most tracts mature after 2 to 3 weeks. Do not attempt to replace a tube with an immature tract.**[19] First determine, if possible, which type of tube is being used. If the tube is available, replacement with the same size is usually possible. If the tube is not available, it can be difficult to determine whether the tract is for a jejunostomy or gastrostomy tube. Location site on the abdominal wall is not helpful to differentiate the two. A tract for a gastrostomy tube is usually larger. Old records may be useful and should be obtained, if possible. After determining the type of tract and size of tube used previously, insert the tube using a water-soluble lubricant. If the size of the tube being replaced is not known, it is reasonable to start with a 16- or 18-F replacement gastrostomy tube or Foley catheter. The lubricated tube should pass easily into the stoma without additional equipment. If resistance is met, abandon the attempt. A smaller tube can be tried to keep the tract open. After replacing the tube, instill a 20- to 30-mL bolus of a water-soluble contrast material (e.g., diatrizoate meglumine and diatrizoate sodium solution [Gastrografin]) through the tube, and obtain a supine abdominal x-ray within 1 to 2 minutes. The x-ray should demonstrate rugae of the stomach for a gastrostomy tube and flow into the small bowel for a jejunostomy tube. US can also be used to verify gastric placement. The tip of the tube can be visualized within the stomach, and confirmation of placement can be done by injecting 10 cc of normal saline into the tube and observing the fluid entering the stomach, using real-time US. Another way of determining placement is to withdraw gastric fluid and check pH to make sure it is acidic. If there is any question of improper placement, obtain immediate consultation.

A special caution regarding jejunostomy tubes should be noted. Jejunostomy tracts are smaller, and smaller tubes are used (8- to 14-F). These tubes usually are not sutured in place and frequently become dislodged. They can be replaced with catheters made specifically for jejunostomies or with Foley catheters. **If a Foley catheter is used to replace a lost jejunostomy catheter, the balloon should never be inflated** because it can cause a bowel obstruction or damage the jejunum. The tube is lubricated, inserted into the stoma, and advanced 20 cm. These tubes are easily replaced if the tract is mature; however, if resistance is met, referral to a radiologist for fluoroscopic placement using guidewires is recommended.

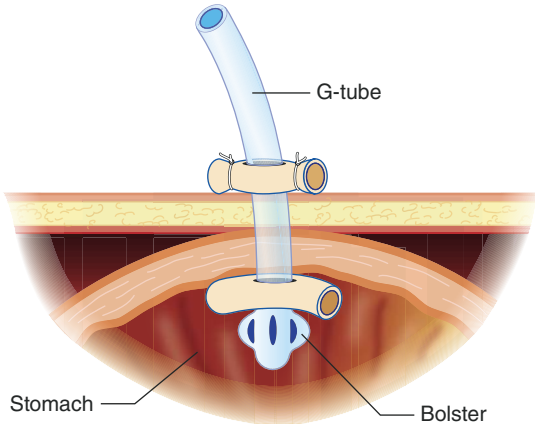

FIGURE 86-4. Percutaneous endoscopic gastrostomy tube (G-tube) with a mushroom bolster in place.

CHAPTER 87

Complications of General Surgical Procedures

Edmond A. Hooker

INTRODUCTION

Outpatient surgical procedures are common, and with increasing pressure for cost containment, admitted patients are being discharged earlier in their postoperative course. As a result, more patients are coming to the ED with postoperative fever, respiratory complications, GU complaints, wound infections, vascular problems, and complications of drug therapy (**Table 87-1**). This chapter reviews the complications common to all surgical procedures and those specific to a single procedure.

The operating surgeon should be called when one of his or her patients appears in the ED with a surgical complication. This is not just a courtesy, but provides continuity of care important for the patient's well-being.

FEVER

Fever is a common presenting complaint (**Table 87-2**). A mnemonic for the common causes of postoperative fever is the "five Ws": *wind* (atelectasis or pneumonia), *water* (urinary tract infection), *wound*, *walking* (deep vein thrombosis), and *wonder drugs* (drug fever or pseudomembranous colitis).[1] Respiratory complications, such as atelectasis, and IV catheter–related problems, such as thrombophlebitis, are the predominant causes of fever in the first 72 hours. Necrotizing streptococcal and clostridial infections also occur in surgical wounds early in the postoperative course.

Urinary tract infections become evident 1 to 5 days postoperatively. Seven to 10 days postoperatively, clinical manifestations of wound

TABLE 87-1 Complications of General Surgical Procedures

Complication	Important Points
Fever	"Five Ws" (wind, water, wound, walking, wonder drugs) are common causes
Pulmonary complications	
Atelectasis	<24 h, treat with pulmonary toilet, discharge unless ill or hypoxemic
Pneumonia	2–7 d, polymicrobial, most require admission
Pneumothorax	Multiple causes, consider expiratory views, consider needle aspiration
Pulmonary embolism	Dyspnea is main symptom, high index of suspicion
GI complications	
Intestinal obstruction	Obtain radiographs, search for causes
Intra-abdominal abscess	CT diagnosis, early administration of broad-spectrum antibiotics
Pancreatitis	Always consider in postoperative patients with abdominal pain
Cholecystitis	Usually in older patients, can be acalculous
Fistulas	Can be high output, admit if concerns over output
GU complications	
Urinary tract infection	2–5 d, oral antibiotics, most discharged
Urinary retention	Rapid catheter drainage, most discharged
Acute renal failure	Prerenal, renal, and postrenal causes, most admitted
Wound complications	
Hematoma	Caused by poor hemostasis, can drain most, but be careful with neck hematomas and hematomas after vascular surgery
Seroma	Painless swelling, clear fluid, drain and discharge
Infection	Open, drain, and culture specimens; be careful with wounds associated with respiratory tract, GI tract, or GU tract, or secondary to trauma
Necrotizing fasciitis	Pain out of proportion to physical findings
Dehiscence	Be careful with abdominal incisions (potential for evisceration)
Vascular complications	
Superficial thrombophlebitis	Usually aseptic, provide local therapy and discharge
Deep venous thrombosis	Upper and lower extremity, perform Doppler studies
Complications of drug therapy	
Diarrhea	Consider pseudomembranous colitis
Drug fever	Many drugs implicated, requires admission
Tetanus	Can occur after GI surgery
Procedure-specific complications	See text

infections develop. Deep venous thrombosis can result in fever any time but usually not until the fifth postoperative day. Antibiotic-induced pseudomembranous colitis occurs up to 6 weeks postoperatively. An approach for evaluating and managing fever in postoperative patients is presented in **Table 87-3**.

RESPIRATORY COMPLICATIONS

ATELECTASIS

Atelectasis, the collapse of pulmonary alveoli, is very common. Contributing factors include inadequate clearance of secretions after general anesthesia, decreased intra-alveolar pressure, and postoperative pain, which results in hypoventilation. Although atelectasis can occur after any procedure, it frequently occurs after upper abdominal and thoracic surgery. The presentation varies from an isolated fever to tachypnea, dyspnea, and tachycardia.

Evaluation includes chest radiography, pulse oximetry, and a CBC. Chest radiographs may show normal findings or exhibit platelike linear densities, triangular densities, or lobar consolidation. Mild hypoxemia from ventilation and perfusion mismatch is common, but hypercarbia is uncommon. Patients with mild atelectasis and no evidence of hypoxemia may be managed as outpatients with pain control and increased deep breathing. Admission is indicated for aggressive pulmonary toilet and supplemental oxygenation in debilitated patients, patients with underlying lung disease, patients with hypoxemia, or those in whom the diagnosis is in question.

PNEUMONIA

Pneumonia usually becomes evident between 24 and 96 hours postoperatively. Predisposing factors include prolonged ventilatory support and atelectasis. Presenting symptoms can include dyspnea, chest pain, productive cough, fever, and tachypnea. Postoperative pneumonia is likely to be polymicrobial. After specimens of sputum and blood are obtained for culture, parenteral antimicrobial therapy is given. There are many options for polymicrobial coverage. One option is levofloxacin, 750 milligrams IV once daily, *and* vancomycin, 1 gram IV twice daily. Admission to the hospital is generally indicated.

PNEUMOTHORAX

Pneumothorax can occur as a complication of thoracic wall surgery, breast biopsy, laparoscopic abdominal surgery, abdominal paracentesis, nasogastric and feeding tube insertion, thoracic surgery, central venous catheter insertion, endoscopic procedures, shoulder arthroscopy, and tracheostomy. For further discussion, see chapter 68, "Pneumothorax."

TABLE 87-2 Common Causes of Postoperative Fevers in General Surgical Patients

Cause of Fever	Presentation	Signs and Symptoms	Diagnostic Test	Treatment
Atelectasis	First 24 h	Isolated fever; may have tachypnea, dyspnea, and/or tachycardia	Chest radiography	Pulmonary toilet; admission if unsure or patient is ill appearing
Pneumonia	3–7 d	Dyspnea, chest pain, productive cough, fever, and/or tachypnea	Chest radiography	Admission and coverage with broad-spectrum antibiotics
Urinary tract infections	2–5 d	Often none; possibly dysuria	Urinalysis	Admission if patient is elderly or toxic
Skin and soft tissue infection	5–10 d	Increasing pain, erythema, swelling, drainage, and tenderness at incision site	Examination, aspiration and/or opening of wound	Drainage, packing, and outpatient antibiotic therapy
Thrombophlebitis (septic and sterile)	<3 d	Warm, tender, and swollen vein	None	If not septic, warm soaks If septic, surgical removal
Deep vein thrombosis	4–6 d	Extremity swelling and pain	US	Admission and anticoagulation
Intra-abdominal abscesses	4–21 d	Fever and elevated WBC count without specific focal abdominal findings	CT	Admission and antibiotic administration
Pseudomembranous colitis	Anytime	Diarrhea	Stool testing using immunoassay	Vancomycin administration
Peritonitis	4–21 d	Tachycardia and abdominal pain, peritoneal irritation	CT	Admission and antibiotic administration
Pulmonary embolism	Anytime	Shortness of breath, tachypnea, and/or hemodynamic instability	CT or ventilation–perfusion scanning	Admission and anticoagulation
Transfusion reaction	First 24 h	Fever, chills	Transfusion check for incompatibility	Admission depending on condition of patient

PULMONARY EMBOLUS

Pulmonary embolism may present any time during the postoperative period. For further discussion of signs, symptoms, and treatment, see chapter 56, "Venous Thromboembolism."

TABLE 87-3 Evaluation and Management of Postoperative Fever

History
Presenting signs and symptoms
Onset of symptoms, time since procedure
Procedures performed and complications
Medications
History of blood transfusion
Physical examination
Particular attention to
Operative sites and contiguous areas
Sites of catheters and invasive monitors
Signs of deep venous thrombosis and pulmonary embolism
Decubitus ulcers
Lungs
Ancillary studies
CBC with differential
Chest radiograph
Gram stain and culture of wound exudate
Urinalysis (urine culture if infected)
Sputum Gram stain and culture
Blood cultures
CT to exclude intra-abdominal pathology
If diarrhea present, consider immunoassay of specimen for *Clostridium difficile* toxin
Further tests as indicated (e.g., CT, radionuclide studies, venography, arteriography)
Treatment
If source identified, start antibiotics; admission based on condition of patient
If no source identified, consider admission, change all catheters and culture catheter specimens, stop all medication that might cause fever

GU COMPLICATIONS

URINARY TRACT INFECTION

Urinary tract infections can occur after any surgical procedure, but the incidence increases in patients who have undergone instrumentation of the GU tract or bladder catheterization. The cause is direct contamination of the urinary bladder, most commonly with *Escherichia coli*. Other organisms isolated include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Proteus mirabilis*, *Klebsiella*, *Pseudomonas*, and enterococci. Oral antibiotics (ciprofloxacin, 500 milligrams PO twice daily, or levofloxacin, 750 milligrams PO once daily) are appropriate for most infections, and choice of antibiotic should be based on local susceptibility patterns. Elderly or debilitated patients and those with sepsis require admission for parenteral administration of antibiotics (usually levofloxacin, 750 milligrams IV once daily).

URINARY RETENTION

Postoperative acute urinary retention is a common problem for surgical patients.[2] Urinary retention occurs as the result of catecholamine stimulation of α-adrenergic receptors in the bladder neck and urethral smooth muscle. Increased incidence of urinary retention is likely to occur in elderly men, patients receiving excessive fluid administration during surgery, those undergoing anorectal surgery, patients undergoing longer procedures (>2 hours), and those for whom spinal or epidural anesthesia was used.[3,4]

Patients with urinary retention present with lower abdominal discomfort, urinary urgency, and inability to void. The diagnosis is confirmed by use of a bladder scanner or placement of a Foley catheter. The bladder can be safely drained quickly, and there appears to be no foundation for the fears of hematuria, postobstructive diuresis, and hypotension. For patients with normal renal function and no anatomic obstruction, continued catheter drainage is not necessary. For patients with retention after GU procedures, a urologist should be consulted. Antibiotics can be given if the GU tract has been instrumented, if retention is prolonged, or if the patient is at risk for infection (see "Urinary Tract Infection" section above).

ACUTE RENAL FAILURE

Acute renal failure is classified according to the primary cause: prerenal, intrinsic, or postrenal. Volume depletion is the most common prerenal cause. The patient should be examined for signs of hypovolemia and a

urinary catheter placed. Indwelling urinary catheters should be irrigated or replaced. A fluid bolus should be given. Intrinsic causes include acute tubular necrosis and drug nephrotoxicity. Obstructive uropathy is a common cause of postrenal failure. In patients with urinary outlet obstruction, placement of a urinary catheter is diagnostic and therapeutic. Renal US is needed to identify hydronephrosis or hydroureter.

WOUND COMPLICATIONS

Inform the operative surgeon about all postoperative wound complications.

HEMATOMAS

Wound hematomas result from unrecognized inadequate hemostasis. Patients have pain, pressure, and swelling within the wound. Patients with wound hematomas may be febrile and have sanguineous or serous wound drainage. Differentiating between hematoma and wound infection can be difficult. A few sutures should be removed to allow the hematoma to drain, and culture of wound specimens should be performed. If there is no evidence of infection and hemostasis can be maintained, the patient can be discharged. In patients who have a hematoma of the neck or who have undergone vascular surgery, extreme caution and consultation are appropriate.

SEROMAS

A seroma, a collection of serous fluid, is usually the result of inadequate control of lymphatics during dissection but can occur under split-thickness skin grafts and in areas with large dead spaces (e.g., axilla, groin, neck, or pelvis). Patients have painless swelling below the wound or graft, and needle aspiration yields a serous fluid. Aspiration confirms the diagnosis and alleviates the problem, although aspiration may have to be repeated later.

INFECTION

Systemic factors (e.g., extremes of age, poor nutrition, or diabetes) contribute to wound infections. However, local factors (e.g., necrotic tissue, poor perfusion, foreign bodies, and hematomas) are of greatest significance. In nontraumatic, uninfected operative wounds in which the respiratory, alimentary, and GU tracts were not entered, infection rates are low. In such cases, the infecting organism is usually from the skin but can originate from remote infected sources (e.g., urinary tract infection). If there is a remote infected source, the organism is probably the same in both infections. Wounds associated with entering the respiratory, alimentary, or GU tract or wounds secondary to trauma have a higher risk of infection.

Presenting signs and symptoms of wound infections include increasing pain, erythema, swelling, drainage, and tenderness at the incision site. Wounds not involving the perineum and not associated with entry into the GI or biliary tract are most often infected with *S. aureus* or streptococci. Such wounds can be safely managed with drainage, culture of a wound sample, irrigation, loose packing with gauze, and outpatient administration of antibiotics. Wounds involving the perineum or associated with the GI or biliary tract are often infected with multiple organisms, including gram-negative bacteria and anaerobes. Parenteral broad-spectrum antibiotics are administered, and hospital admission is necessary.

NECROTIZING FASCIITIS

Necrotizing fasciitis is a feared complication. The usual cause is direct contamination of the wound with group A streptococci or *S. aureus*. However, mixed aerobic and anaerobic infections have been reported. Risk factors include diabetes mellitus, alcoholism, immunosuppression, and peripheral vascular disease, but necrotizing fasciitis also occurs in young, otherwise healthy individuals. Early clinical differentiation from cellulitis can be difficult. CT may show asymmetric fascial thickening, gas tracking along fascial planes, or focal fluid collections. MRI is sensitive but not totally specific for necrotizing fasciitis and can be a useful adjunct.[5,6] Hallmarks of fasciitis are the presence of marked systemic toxicity and pain out of proportion to local findings. In more advanced cases, there may be deep pain with patchy areas of surface hypesthesia, crepitation, or bullae. Treatment should include antibiotics and immediate surgical debridement. Antibiotic choice is controversial, but triple antibiotic therapy with penicillin or a cephalosporin, an aminoglycoside, and clindamycin probably should be used.[7] For further discussion, see chapter 152, "Soft Tissue Infections."

WOUND DEHISCENCE

Wound dehiscence can be superficial or can extend into the deeper fascial planes. Dehiscence is caused by inadequate closure or intrinsic host factors, such as malnutrition, glucocorticoid use, or diabetes. Serosanguineous fluid may leak from the wound. Dehiscence of abdominal incisions has the potential for evisceration. If evisceration is not present, conservative management using abdominal binders is appropriate. However, if there is any uncertainty about the extent of dehiscence, operative exploration is indicated.

VASCULAR COMPLICATIONS

SUPERFICIAL THROMBOPHLEBITIS

Superficial thrombophlebitis of the lower extremities is most frequently secondary to stasis in varicose veins. It is usually aseptic. There is redness and warmth of the affected vein. If there is no evidence of surrounding cellulitis or lymphangitis and no evidence of deep vein involvement on US, treatment is local heat, elevation, and nonsteroidal anti-inflammatory drugs. Suppurative superficial thrombophlebitis is characterized by erythema, palpable tender cord, lymphangitis, and pain. Suppurative thrombophlebitis requires excision of the affected vein.

DEEP VENOUS THROMBOSIS

When lower extremity superficial thrombophlebitis is seen in a postoperative patient, the possibility of concurrent deep venous thrombosis should be considered. Deep venous thrombosis is typically characterized by leg pain or swelling, or both. For suspected deep venous thrombosis, Doppler US is the preferred diagnostic test. Patients with normal color flow Doppler study results should be treated with elevation and bed rest. Repeat color flow Doppler US studies should be performed in 3 days if symptoms persist, but sooner if symptoms worsen. For further discussion, see chapter 56, "Venous Thromboembolism."

COMPLICATIONS OF DRUG THERAPY

Complications of drug therapy are numerous, but the most commonly encountered problem in the ED is an allergic reaction.[8] Another common problem is antibiotic-associated diarrhea. Many antibiotics can cause diarrhea, but the greatest concern in postoperative patients is pseudomembranous colitis. Pseudomembranous colitis is due to the toxin produced by the bacterium *Clostridium difficile*. Pseudomembranous colitis is related to antibiotic use, which destroys the normal enteric bacterial flora, allowing an overgrowth of *C. difficile*. Even short courses of antibiotics have been associated with pseudomembranous colitis. Patients have watery and sometimes bloody diarrhea, fever, and crampy abdominal pain. There are three common ways to diagnose *C. difficile*: nucleic acid amplification tests, glutamate dehydrogenase, and enzyme immunoassay. The current recommendation for symptomatic patients is to use a nucleic acid amplification test technology like polymerase chain reaction.[9] For patients with moderate disease, discontinue the offending antibiotic and prescribe metronidazole. For severe disease, discontinue the offending antibiotic and give vancomycin.[9] For further discussion, see chapters 71, "Acute Abdominal Pain" and 73, "Disorders Presenting Primarily with Diarrhea."

Many medicines can cause drug fever, but antibiotics are the drug class most commonly implicated. The mechanisms proposed are hypersensitivity reactions, pyogenic effect, and disturbed thermoregulation. In patients in whom no source for fever can be found, it is appropriate to consider stopping medications known to cause drug fever. Most often, the patient will require admission to rule out this diagnosis.

COMPLICATIONS OF BREAST SURGERY

Complications of breast surgery are infrequent, but patients can develop minor wound infections and hematomas. Rarely, pneumothorax has been reported. Wound hematomas frequently require operative control for proper evacuation and hemostasis.

Early complications seen with mastectomies include wound infection, necrosis of skin flaps, and the accumulation of seromas. The incidence of postmastectomy lymphedema ranges from a low of 5.5% to a high of 80%.

COMPLICATIONS OF GI SURGERY

In addition to the complications already reviewed, patients who have undergone any GI surgery may have intestinal obstruction, intra-abdominal abscess, pancreatitis, cholecystitis, fistulas, and tetanus. Certain procedures, such as anastomoses, bariatric surgery, placement of gastrostomy tubes, biliary tract surgery, other laparoscopic surgery, stoma creation, colonoscopy, and rectal surgery, are associated with specific complications.

INTESTINAL OBSTRUCTION

Ileus, a functional obstruction of the bowel, is postulated to be the result of stimulation of the splanchnic nerves, leading to neuronal inhibition of coordinated intrinsic bowel wall motor activity. It is expected after any operation in which the peritoneal cavity is violated. After GI surgery, small bowel tone usually returns to normal within 24 hours, and colonic function returns within 3 to 5 days. Ileus can also occur after non-GI procedures and is usually secondary to anesthetic agents; function returns to normal after 24 hours. Prolonged ileus can be caused by peritonitis, intra-abdominal abscess, hemoperitoneum, pneumonia, electrolyte imbalance, sepsis, and medications.

Presenting symptoms of ileus include nausea, vomiting, obstipation, constipation, abdominal distention, and abdominal pain. When these symptoms are present in the first few days after surgery, they are most often due to adynamic ileus. The symptoms of adynamic ileus are most often mild and respond to nasogastric suction, bowel rest, and IV hydration. However, in cases of prolonged ileus, look for an underlying cause. Evaluation includes abdominal radiography to identify air-fluid levels, chest radiography, CBC, measurement of electrolyte levels, and urinalysis to search for secondary causes of ileus.

Mechanical ileus of the bowel is most often secondary to adhesions. Symptoms are abdominal distention and pain. Abdominal radiographs demonstrate multiple air-fluid levels and a paucity of gas in the colon; however, with high obstruction, above the ligament of Treitz, there may be no air-fluid levels. In the ED, differentiating between functional ileus and mechanical bowel obstruction can be difficult. Both disorders result in different degrees of abdominal pain, distention, nausea, vomiting, and failure to pass flatus and/or feces. Abdominal CT scanning is helpful to exclude obstruction due to bowel strangulation.[10] Results may have an impact on the decision to manage the obstruction expectantly or not. Once the diagnosis of mechanical obstruction is suspected or confirmed, surgical consultation is indicated.

INTRA-ABDOMINAL ABSCESS

Intra-abdominal abscess is caused most frequently by preoperative contamination, spillage of bowel contents during surgery, contamination of a hematoma, or postoperative anastomotic leaks. Patients may have abdominal pain, nausea, vomiting, ileus, abdominal distention, fever, chills, anorexia, and abdominal tenderness. If the diagnosis is suspected, obtain CT or US of the abdomen. The patient should receive broad-spectrum antibiotics (see chapter 71, "Acute Abdominal Pain"). Treatment is percutaneous drainage or surgical exploration.

PANCREATITIS

Pancreatitis after abdominal surgery is secondary to direct manipulation or retraction of the pancreatic duct. Pancreatitis most commonly occurs after gastric resection, biliary tract surgery, and endoscopic retrograde cholangiopancreatography. Clinical presentation varies from mild nausea, vomiting, and abdominal discomfort to intractable vomiting, leukocytosis, and left-sided pleural effusion. Severe hemorrhage can cause lumbar pain accompanied by blue-gray discoloration of the skin in the flank area (Turner sign) or similar changes around the umbilicus (Cullen sign). Although the serum amylase level rises in acute pancreatitis, it is also elevated in patients with severe cholecystitis, renal insufficiency, intestinal obstruction, perforated ulcer, or ischemic bowel. A serum lipase measurement may help to identify those with true pancreatitis, although it may be elevated in a patient with a perforated viscus and other conditions. Abdominal radiographs may show localized ileus in the region of the pancreas (sentinel loop). US and CT are useful in defining pancreatic fluid collections or abscesses. In general, the treatment of postoperative pancreatitis is similar to the treatment of nonoperative pancreatitis (see chapter 79, "Pancreatitis and Cholecystitis").

CHOLECYSTITIS

Postoperative complications related to the gallbladder include biliary colic, acute calculous cholecystitis, or acute acalculous cholecystitis. The cause of these disorders in the postoperative period is not clear. US studies of the gallbladder and pancreas should be performed to aid in the diagnosis.

Acalculous cholecystitis is of particular concern in the postoperative period. The disorder seems to be more common in elderly men, but can occur in any sex and age group. Signs and symptoms are similar to those for calculous cholecystitis. Results of liver function studies and the neutrophil count may be normal. Important findings on US include gallbladder enlargement, wall thickening, and pericholecystic fluid collection, but no gallstones. Hepatobiliary scintigraphy may be helpful. Early diagnosis is critical, because early operative intervention can reduce morbidity and mortality.

FISTULAS

Enterocutaneous fistulas can occur almost anywhere in the GI tract and are usually the result of technical complications or direct bowel injury. High-output fistulas can result in electrolyte abnormalities and volume depletion. Fistulas involving the proximal GI tract are frequently high output and are of the greatest concern. Sepsis is the other major complication. Most patients require admission, although many fistulas ultimately close spontaneously.

TETANUS

Although most cases of tetanus in the United States occur after minor trauma, there have been numerous reports of tetanus after general surgical procedures.[11] *Clostridium tetani* is found in the GI tract of 1% of the population. During GI surgery, there is spillage of *C. tetani*. Proliferation of the organism is facilitated by the presence of devitalized tissue, blood clots, and surgical suture. Incubation can take from 0 to 73 days, at which time the toxin leads to clinical tetanus. The classic symptoms of tetanus, trismus, and opisthotonos may not be evident initially. Patients may present with nonspecific symptoms of abdominal discomfort, fever, and abdominal wall rigidity. Diagnosis is based on physical examination and a history of inadequate immunization.

ANASTOMOTIC LEAKS

Anastomotic leaks occur most frequently after esophageal and colonic surgeries and least frequently after gastric and small-intestinal anastomoses. The cause of anastomotic leakage is related mainly to surgical technique.

Intrathoracic esophageal anastomotic leaks usually manifest within 10 days of surgery. The presentation is dramatic, with fever, chest pain, tachypnea, tachycardia, and possibly shock. Chest radiograph may reveal a pneumothorax with pleural effusion. Disruption can be confirmed by contrast esophagography using a water-soluble contrast agent. Even with immediate reoperation, morbidity and mortality rates are high.

The signs and symptoms of gastric anastomotic leaks include abdominal pain, fever, leukocytosis, gastric outlet obstruction, hyperamylasemia, hyperbilirubinemia, peritonitis, and shock. Plain radiographs may reveal pneumoperitoneum or air-fluid levels. Provide volume resuscitation,

parenteral broad-spectrum antibiotics, and nasogastric tube drainage. Immediate surgery is required.

Small-intestinal anastomoses infrequently leak because of the excellent blood supply and rapid healing of the area. However, if a leak occurs, the patient usually presents with local abscess formation or peritonitis. Treatment is immediate reoperation.

Colorectal anastomoses are prone to disruption because of the large number of pathogenic bacteria found, the propensity for colonic distention, and the presence of only a single thin layer of circular muscle to support sutures. The patients usually present 7 to 14 days postoperatively with fever and abdominal pain. CT confirms the diagnosis. Patients should receive broad-spectrum parenteral antibiotics, nasogastric tube drainage, and adequate fluid resuscitation in preparation for surgery.

BARIATRIC SURGERY COMPLICATIONS

Four main bariatric procedures are currently being performed for morbid obesity: laparoscopic adjustable gastric banding using the LAP-BAND® device (Allergan, Inc., Irvine, CA), sleeve gastrectomy, Roux-en-Y gastric bypass, and biliopancreatic diversion with duodenal switch (see Figure 298-1 in chapter "The Patient With Morbid Obesity"). Overall operative mortality is <2%, but postoperative complications are common and are likely related to the technical skill of the surgeon.[12] Common complications are listed in **Table 87-4**.[13,14]

Nausea, vomiting, and abdominal pain are common symptoms in ED patients with a history of bariatric surgery. In the first few postoperative weeks, consider life-threatening problems like anastomotic leak and intra-abdominal bleeding. In patients with abdominal pain, tachycardia, or abdominal tenderness in the early postoperative period, a CT scan is often required to rule out these diagnoses.

A common complication of the Roux-en-Y gastric bypass is dumping syndrome, which can occur either right after the meal (early) or 2 to 4 hours later (late). Dumping symptoms occur when the pylorus is bypassed or removed. The hyperosmolar chyme contents of the stomach are dumped into the jejunum, causing rapid influx of extracellular fluid and an autonomic response. Patients experience nausea, epigastric discomfort, palpitations, colicky abdominal pain, diaphoresis, and, in some cases, dizziness and syncope. Patients with early dumping symptoms experience diarrhea, whereas those with late dumping symptoms, 2 to 4 hours postprandially, usually do not. The late dumping syndrome is believed to be due to a reactive hypoglycemia. The mainstay of treatment is dietary modification; consumption of small, dry meals; and separation of solids from liquids. In refractory cases, pyloroplasty can be tried. Most patients with dumping syndrome do not require hospital admission.

Patients with gastroesophageal reflux disease present with burning epigastric pain that is aggravated by meals and unrelieved by vomiting. The syndrome is caused by reflux of bile into the stomach. Diagnosis is made clinically, but other potential diagnoses are often ruled out with endoscopic examination.

Wernicke's encephalopathy is a rare, but serious, complication that must be considered in a patient with a history of bariatric surgery who presents with any cerebellar signs, ophthalmoplegia, weakness, and/or memory disturbances. Although vitamin deficiencies are common with both Roux-en-Y gastric bypass and biliopancreatic diversion, vitamin B_{12} deficiency is the only one that requires emergent intervention.

NONBARIATRIC GASTRIC SURGERY

Patients who have undergone partial or complete gastrectomy for nonbariatric reasons can present with a few distinct syndromes: dumping syndrome, alkaline reflux gastritis, afferent loop syndrome, and postvagotomy diarrhea. Although these complications are rare, the symptoms can be disabling. Dumping syndrome as a result of nonbariatric gastric surgery is treated in the same way as dumping syndrome after bariatric procedures.

Patients with afferent loop syndrome also develop severe epigastric pain 1 to 2 hours after eating, which is relieved by vomiting. The vomitus is bilious, without food. The syndrome occurs in patients who have undergone gastroenterostomy (Billroth II) reconstruction after partial gastrectomy. Diagnosis is made by contrast radiography or endoscopy. Operative reconstruction is required.

Truncal vagotomy usually results in increased bowel movements, but occasionally results in diarrhea. Diarrhea is variable in occurrence and not associated with food intake. It is often unpredictable and explosive, which can lead to weight loss, malnutrition, and severe social complications. The incidence of the diarrhea decreases with time, and treatment is mostly symptomatic.

Gastrostomy Tubes Most gastrostomy tubes are now placed by an endoscopist by percutaneous endoscopy or by a radiologist by percutaneous fluoroscopy. If the patient has undergone a laparotomy, the general surgeon may place a gastrostomy tube at the time of surgery.

TABLE 87-4 Complications of Gastric Bypass Procedures

Complication	Presentation	Signs and Symptoms	Diagnostic Test
Anastomotic leak	0–28 d	Tachycardia, fever, abdominal pain, nausea, vomiting, hypotension	Clinical suspicion. CT scan or upper GI study are useful, but may be negative
Intra-abdominal bleeding	0–28 d	Tachycardia, abdominal pain, hypotension	CT scan or upper GI study
Intraluminal GI bleeding	Hours to months	Melena, hematemesis, hypotension, altered mental status	Emergent endoscopy
Ventral hernia	Anytime	Pain at incision site or palpable hernia	Clinical diagnosis
Bowel obstruction	1 week to 8 months	Nausea, vomiting, abdominal pain	Plain radiography or CT looking for air-fluid levels
Stomal stenosis	2 months to 1 year	Postprandial abdominal pain, nausea, vomiting	Endoscopy or upper GI study
Stomal ulcer	Months to years	Abdominal pain, upper GI bleed	Endoscopy
Stomal obstruction	Months to years	Nausea and vomiting with solids and liquids	Endoscopy
Cholelithiasis/cholecystitis	Months to years	Abdominal pain with fatty foods, fever, tachycardia	US
Dumping syndrome	Anytime	Diarrhea, abdominal cramps, nausea, vomiting, tachycardia, palpitations, flushing, dizziness, syncope	Clinical diagnosis or endoscopy
Vitamin deficiencies	Months to years	Weakness, bone loss, anemia, fractures, neuropathy, hypercalcemia	CBC, iron studies, parathyroid hormone studies, vitamin levels
Gastric slippage	Days to years	Abdominal pain, dysphagia, food intolerance, reflux	Upper GI study
Esophageal, gastric pouch dilation	After band adjustment	Epigastric abdominal pain, dysphagia, reflux	Upper GI study
Gastric necrosis	Anytime	Abdominal pain	Upper GI study

TABLE 87-5 Complications of Cholecystectomy

Bile leak
Bile duct stricture
Bleeding
Bowel injury
Intra-abdominal abscess
Acute myocardial infarction
Pancreatitis
Peritonitis
Pulmonary complications
Retained common duct stones or stones spilled into peritoneum
Splenic injury
Umbilical hernia
Wound infection

If the tube was placed by the surgeon and has not been replaced, it will have a bumper holding the tube in place. The tube has to be cut and the bumper allowed to pass, or the bumper has to be removed by endoscopic technique. For further discussion, see chapter 86, "Gastrointestinal Procedures and Devices."

LAPAROSCOPIC SURGERY

BILIARY TRACT SURGERY

More than 90% of all cholecystectomies are now performed laparoscopically. Complications can occur after open and laparoscopic cholecystectomies (**Table 87-5**); complications can also be related to the laparoscopic technique (**Table 87-6**).[15]

The evaluation of abdominal pain after cholecystectomy depends on the clinical condition of the patient. If there are signs of peritoneal irritation or fever, an injury to the biliary system is likely. Obtain an abdominal CT in addition to a CBC, electrolyte measurements, liver function tests, and serum lipase level. A collection of bile can be seen on CT, but endoscopic retrograde cholangiopancreatography is required to identify the specific site of the injury. Depending on the endoscopic retrograde cholangiopancreatography results, reoperation may be necessary. Small collections of bile may require only observation or percutaneous drainage.

Patients presenting soon after cholecystectomy with pain, pancreatitis, and/or jaundice may have retained common duct stones. If US does not demonstrate a dilated common bile duct, or if CT does not reveal an intra-abdominal collection of fluid, an endoscopic retrograde cholangiopancreatography should be performed. Endoscopic sphincterotomy is usually an effective means of dealing with retained stones. Patients presenting late after cholecystectomy with fever, pain, and jaundice may have bile duct stricture. Diagnosis requires endoscopic retrograde cholangiopancreatography. Insertion of stents is usually tried first, but surgical repair may be necessary. A more recent concern has been the spillage of gallstones into the peritoneal cavity at the time of surgery. Initially, such stones were thought to be innocuous. However, they have been linked to abdominal pain, pelvic pain, dysmenorrhea, intra-abdominal abscess, colocutaneous fistula, and implantation into the ovary with subsequent infertility.

TABLE 87-6 Complications of Laparoscopy

Related to pneumoperitoneum
Cardiac arrhythmias during the procedure
Subcutaneous emphysema
Pneumothorax
Pneumomediastinum
Carbon dioxide embolization
Related to insertion of needle and trocar
Bleeding from trocar site
GI tract injuries
Laceration
Intestinal burns
GU tract injuries
Major vessel injuries
Hernia from trocar site
Wound infection
Miscellaneous
Retained intra-abdominal gallstones
Biliary cutaneous fistula
Chronic pain
Infertility
Cholelithiasis
Metastases to the trocar site

OTHER LAPAROSCOPIC SURGERIES

Laparoscopic techniques are used for cholecystectomy, appendectomy, colon resection, antireflux surgery, herniorrhaphy, fundoplication, and most gynecologic and urologic surgical procedures. As with any laparoscopic procedure, there are risks related to the pneumoperitoneum and insertion of the trocar (Table 87-6). In addition to the potential for bowel injury, major vessel injury, and splenic injury, gynecologic and urologic procedures carry a risk of injury to the urinary bladder and ureters.

STOMAS

The two most commonly placed stomas are the ileostomy and the colostomy. Problems with stomas can be quite debilitating. Most acute complications are related to technical errors of stoma placement. Other complications include the development of Crohn's disease or carcinoma at the stomal site, stomal ischemia and necrosis, peristomal skin irritation, peristomal hernia, and stomal prolapse.

Ischemia and stomal necrosis are manifested very early in the postoperative course. The cause is inadequate blood supply to the stoma. Normally, the stoma is pink, without evidence of cyanosis. Any evidence of compromised blood flow requires surgical evaluation.

Peristomal maceration and skin destruction are most likely secondary to a poor seal of the stomal appliance. Consult an enterostomal therapist for a properly fitting appliance.

Stomal prolapse can occur with ileostomies and colostomies. The cause is usually inadequate fixation of the intra-abdominal portion or too large an abdominal wall opening. Patients present with stoma protrusion, with or without pain. Examine the stoma for viability. It should be pink and painless. If the tissue is viable, attempt reduction and follow with surgical consultation. Definitive therapy requires surgical revision.

Parastomal hernias can develop if the abdominal wall opening is too large. Determine if the hernia is incarcerated, attempt reduction, and consult a surgeon. Definitive therapy requires local reconstruction of the orifice.

COLONOSCOPY

Potential complications of colonoscopy include hemorrhage, perforation, retroperitoneal abscess, pneumoscrotum, pneumothorax, volvulus, postcolonoscopy distention, splenic rupture, appendicitis, bacteremia, and infection.[16] Hemorrhage is the most common complication and can be secondary to polypectomy procedures, biopsies, laceration of the mucosa by the instrument, or tearing of the mesentery or spleen. If the bleeding is intraluminal, the patient will develop rectal bleeding. Patients with mesenteric or splenic injury have signs of intra-abdominal bleeding. Treatment of intraluminal bleeding depends on the magnitude of hemorrhage. Intra-abdominal bleeding requires emergency laparotomy. Colon perforation with pneumoperitoneum usually is evident immediately but can take several hours to manifest.[17] Perforation is usually

secondary to intrinsic disease of the colon (e.g., diverticulitis) or to vigorous manipulation during the procedure. Most patients require immediate laparotomy, but in some patients presenting late (1 to 2 days later) without signs of peritonitis, hospital observation may be appropriate.

RECTAL SURGERY

Patients who have undergone hemorrhoidectomy frequently have problems with postoperative urinary retention, the management of which has been discussed previously in the section "Urinary Retention." Three other problems that can occur are constipation, rectal hemorrhage, and rectal prolapse.

The management of constipation in a patient who has undergone rectal surgery is no different from management in any other patient. Perform gentle rectal examination to identify fecal impaction, and if present, remove the impaction. Otherwise, enemas can be used. Posthemorrhoidectomy rectal hemorrhage can occur immediately postoperatively but may be delayed up to weeks after the surgery. Causes of delayed bleeding include sepsis of the pedicle, disruption of a clot, and sloughing of tissue. Bleeding can be scant or massive. Temporary balloon tamponade using a Foley catheter may temporize until surgical ligation of the involved vessel is performed.

Mucosal prolapse occurs when the surgeon has not removed all redundant mucosa during hemorrhoidectomy and is much more common than rectal prolapse. Local treatment by a surgeon is usually corrective. *Rectal prolapse* can occur after any anorectal surgical procedure and likely is related to injury of the puborectalis muscle. The diagnosis is obvious on examination. The treatment is reduction (see chapter 85, "Anorectal Disorders") and surgical consultation.

Infection after anorectal surgery is surprisingly uncommon. The patient usually complains of increasing pain and fever. Examination of the area is necessary to detect an abscess or cellulitis. Fournier's gangrene may follow anorectal surgery. If this is suspected, give broad-spectrum parenteral antibiotics immediately. The patient must undergo immediate surgical debridement.

CHAPTER 88

Acute Kidney Injury

Richard Sinert
Peter R. Peacock, Jr.

INTRODUCTION AND EPIDEMIOLOGY

Acute kidney injury is the deterioration of renal function over hours or days resulting in the accumulation of toxic wastes and the loss of internal homeostasis. Definitions based on renal function are listed in **Table 88-1**.[1]

Community- and hospital-acquired kidney injuries differ by cause, treatment, and outcome (**Table 88-2**). **Community-acquired renal failure** is diagnosed in only 1% of hospital admissions at the time of presentation[2,3] and is usually secondary to volume depletion; thus, the vast majority of cases presenting to the ED have a reversible cause.[3] Mortality among patients presenting to the ED with prerenal acute renal failure may be as low as 7%.[4]

Hospital-acquired renal failure is only apparent after admission.[5] Hospital factors include advanced patient age, potential nephrotoxic exposures in a hospital setting, sepsis,[6] and multiorgan system illness in hospitalized patients. There is an almost linear relationship between increasing severity of renal injury and mortality rate: no renal injury, 4.4%; *risk* category/stage 1, 15.1%; *injury* category/stage 2, 29.2%; and *failure* category/stage 3, 41.1%.[6]

PATHOPHYSIOLOGY

Renal insult is classified as **prerenal** (decreased perfusion of a normal kidney), **intrinsic** (pathologic change within the kidney itself), or **postobstructive** (obstruction to urine outflow).

The functions of the kidneys are glomerular filtration, tubular reabsorption, and secretion. Normal glomerular filtration rate (GFR) in early adulthood is approximately 120 mL/min/1.73 m^2 and typically decreases by 8 mL/min/1.73 m^2 every decade thereafter. The driving force for glomerular filtration is glomerular capillary pressure, which depends on renal blood flow and autoregulation. For most causes of acute renal failure, global or regional decrease in renal blood flow is the final common pathway. Recovery from acute renal failure first depends on restoration of renal blood flow.

In **prerenal failure**, tubular and glomerular functions are still maintained. Restoration of circulating blood volume is usually sufficient to restore function. **Postobstructive renal failure** initially results in an increase in tubular pressure, which decreases the driving force for filtration. This pressure gradient soon equalizes, and the maintenance of depressed GFR depends on vasoconstrictors. Rapid relief of urinary obstruction in **postrenal failure** results in a prompt decrease of vasoconstriction.

Intrinsic renal failure occurs with diseases of the glomerulus, small vessels, interstitium, or tubule and is associated with the release of renal vasoconstrictors. The most common cause of intrinsic renal failure is **ischemic injury or ischemic tubular necrosis** (also historically called **acute tubular necrosis)**, when renal perfusion is decreased so much that the kidney parenchyma is affected.

During the period of depressed renal blood flow, the kidneys are especially vulnerable to further insults. Exposure at this time to known nephrotoxins such as radiocontrast agents and aminoglycosides causes iatrogenic acute renal failure. **Figure 88-1** illustrates the cellular and subcellular events leading to ischemic tubular necrosis.

TABLE 88-1 AKIN and RIFLE Criteria for Acute Kidney Injury

AKIN Stage	RIFLE Category	GFR Criteria	Urine Output Criteria
Stage 1	Risk	Serum Cr increased 1.5 times* *or* (AKIN only) Cr increase >0.3 milligrams/dL over <48 h* *or* GFR decrease 25%–50%*	0.5 mL/kg/h for 6 h
Stage 2	Injury	Serum Cr increased 2.0–3.0 times* *or* GFR decrease 50%–75%*	0.5 mL/kg/h for 12 h
Stage 3	Failure	Serum Cr increased >3.0 times* *or* Cr >4 milligrams/dL and acute increase >0.5 milligrams/dL* *or* GFR decrease >75%*	0.3 mL/kg/h for 24 h *or* Anuria for 12 h
N/A	Loss	Complete loss of kidney function for >4 wk	
	End-stage renal disease	Need for renal replacement therapy for >3 months	

Abbreviations: AKIN = Acute Kidney Injury Network; Cr = creatinine; GFR = glomerular filtration rate; N/A = not applicable; RIFLE = Risk, Injury, Failure, Loss, End Stage.
*All changes are relative to the patient's premorbid baseline.

In **intrinsic renal failure,** clearance of tubular toxins and initiation of therapy for glomerular diseases decrease vasoconstriction and help restore renal blood flow. Once the cause of injury is resolved, the remaining functional nephrons increase filtration and eventually hypertrophy. Depending on the size of the remnant nephron pool, GFR will proportionately recover. If the number of remaining nephrons is below some critical number, continued hyperfiltration results in progressive glomerular sclerosis, eventually leading to nephron loss. A vicious cycle then ensues until complete renal failure occurs. This sequence explains the commonly observed scenario in which progressive renal failure occurs after initial recovery from acute renal failure.

CLINICAL FEATURES

HISTORY AND COMORBIDITIES

Renal failure itself has few symptoms until severe uremia develops. Nausea, vomiting, drowsiness, fatigue, confusion, and coma are findings in uremia. Patients are more likely to present with symptoms related to the

TABLE 88-2 Causes of Community-Acquired and Hospital-Acquired Acute Renal Failure

Community Acquired		Hospital Acquired	
Prerenal	70%	Prerenal	20%
Intrinsic	20%	Acute tubular necrosis	70%
Postrenal	10%	Postrenal	10%

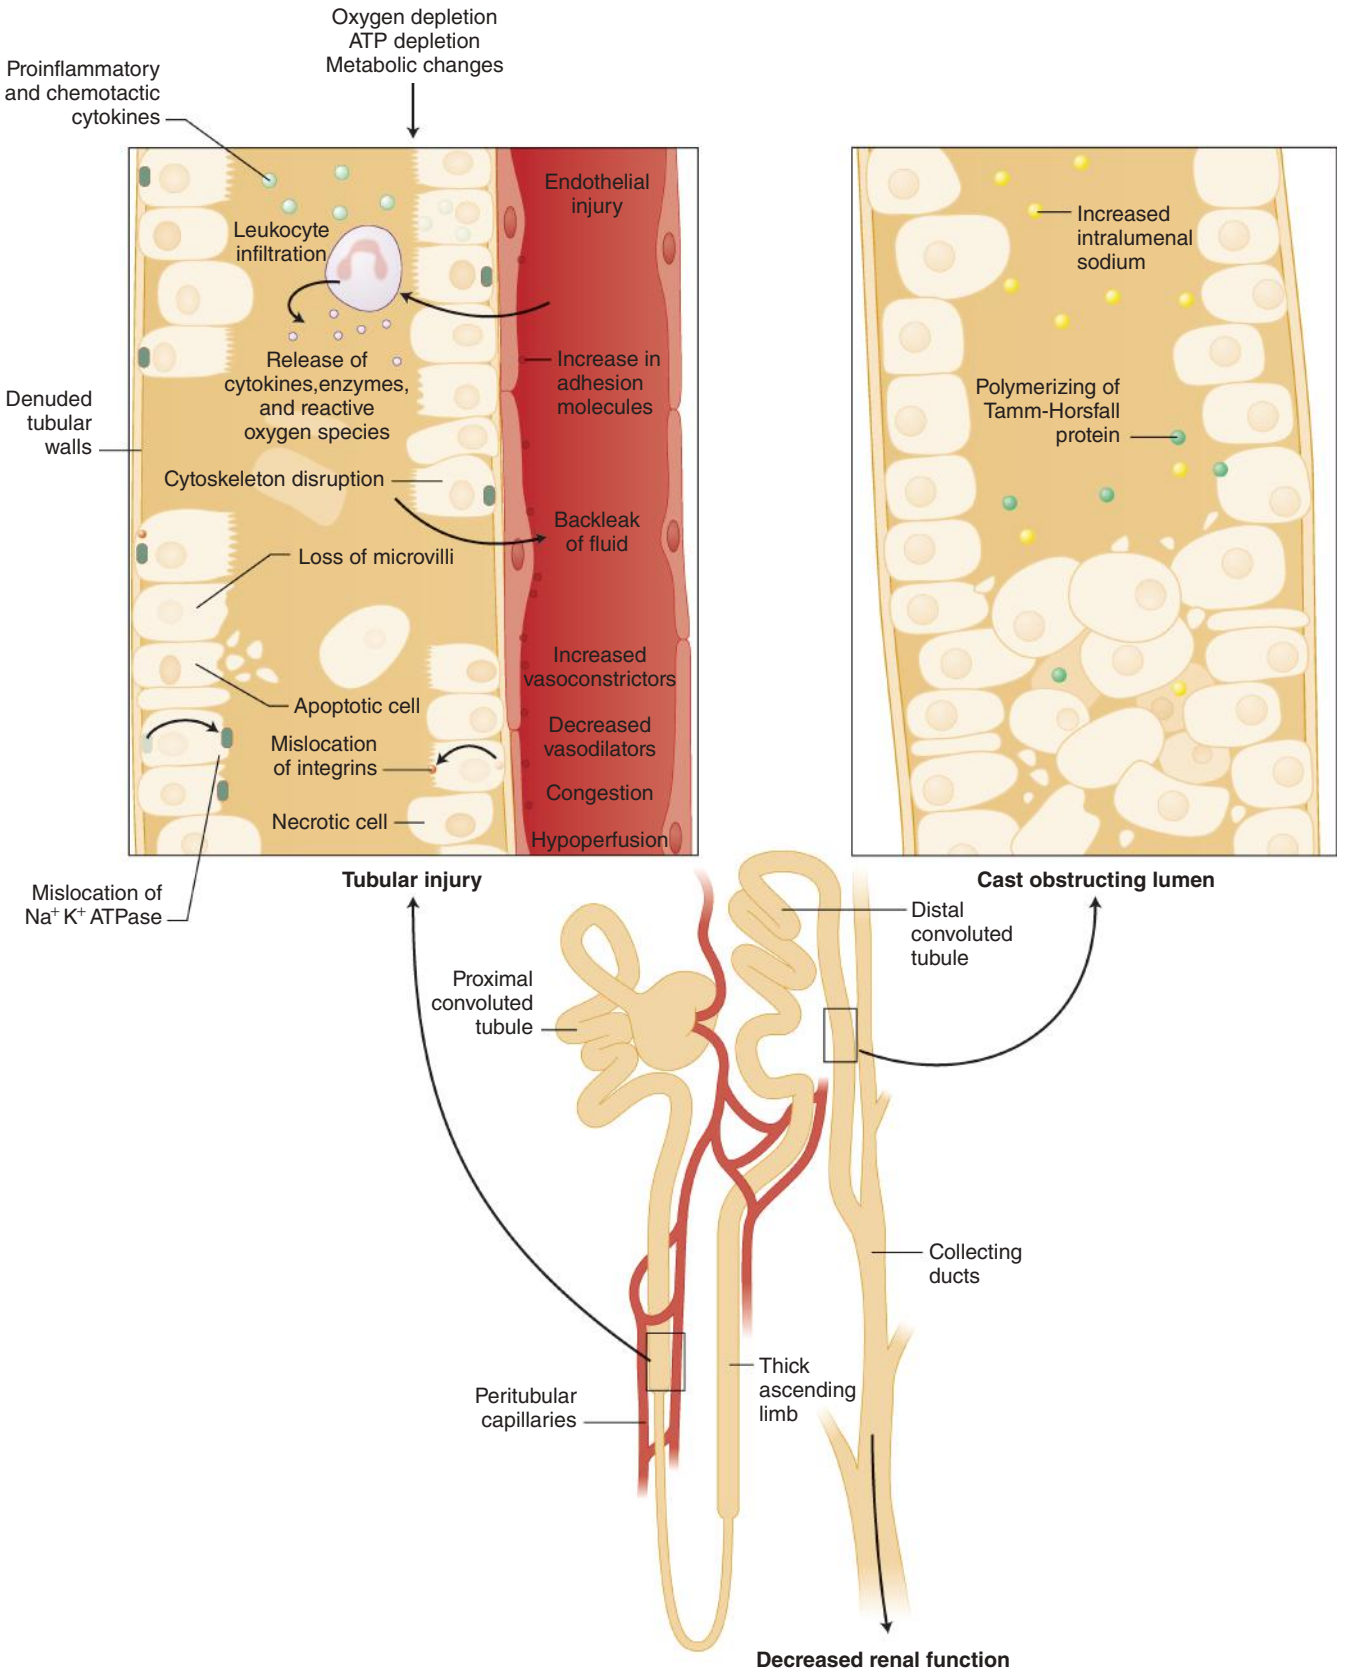

FIGURE 88-1. Ischemic tubular necrosis. Tubular injury is a direct consequence of vasoconstriction, inflammation, endothelial changes, disruption of cell-cell andcell-matrix connections, and apoptotic changes.

TABLE 88-3 Risk Factors for Renal Disease

Risk Factor	Comments
Medications	
COX-1 and COX-2 inhibitors	
ACE inhibitors	
Failure to dose medications for renal insufficiency	Antibiotics, metformin, proton pump inhibitors
Statins	Myopathy, rhabdomyolysis
Antiretroviral therapy	
Angiotensin receptor blockers	
Gabapentin, pregabalin, vigabatrin	>90% renal excretion
Levetiracetam	66% renal excretion
Topiramate	Low risk of renal tubular acidosis and nephrolithiasis
Eslicarbazepine	
Immunosuppressives	Tacrolimus, cyclosporine
Drugs of abuse	
Cocaine, ethanol, ethylene glycol	
Contrast agents	
Iodinated contrast media	
Gadolinium	Nephrogenic systemic fibrosis
Systemic disease	
Gout	
Coronary artery disease	
Hypertension	
Sepsis	
Hepatic disease	
Vascular disease	
Diabetes	
Outflow obstruction: prostatic/urethral disease	
Advanced age	
Heart failure	
Dehydration	
Multiple myeloma/hypercalcemia	
Vasculitis/autoimmune disease	
Systemic embolism: atrial fibrillation, endocarditis	
Malignancy	Drug effects; renal parenchymal invasion; bladder obstruction; light-chain proteins
Eclampsia and pre-eclampsia	
Kidney transplantation	Rejection, infection

Abbreviations: ACE = angiotensin-converting enzyme; COX = cyclooxygenase.

underlying cause of renal failure (**Table 88-3**), which should prompt assessment of renal function.[7]

Patients with **prerenal acute renal failure** commonly develop thirst, orthostatic light-headedness, and decreased urine output. Excessive vomiting, diarrhea, urination, hemorrhage, fever, or sweating can reduce circulating volume enough to precipitate acute renal failure. Causes of endothelial leak and third spacing, such as sepsis, pancreatitis, burns, and hepatic failure, can also result in prerenal failure, although these settings may also be associated with renal parenchymal injury. Progression of heart failure from any cause or overdiuresis of the patient with compensated congestive heart failure can result in renal failure. Decreased fluid intake from physical or cognitive disability can result in hypovolemia.

Intrinsic renal diseases can often be anticipated because of symptoms of the precipitating cause. Anticipate **ischemic acute kidney injury** after cardiac arrest, in severe sepsis, or with other causes of systemic hypotension. Renal failure from **crystal-induced nephropathy, nephrolithiasis, and papillary necrosis** can present as flank pain and hematuria. Suspect pigment-induced renal failure in **rhabdomyolysis**[8] (see chapter 89, "Rhabdomyolysis") or with hemolysis after recent blood transfusion. Darkening urine and edema with or without constitutional symptoms such as fever, malaise, and rash suggest **acute glomerulonephritis**, which may have been preceded by pharyngitis or cutaneous infection. Fever, arthralgia, and rash are common with **acute interstitial nephritis**. **Acute renal arterial occlusion** is usually marked by severe flank pain. Cough, dyspnea, and hemoptysis raise the possibility of **Goodpasture's syndrome** or **Wegener's granulomatosis**.

Suspect **postrenal failure** in men with prostatic disease or advanced age and patients with indwelling bladder catheters. Anuria strongly suggests obstruction, although vascular obstruction and fulminant renal disease are also possible. Alternating oliguria and polyuria is virtually pathognomonic of obstruction.

PHYSICAL EXAMINATION

Assess and correct volume status. Evaluate mucous membranes, jugular vein distention, lung auscultation, peripheral edema, and tissue turgor to identify dehydration. Base deficit, lactate level, central venous pressure and oxygen saturation, and US (see Imaging) can be reliable indicators of hypovolemia. Carefully assess for rashes, evidence of vasculitis, jaundice, abdominal or pelvic masses, or a distended palpable urinary bladder. On cardiac exam, check for atrial fibrillation, abdominal aortic aneurysm, and signs of heart failure, and assess extremity pulses.

DIAGNOSIS

In the ED, the goals are to identify patients at risk for acute kidney injury who aren't obviously ill and for those with diagnosed kidney injury to correct metabolic effects, decrease ongoing renal injury, and prevent iatrogenic injury. **Determine if kidney injury is prerenal, postrenal, or intrinsic.**

Obtain CBC, electrolyte levels including magnesium and phosphorus, and hepatic function tests and blood cultures if clinically appropriate. Obtain urinalysis, urine osmolality, and urine culture.

ECG is often the fastest screening test for **hyperkalemia**, but sensitivity for a level over 6.5 mmol/L ranges from 14% to 60%.[9,10] Although ECGs were read as "abnormal" in 83% of patients in one study, peaked T waves were only seen in 34%, which led to delayed therapy for most patients for whom peaked T waves were not evident[11] (see chapter 17, "Fluids and Electrolytes"). Chest radiography helps evaluate for increased volume, effusions, and pneumonia, all of which can result from or precipitate renal failure.

Obtain bedside US to assess urinary bladder volume. A large postvoid bladder residual volume (>125 mL) suggests bladder outlet obstruction for which you would place a urethral catheter. See chapter 92, "Acute Urinary Retention" for further discussion. Anuria is 100 mL urine per day and can be present with prerenal, postrenal, or intrinsic kidney disease. Alternating oliguria and polyuria is virtually pathognomonic of obstruction.

LABORATORY EVALUATION

Creatinine and Glomerular Filtration Rate Creatinine (Cr) is the mainstay for measuring renal function; it is a breakdown product of the skeletal muscle protein creatine, and its level is thus linked to muscle mass. **In patients with no renal function (GFR = 0), serum Cr level increases 1 to 3 milligrams/dL a day.** Lesser increases in Cr indicate residual renal function, whereas faster increases suggest rhabdomyolysis. Elevation of serum Cr may take 48 hours to accumulate after onset of decreased function, and a patient with a very low baseline Cr level can lose more than half of the functioning nephrons before serum Cr elevates to an abnormal level.

Cr clearance is used to estimate GFR, and although it is not perfect, it is a useful measure in the ED. Patients with lower muscle mass (e.g., older patients and women) have lower actual GFRs for any given Cr level. Glomerulonephritis increases tubular secretion of Cr, but trimethoprim, cimetidine, and salicylates decrease tubular secretion of Cr, thus altering the Cr level independently of the GFR.

GFR calculations are provided online, for hand-held devices, and in electronic medical record systems, and there are several formulas for GFR calculation. **Normal kidney function is a GFR >90 mL/min/1.73 m²**, where 1.73 m^2 is used as the average body surface area. Stages of kidney disease are characterized by GFR: stage 1, GFR 90 mL/min/1.73 m^2; stage 2, GFR 60 to 89 mL/min/1.73 m^2; stage 3, GFR 30 to 59 mL/min/1.73 m^2; stage 4, GFR 15 to 29 mL/min/1.73 m^2; and stage 5, GFR <15 mL/min/1.73 m^2 (dialysis or transplant needed).

BUN:Cr Ratio The ratio of BUN to Cr can suggest hypovolemia because of differences in the way each is handled in the nephron. Both substances are passively filtered at the glomerulus, but whereas Cr remains within the tubule, the renal tubule is highly permeable to urea, which is passively reabsorbed with sodium. Therefore, in the setting of avid sodium retention, urea clearance is as low as 30% of GFR, whereas in the setting of adequate volume and sodium, urea clearance can increase to 70% to 100% of GFR. **Thus, if the patient has normal concentrating ability, in the setting of prerenal failure, the serum ratio of BUN to Cr is typically >10.** BUN level is depressed in patients with malnutrition and hepatic synthetic dysfunction and **can be increased in the setting of protein loading, GI hemorrhage, or trauma**. Although an elevated ratio of BUN to Cr had been assumed to suggest more reversible prerenal physiology, recent evidence has called that into question.[12]

Fractional Excretion of Sodium The fractional excretion of sodium ($Fe_{Na} = U_{Na}/P_{Na} \div U_{Cr}/P_{Cr}$, where U = urine and P = plasma) is another indicator that is commonly used to identify hypovolemia, but it has important limitations. For example, in the setting of intrinsic renal failure in which tubular concentrating capacity is retained, as in the case of glomerulonephritis, the fractional excretion of sodium may be depressed if there is concomitant volume depletion. With tubular injury such as ischemic acute tubular necrosis, the loss of concentrating ability results in a dilute urine, with a fractional excretion of sodium >1%, even if the patient is volume depleted (**Table 88-4**).

TABLE 88-4 Laboratory Findings in Conditions That Cause Acute Renal Failure

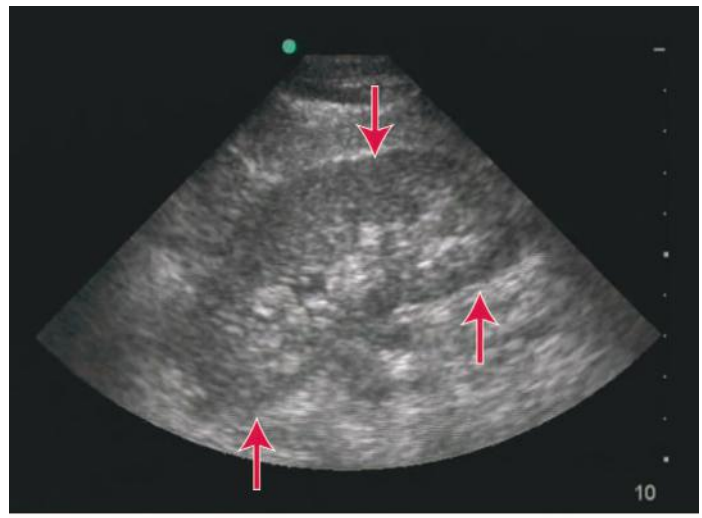
Category	Dipstick Test	Sediment Analysis	Urine Osmolality (mOsm/kg)	Fractional Excretion of Sodium (%)
Prerenal	Trace to no proteinuria, SG >1.015	A few hyaline casts possible	>500	<1
Renal				
Ischemia	Mild to moderate proteinuria	Pigmented granular casts, renal tubular epithelial cells	<350	>1
Nephrotoxins	Mild to moderate proteinuria	Pigmented granular casts	<350	>1
Acute interstitial nephritis	Mild to moderate proteinuria; hemoglobin, leukocytes	White cells, eosinophils, casts, red cells	<350	>1
Acute glomerulonephritis	Moderate to severe proteinuria; hemoglobin	Red cells and red cell casts; red cells can be dysmorphic	>500	Depends on volume status
Postrenal	Trace to no proteinuria; hemoglobin and leukocytes possible	Crystals, red cells, and white cells possible	<350	>1

Abbreviation: SG = specific gravity.

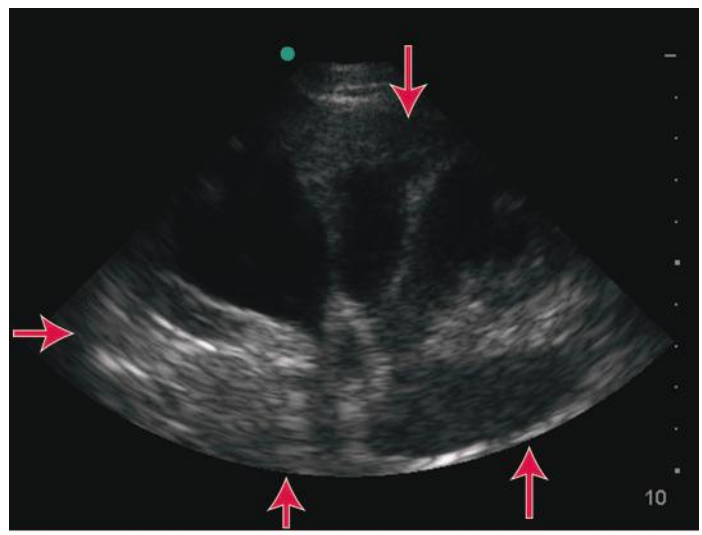
Urinalysis Microscopic examination of urine is useful in establishing the differential diagnosis. In acute glomerulonephritis, red blood cells enter the filtrate at the glomerulus and, on microscopic urinalysis, appear as casts and dysmorphic cells due to the increased tonicity of the renal medulla. In acute tubular necrosis, the tubular epithelium breaks down and allows protein to leak into the filtrate, and tubular epithelial cells may be seen in the sediment.

Hyaline casts are common in prerenal failure and can be a normal finding, but pigmented granular casts are common with ischemic or toxic tubular injury. Brown granular casts are common in hemoglobinuria or myoglobinuria. **The finding of hemoglobin on urine dipstick analysis with no red cells on microscopy suggests myoglobinuria.** Some crystals may be present in a normal urinalysis. Crystals are best seen with polarized light microscopy. Red cell casts and proteinuria suggest glomerulonephritis or an underlying autoimmune disease.

Imaging Renal US is the test of choice for urologic imaging in the setting of acute kidney injury. It has approximately 90% sensitivity and specificity for detecting hydronephrosis due to mechanical obstruction. **Figure 88-2** contrasts normal kidney US findings with US findings indicating hydronephrosis. If renal US detects hydronephrosis, a secondary imaging study to define the location of obstruction may be required.



A



B

FIGURE 88-2. US of normal kidney and kidney showing hydronephrosis. A. Normal kidney, capsule margin at *arrows*. B. Hydronephrosis as would be expected in obstructive uropathy; the dilated kidney fills the majority of the screen, capsule at *arrows*. [Image used with permission of Michael B. Stone, MD, RDMS.]

Bipolar renal length is easy to assess by US, and **kidney dimension of <9 cm suggests chronic renal failure**. Renal parenchyma should be isoechoic or hypoechoic compared with that of the liver and spleen. Hyperechogenicity indicates diffuse parenchymal disease. Color flow Doppler US allows assessment of renal perfusion and can allow diagnosis of large-vessel causes of renal failure. Resistive index is the ratio of the difference between systolic and diastolic flow to systolic flow [$(V_{max} - V_{min})/V_{max}$] as measured by color flow Doppler. In the vasoconstrictive phase of ischemic renal failure, in which there may be no diastolic flow, the ratio may be as high as 1.0. The normal ratio is <0.7.

In *intermittent or partial obstruction*, hydronephrosis may *not* be present, and it may even be *absent* in *complete obstruction* in the setting of retroperitoneal fibrosis. Furthermore, functional dilatation can occur in the setting of chronic reflux.

Noncontrast CT has sensitivity for hydronephrosis that is equivalent to that of US and has the added advantage of demonstrating the site and often the cause of obstruction. If functional obstruction is a consideration in the presence of a dilated GU tract, radionuclide scans and magnetic resonance urographs before and after administration of diuretics can be obtained.

TREATMENT

In the critically ill patient, resuscitation is the first priority, and multiple diagnostic and therapeutic processes advance simultaneously. Treat hypovolemia, and identify and treat sepsis, myocardial ischemia, and occult GI or retroperitoneal hemorrhage. Correct intravascular volume deficits with crystalloid. Crystalloid infusion is often sufficient to treat or improve many forms of acute renal failure, but accurate determination of volume status is essential to prevent volume overload, and often requires invasive hemodynamic monitoring, particularly in the setting of cardiac dysfunction. Bedside US can give some guidance for fluid resuscitation.[13] Inspiratory collapsibility of the intrahepatic segment of the inferior vena cava is one noninvasive measure of volume status and fluid responsiveness[14] (**Figure 88-3**).

Remember that most community-acquired acute kidney injury encountered in the ED is prerenal (see Table 88-2).

Make sure that renal dose adjustments are made for medication orders and prescriptions and that renal function is assessed before ordering radiographic contrast studies. In general, for IV contrast studies in patients with GFR of 30 to 59 mL/min/1.73 m^2, weigh benefits of the study against the risk of renal function decline. For patients with GFR <30 mL/min/1.73 m^2, avoid IV contrast studies if possible. Emergency contrast studies for major trauma, aortic dissection, or ST-segment elevation myocardial infarction are examples in which benefits typically outweigh risk. Make sure to avoid gadolinium for GFR <30 mL/min/1.73 m^2.

PRERENAL FAILURE

The causes of prerenal azotemia can be broken down into volume loss, hypotension, and diseases of the large and small renal arteries (**Table 88-5**). Prerenal failure is also a common precursor to ischemic and nephrotoxic conditions, leading to intrinsic renal failure.

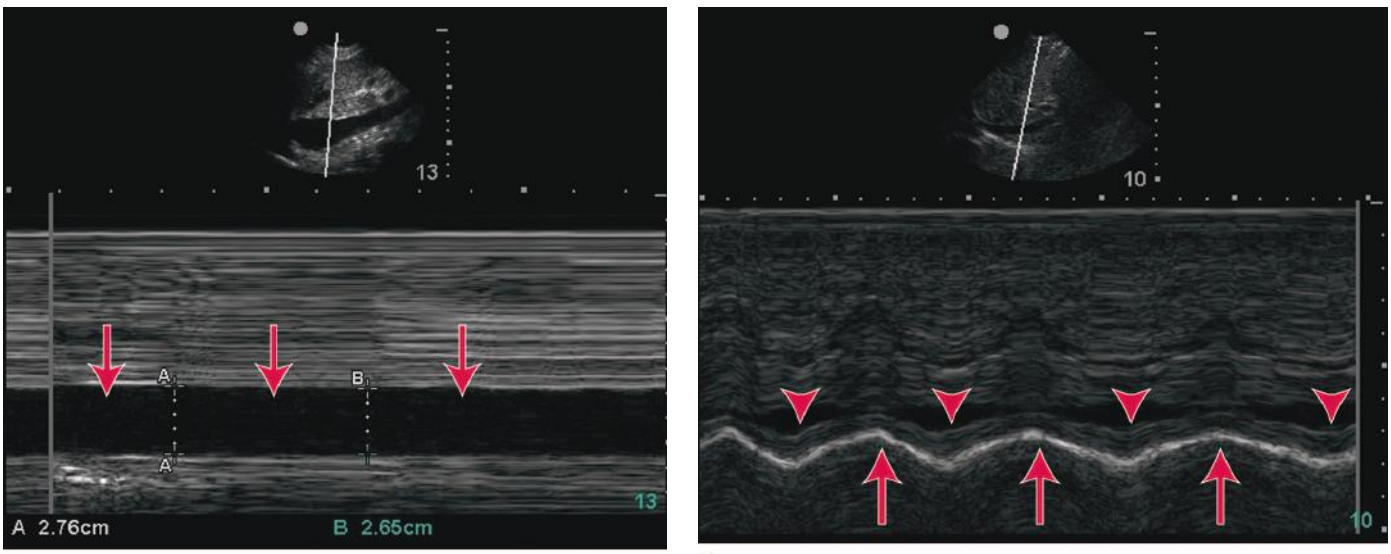
POSTOBSTRUCTIVE RENAL FAILURE

Postrenal or postobstructive kidney injury accounts for 5% to 17% of all community-acquired disease, and in the elderly population, the rate is as high as 22% (**Table 88-6**). Risk factors include both extremes of age, male sex, malignancy, nephrolithiasis, retroperitoneal disease, GU surgery, and indwelling urinary catheters. Timely relief of obstruction is essential for the return of normal renal function. **Permanent loss of renal function develops over the course of 10 to 14 days in the setting of complete obstruction. The risk of permanent renal failure increases significantly if obstruction is complicated by urinary tract infection.** For more discussion of postobstructive renal failure, see chapter 92.

INTRINSIC RENAL FAILURE

Intrinsic kidney injury is not common in patients with community-acquired disease, but it is the most common cause in hospitalized patients. Intrinsic renal failure can result from injury to the glomerulus, tubule, interstitium, and vasculature. In community-acquired intrinsic renal failure, drugs (**Table 88-7**) and infection are common precipitants, whereas in the hospital, toxic and ischemic insults cause most cases.[2-4]

Radiocontrast-induced nephropathy can be provoked by imaging with an IV contrast agent in the ED (see discussion below). Incidence ranges from 2% to 12%, with some reporting an even higher incidence. The typical course is an increasing Cr level, 25% above baseline, over 3 to 5 days, followed by complete resolution. Risk factors include chronic renal insufficiency, diabetes, heart failure, liver disease, and hypertension.[15,16]



A B

FIGURE 88-3. US of the inferior vena cava. A. Dilated inferior vena cava (*arrows*) with little respiratory variation as might be expected in volume overload. B. An almost fully collapsed inferior vena cava at inspiration (*arrows*) and expiration (*arrowheads*) as might be expected in prerenal acute kidney injury. [Image used with permission of Michael B. Stone, MD, RDMS.]

TABLE 88-5 Causes of Prerenal Failure

Hypovolemia
GI: decreased intake, vomiting and diarrhea
Pharmacologic: diuretics
Third spacing
Skin losses: fever, burns
Miscellaneous: hypoaldosteronism, salt-losing nephropathy, postobstructive diuresis
Hypotension (overt and relative)
Septic vasodilation
Hemorrhage
Decreased cardiac output: ischemia/infarction, valvulopathy, cardiomyopathy, tamponade
Pharmacologic: β-blockers, calcium channel blockers, other antihypertensive medications
High-output failure: thyrotoxicosis, thiamine deficiency, Paget's disease, arteriovenous fistula
Renal artery and small-vessel disease
Embolism: thrombotic, septic, cholesterol*
Thrombosis: atherosclerosis, vasculitis, sickle cell disease*
Dissection*
Pharmacologic: NSAIDs, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers (these act on the microvasculature but have prerenal physiology)
Cyclosporine and tacrolimus
Microvascular thrombosis: pre-eclampsia, hemolytic-uremic syndrome, disseminated intravascular coagulation, vasculitis, sickle cell disease*
Hypercalcemia

Abbreviation: NSAIDs = nonsteroidal anti-inflammatory drugs.
*These causes include a component of ischemic acute kidney injury.

TABLE 88-6 Causes of Postobstructive Renal Failure

Infants and children
Urethra and bladder outlet
Anatomic malformations: urethral atresia, meatal stenosis, anterior and posterior urethral valves (males)
Ureter
Anatomic malformations: vesicoureteral reflux (female preponderance), ureterovesical junction obstruction, ureterocele, megaureter (prune belly) syndrome, retrocaval ureter
Retroperitoneal tumor
All ages (various locations in the GU tract)
Trauma
Blood clot in bladder or urethra
Urethra and bladder outlet obstruction
Phimosis or urethral stricture (male preponderance)
Neurogenic bladder: diabetes mellitus, spinal cord disease, multiple sclerosis, Parkinson's disease; pharmacologic: anticholinergics, α-adrenergic antagonists, opiates
Calculus: in children in Southeast Asia, in adults typically a complication of mechanical intervention; in melamine-contaminated milk in China
Adults
Urethra and bladder outlet
Benign prostatic hypertrophy
Cancer of prostate, bladder, cervix, or colon
Obstructed catheters
Ureter obstruction
Calculi, uric acid crystals
Papillary necrosis: sickle cell disease, diabetes mellitus, pyelonephritis
Tumor: carcinoma of ureter, uterus, prostate, bladder, colon, rectum; retroperitoneal lymphoma; uterine leiomyomata
Retroperitoneal fibrosis: idiopathic, tuberculosis, sarcoidosis, methysergide, propranolol
Stricture: tuberculosis, radiation, schistosomiasis, nonsteroidal anti-inflammatory drugs
Miscellaneous: aortic aneurysm, pregnant uterus, inflammatory bowel disease, blood clot, trauma, accidental surgical ligation

CRYSTAL-INDUCED NEPHROPATHY

Crystal-induced nephropathy is precipitation of crystals within the renal tubules, resulting in mechanical and inflammatory injuries of the tubular epithelium. Chronic renal insufficiency and hypovolemia predispose patients to this form of renal injury, and urinary pH affects the formation of many of these crystals. Elevated uric acid levels in the setting of **tumor lysis syndrome** and some medications—in particular, acyclovir, sulfonamides, indinavir, and triamterene—are the most common causes of crystal-induced acute kidney injury.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors can simultaneously decrease the GFR and increase renal blood flow. These changes naturally result in a modest (10% to 20%) increase in serum Cr, but in rare cases, the increase can be more dramatic. The increases in Cr are typically observed shortly after initiation of ACE inhibitor therapy.[17] Overt acute kidney injury in the setting of ACE inhibitor initiation should prompt consideration of **bilateral renal artery stenosis**. Volume depletion and concomitant use of vasoconstricting medications are other common precipitators of ACE inhibitor–induced renal failure. Angiotensin receptor blockers (ARBs) have similar effects. Hyperkalemia, usually mild, is a relatively common complication of ACE inhibitor administration. Because ACE inhibitors actually improve renal blood flow while decreasing GFR, renal insufficiency and renal failure are not contraindications to the use of ACE inhibitors in appropriate patients (e.g., those with acute congestive heart failure exacerbation).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Cyclooxygenase inhibitors (most nonsteroidal anti-inflammatory drugs [NSAIDs]) can also cause renal failure. This family of medications decreases synthesis of vasodilatory prostaglandins, which results in decreases of both GFR and renal blood flow. Renal effects of selective cyclooxygenase-2 inhibitors seem to be very similar to those of nonselective inhibitors.[18] Risk factors for adverse reactions to these medications are older age, chronic renal insufficiency, congestive heart failure, diabetes, volume depletion, and use of diuretics or ACE inhibitors. Edema and renal insufficiency are typically observed early in the course

TABLE 88-7 Intrinsic Renal Failure Due to Drugs

Reduced renal perfusion by altered intrarenal hemodynamics	Amphotericin B, ACE inhibitors, cyclosporine, interleukin-2, NSAIDs, radiocontrast agents, tacrolimus
Direct tubular toxicity	Aminoglycoside antibiotics, amphotericin B, cisplatin, cyclosporine, foscarnet, heavy metals, IV immunoglobulin methotrexate, organic solvents, pentamidine, radiocontrast agents, tacrolimus
Rhabdomyolysis	Cocaine, ethanol, lovastatin
Intratubular obstruction	Acyclovir, chemotherapeutic agents, ethylene glycol, methotrexate, sulfonamides
Allergic interstitial nephritis	Allopurinol, cephalosporins, cimetidine, ciprofloxacin, furosemide, NSAIDs, phenytoin, penicillins, sulfonamides, rifampin, thiazide diuretics
Hemolytic-uremic syndrome	Cocaine, cyclosporine, conjugated estrogens, mitomycin, quinine, tacrolimus

Abbreviations: ACE = angiotensin-converting enzyme; NSAIDs = nonsteroidal anti-inflammatory drugs.

of treatment and are dose dependent. In reported cases, renal failure has resolved with discontinuation of the medication.

ANTIBIOTICS

Antibiotics and particularly **aminoglycosides** are another important cause of iatrogenic renal injury. Although peak concentration is typically most important for bactericidal activity, trough concentration appears to be more relevant in predicting renal injury, and once-daily dosing can reduce the incidence of nephrotoxicity.[19-22] Increased trough levels used with current **vancomycin** dosing for severe sepsis and septic shock are associated with increased rates of acute kidney injury. There is also evidence that **fluoroquinolones** may predispose to the condition.[23,24]

PIGMENTS

Hemoglobin and myoglobin from hemolysis or rhabdomyolysis are deposited and concentrated in the renal tubules. Renal injury occurs through tubular obstruction and direct toxicity. Large-volume crystalloid infusion is the cornerstone of treatment for rhabdomyolysis and hemoglobinuria (see chapter 89, "Rhabdomyolysis"). **Myeloma light-chain nephropathy** may also cause tubular obstruction.

TREATMENT OF INTRINSIC RENAL FAILURE

Low ("renal")-dose dopamine does not improve renal recovery or decrease mortality.[25] Fenoldopam is a potent dopamine D_1-selective receptor agonist that increases blood flow to the renal cortex and outer medulla while lowering systemic blood pressure. It reduces mortality and provides renal protection in critically ill patients with or at risk for renal failure.[26] Because it is titratable and reliably controls severe hypertension, **fenoldopam is considered by some to be the agent of choice for hypertensive emergencies with renal dysfunction** (see chapter 57, "Systemic Hypertension").

Venodilators (nitrates) and dialysis are the best treatment for volume overload. Diuretics may be helpful for volume overload, but high-dose **furosemide** can cause ototoxicity and otherwise provides no benefit to patients with acute kidney injury.[27,28] **Calcium channel blockers and mannitol have no role in the treatment of acute kidney injury.** Indications for emergency dialysis are listed in **Table 88-8**.

SPECIAL CONSIDERATIONS

RADIOCONTRAST-INDUCED NEPHROPATHY

Radiocontrast-induced nephropathy is an important consideration in the ED because of the high rate of use of radiocontrast-enhanced imaging (see **Table 88-9**). Risk for this condition is very closely related to existing renal insufficiency and the presence of concomitant renal insults, including diabetes, hypovolemia, sepsis, and use of nephrotoxic medications. Risk-scoring tools[29] have focused on coronary angiography. **Radiocontrast-induced nephropathy begins as a significant concern when GFR is <60 mL/min/1.73 m².[30] Do not give gadolinium-based contrast for MRI if the GFR is ≤30 mL/min/1.73 m² due to the risk of nephrogenic systemic fibrosis.**

The use of sodium bicarbonate appears promising and is translatable to the ED. A recent large meta-analysis reported that sodium bicarbonate–based hydration is superior to normal saline hydration with an odds ratio of 0.56 (confidence interval, 0.36 to 0.86) with a number needed to treat of 26.[31] However, the dosage, alkaline end points (blood versus urine pH), and mode of administration (single IV bolus versus continuous infusion) have not been defined.

TABLE 88-8 Indications for Emergent Dialysis

Uncontrolled hyperkalemia (K^+ >6.5 mmol/L or rising)
Intractable fluid overload in association with persistent hypoxia, or lack of response to conservative measures
Uremic pericarditis
Progressive uremic/metabolic encephalopathy; asterixis, seizures
Serum sodium level <115 or >165 mEq/L
Severe metabolic acidosis with concomitant acute kidney injury; treat underlying source of lactic acidosis and tolerate pH >7.2 in setting of permissive hypercapnia
Life-threatening poisoning with a dialyzable drug, such as lithium, aspirin, methanol, ethylene glycol, or theophylline
Bleeding dyscrasia secondary to uremia
Excessive BUN and Cr levels: trigger levels are arbitrary; it is generally advisable to keep BUN level <100 milligrams/dL, but each patient should be evaluated individually

TABLE 88-9 Minimizing Risk of Contrast-Induced Nephropathy

Identify patients at risk	Determine serum Cr and GFR before ordering contrast studies	Seriously consider risk of contrast if serum Cr >1.5 or GFR <60
Do not coadminister potentially nephrotoxic medications		Avoid parenteral NSAIDs
Provide hydration before and after test for at-risk patients	Before and after test as long as no congestive heart failure	Volume expansion improves renal blood flow, causes diuresis and dilutes contrast material within the tubules, and reduces activation of the renin-angiotensin system
Sodium bicarbonate	Seems to offer increased protection over normal saline[31]	Most commonly described dosing is 3 mL/kg bolus of a solution of 154 mmol/L $NaHCO_3$ in 5% dextrose in water, followed by 1 mL/kg/h (Merten Protocol)[32]
Use low- or iso-osmolar contrast agents		
Withhold metformin in diabetics	No metformin on day of test and for 48 h afterward	Risk of contrast nephropathy very low in diabetics with normal renal function; in patients with reduced renal function, clearance of metformin is decreased and lactic acidosis can result
N-Acetylcysteine	Value unproven; not recommended

CHAPTER 89

Rhabdomyolysis

Francis L. Counselman
Bruce M. Lo

INTRODUCTION AND EPIDEMIOLOGY

Rhabdomyolysis is the destruction of skeletal muscle, caused by any mechanism that results in injury to myocytes and their membranes. Direct muscle injury and genetic and biochemical factors can predispose to rhabdomyolysis. Acute necrosis of skeletal muscle fibers and the leakage of cellular contents into the circulation result in myoglobinuria.

Several classification systems have been developed to characterize the numerous causes of rhabdomyolysis. None of these systems is universally recognized, and each has its limitations.

TABLE 89-1 Common Conditions Associated with Rhabdomyolysis in Adults

Trauma	**Immunologic diseases involving muscle**	**Ischemic injury**
Crush injury	Dermatomyositis	Compartment syndrome
Electrical or lightning injury	Polymyositis	Compression
Drugs of abuse	**Bacterial infection**	**Medications**
Amphetamines [including ecstasy (3,4-methylenedioxymethamphetamine)]	*Clostridium*	Antipsychotics
	Group A β-hemolytic streptococci	Barbiturates
Caffeine	*Legionella*	Benzodiazepines
Cocaine	*Salmonella*	Clofibrate
Ethanol	*Shigella*	Colchicine
Heroin	*Staphylococcus aureus*	Corticosteroids
Lysergic acid diethylamide	*Streptococcus pneumoniae*	Diphenhydramine
Methamphetamines	**Viral infection**	Isoniazid
Opiates	Coxsackievirus	Lithium
Phencyclidine	Cytomegalovirus	Monoamine oxidase inhibitors
Environment and excessive muscular activity	Epstein-Barr virus	Narcotics
Contact sports	Enterovirus	Neuroleptic agents
Delirium tremens	Hepatitis virus	Phenothiazines
Dystonia	Herpes simplex virus	Propofol
Psychosis	Human immunodeficiency virus	Salicylates
Seizures	Influenza virus (A and B)	Selective serotonin reuptake inhibitors
Marathons, military basic training	Rotavirus	Statins
Heat stroke	*Mycoplasma*	Theophylline
Genetic disorders		Tricyclic antidepressants
Glycolysis and glycogenolysis disorders		Zidovudine
Fatty acid oxidation disorders		Some novel cancer chemotherapeutic agents
Mitochondrial and respiratory chain metabolism disorders		

Table 89-1 lists commonly recognized conditions associated with rhabdomyolysis. **In general, the most common causes of rhabdomyolysis in adults appear to be alcohol and drugs of abuse, followed by medications, muscle diseases, trauma, neuroleptic malignant syndrome, seizures, immobility, infection, strenuous physical activity, and heat-related illness.**[1,2] A host of drugs and toxins have been identified that are associated with or causative of rhabdomyolysis.[3] Multiple causes are present in more than half of patients.[1] In children, rhabdomyolysis is less common and is thought to be more benign.[3] In one study of children, the most common causes of nonrecurrent rhabdomyolysis were trauma, viral myositis, and connective tissue disease.[4] For adults and children, inherited metabolic disorders should be suspected with recurrent episodes of rhabdomyolysis, especially if associated with exercise intolerance.

Patients in coma are at risk for rhabdomyolysis from unrelieved pressure on gravity-dependent body parts. Alcohol consumption can result in rhabdomyolysis secondary to coma-induced muscle compression and a direct toxic effect. Nutritional compromise, hypokalemia, hypomagnesemia, and hypophosphatemia, all common in alcoholics, increase the risk of rhabdomyolysis. Alcohol and drugs are thought to play a role in most cases of rhabdomyolysis in adults.[1] Drugs of abuse are commonly implicated in acute rhabdomyolysis, and many commonly prescribed medications have been associated as well.[2] **Statin-related myopathies** include myalgias with or without elevation of creatine kinase level, muscle weakness, and rhabdomyolysis. Statin-related rhabdomyolysis is rare, varies with the particular statin, and is also dose related. Drug combinations, including combinations with cyclosporine, macrolide antibiotics, warfarin, digoxin, and dual statin therapy, carry an increased risk for rhabdomyolysis.[3,5]

A number of bacterial and viral infections have been associated with rhabdomyolysis.[3] Strenuous physical activity, as seen in athletes, marathon runners, military recruits, and outdoor laborers, is a common cause. Physical activity that produces high-force eccentric contractions, such as strength training or heavy lifting, leads to greater breakdown in muscle and higher levels of creatine kinase than concentric contractions, such as endurance-based exercises.[6] Factors that increase the risk in this group of patients include poor physical conditioning, inadequate fluid intake, wearing of restrictive clothing, high ambient temperatures, and high humidity levels.[6]

PATHOPHYSIOLOGY

Rhabdomyolysis is a syndrome characterized by injury to skeletal muscle with subsequent effects from the release of intracellular contents. These contents include myoglobin, creatine kinase, aldolase, lactate dehydrogenase, aspartate aminotransferase, and potassium. Although numerous causes of rhabdomyolysis have been described, the common terminal event appears to involve the disruption of the Na^+K^+ATPase pump and calcium transport, which results in increased intracellular calcium and subsequent muscle cell necrosis. In addition, calcium activates phospholipase A_2 and various vasoactive molecules and proteases and induces the production of free oxygen radicals.[3,7]

CLINICAL FEATURES

The presenting symptoms of rhabdomyolysis are usually acute in onset and include myalgias, stiffness, weakness, malaise, low-grade fever, and dark (usually brown) urine. Muscle symptoms, however, may be present in only half of cases.[4] Nausea, vomiting, abdominal pain, and tachycardia can occur in severe rhabdomyolysis. Mental status changes may develop from urea-induced encephalopathy. Swelling and tenderness of the involved muscle groups and hemorrhagic discoloration of overlying skin may be observed but are not common. Muscle involvement may be localized or diffuse, depending on the cause. Commonly, the postural muscles of the thighs, calves, and lower back are involved. Muscle swelling may

not become apparent until after rehydration with IV fluids. An important point to remember is that acute rhabdomyolysis may be present without any of these signs or symptoms, and the patient may have normal findings on physical examination. For this reason, the diagnosis often is made only after soliciting a historical clue (e.g., recent cocaine use) or finding an elevated serum creatine kinase level or the presence of dark urine on routine laboratory testing.

DIAGNOSIS

An elevated **serum creatine kinase** is the most sensitive and reliable indicator of muscle injury. The degree of elevation correlates with the amount of muscle injury and the severity of illness, but not the development of renal failure or other morbidity. **Most investigators consider a fivefold or greater increase above the upper threshold of normal in serum creatine kinase level, in the absence of cardiac or brain injury, as the requirement for the diagnosis of rhabdomyolysis.** In general, the level begins to rise approximately 2 to 12 hours after the onset of muscle injury, peaks within 24 to 72 hours, and then declines at the relatively constant rate of 39% of the previous day's value. Ongoing muscle necrosis should be suspected in patients with elevated values that fail to decrease in this manner. The isoenzyme CK-MM (found in skeletal and cardiac muscle) is responsible in large part for the elevation in serum creatine kinase. The MB fraction of creatine kinase (found primarily in cardiac but also in skeletal muscle) also may be elevated but should not exceed 5% of the total creatine kinase.

Myoglobin is an oxygen-binding protein found in skeletal and cardiac muscle and is involved in oxidative metabolism. Myoglobinuria develops once skeletal muscle injury is >100 grams.[2] Myoglobin elevation occurs before creatine kinase elevation, and then is rapidly cleared from the plasma through renal excretion and metabolism to bilirubin. Myoglobin enters the urine when the plasma concentration is >1.5 milligrams/dL and causes the typical reddish brown discoloration when the urine myoglobin level is >100 milligrams/dL.[3,8] **Because myoglobin contains heme, qualitative tests such as the dipstick test (which uses the orthotoluidine reaction) do not differentiate among hemoglobin, myoglobin, and red blood cells.** Therefore, suspect myoglobinuria when the urine dipstick test is positive for blood but no red blood cells are present on microscopic examination. Radioimmunoassay is slightly more sensitive than the dipstick technique in identifying myoglobinuria, but usually is not necessary. Because myoglobin levels may return to normal within 1 to 6 hours after the onset of muscle necrosis, the absence of an elevated serum myoglobin level or of myoglobinuria does not exclude the diagnosis. In one study, only 19% of patients with rhabdomyolysis demonstrated myoglobinuria.[1]

Other laboratory studies may be useful to identify the common complications of rhabdomyolysis and the underlying cause. Serum electrolyte, calcium, phosphorus, and uric acid levels should be determined to identify hyperkalemia, abnormal calcium and phosphorus levels, and hyperuricemia. Urinalysis should be obtained for all patients. Serum creatinine and BUN levels are needed to identify acute renal failure. Because disseminated intravascular coagulation is a potential complication, a baseline CBC should be obtained and a coagulopathic screen considered [e.g., prothrombin time, partial thromboplastin time, fibrin split products, and fibrinogen level (see chapter 233, Acquired Bleeding Disorders)]. Other common laboratory findings in rhabdomyolysis include elevated levels of aldolase, lactate dehydrogenase, urea, creatine, and aminotransferases. Further laboratory testing to identify the underlying cause(s) of rhabdomyolysis should be based on the medical history and clinical presentation.

DIFFERENTIAL DIAGNOSIS

Other causes of muscle pain and weakness besides rhabdomyolysis should be considered in the appropriate clinical setting. Such causes include acute myopathies, periodic paralysis, polymyositis or dermatomyositis, or Guillain-Barré syndrome. Rhabdomyolysis associated with strenuous exercise or fasting or repeat episodes of rhabdomyolysis suggest an inherited metabolic myopathy.[3]

TREATMENT

PREHOSPITAL CARE

For victims of **crush injury**, patients strongly suspected of having rhabdomyolysis, or accident victims with prolonged extrication and transport times, early and vigorous IV fluid resuscitation is the most important treatment to prevent acute renal failure.[9,10] Once a limb is extricated, IV normal saline should be initiated at 1 L/h. After extrication, IV normal saline should be continued at 500 mL, alternating with 5% dextrose in normal saline at 1 L/h. **Avoid potassium- or lactate-containing solutions.** There is no evidence that the administration of sodium bicarbonate is beneficial.

ED CARE

Once the patient is in the ED, continue aggressive IV rehydration for the next 24 to 72 hours. One method is rapid correction of the fluid deficit with IV crystalloids followed by infusion of 2.5 mL/kg/h, with the goal of maintaining a minimum urine output of 2 mL/kg/h.[11] Another method is a goal of 200 to 300 mL of urine output each hour.[12]

No prospective controlled studies have demonstrated benefit from alkalinization of the urine with sodium bicarbonate or forced diuresis with mannitol or loop diuretics.[12-14] Bicarbonate is widely recommended but without an evidence base. If bicarbonate is given, maintain an isotonic solution and avoid metabolic alkalosis or hypokalemia.[12] Mannitol may be harmful because it may cause osmotic diuresis in hypovolemic patients.

Place a urinary catheter in patients in critical condition and those with acute renal failure to monitor urine output. Institute cardiac monitoring because electrolyte and metabolic complications can cause dysrhythmias. For patients with heart disease, comorbid conditions, or preexisting renal disease or for elderly patients, hemodynamic monitoring may be necessary to avoid fluid overload. Serial measurements of urine pH, electrolytes, creatine kinase, calcium, phosphorus, BUN, and creatinine are needed.

Hypocalcemia observed early in rhabdomyolysis usually requires no treatment. Calcium should be given only to treat hyperkalemia-induced cardiotoxicity or profound signs and symptoms of hypocalcemia. If hypercalcemia is symptomatic, continue saline diuresis. Treat hyperphosphatemia with oral phosphate binders when serum levels are >7 milligrams/dL. Treat hypophosphatemia when the serum level is <1 milligram/dL. Hyperkalemia, which is usually most severe in the first 12 to 36 hours after muscle injury, can be significant and prolonged. Traditional insulin and glucose therapy, although recommended, may not be as effective in rhabdomyolysis-induced hyperkalemia. The use of ion-exchange resins (e.g., sodium polystyrene sulfonate) is effective. Dialysis may be needed (see chapter 17, Fluids and Electrolytes).

Avoid prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs because of their vasoconstrictive effects on the kidney. Finally, treat the underlying cause.

DISEASE COMPLICATIONS

The complications of rhabdomyolysis include acute renal failure, metabolic derangements, disseminated intravascular coagulation, and mechanical complications (e.g., compartment syndrome or peripheral neuropathy)[15] (**Table 89-2**). Factors that contribute to rhabdomyolysis-induced acute renal failure include hypovolemia, acidosis or aciduria, tubular obstruction, and the nephrotoxic effects of myoglobin.[3,12] In exertional rhabdomyolysis, acute renal failure is rare without the presence of factors like dehydration, heat stress, trauma, or underlying disease such as sickle cell anemia.[6] Renal tubular obstruction occurs secondary to precipitation of uric acid and myoglobin. Ferrihemate, the breakdown product of myoglobin, is responsible for the direct toxic effect on the kidneys. This effect, however, appears to occur only in the presence of hypovolemia and aciduria (pH <5.6). Renal failure may be oliguric (most common) or nonoliguric. Patients with initially elevated creatinine and BUN and a large base deficit[16,17] have an increased risk for

TABLE 89-2 Complications of Rhabdomyolysis

Mechanical complications
Compartment syndrome
Peripheral neuropathy

rhabdomyolysis-induced acute renal failure. However, neither the presence of myoglobinuria nor the degree of creatine kinase elevation is predictive of acute renal failure.

Anticipate a rise in the serum potassium level due to release of potassium from injured skeletal muscle. Renal function, however, appears to be the most important determinant of the degree of elevation. Hyperkalemia can be a significant complication of rhabdomyolysis if acute renal failure occurs.

Elevated uric acid levels can occur, especially in crush injures, due to release of muscle adenosine nucleotides and the subsequent conversion to uric acid by the liver. Uric acid levels usually correlate with serum creatine kinase levels.

Serum phosphorus levels initially may be elevated, due to the leakage of phosphorus from injured muscle. Later in the disease course, mild hypophosphatemia may be seen but rarely requires treatment. Hypocalcemia occurs early and is usually asymptomatic. It results from the deposition of calcium salts in necrotic muscle, due to the hyperphosphatemia and decreased levels of 1,25-dihydroxycholecalciferol. Soft tissue calcifications sometimes can be observed on radiographs of the involved limb muscles. Hypocalcemia can occur, however, without elevated levels of phosphorus. Later, as calcium is mobilized from damaged muscle, hypercalcemia may be observed.

Disseminated intravascular coagulation occurs in severe rhabdomyolysis and can result in hemorrhagic complications.

The mechanical complications of rhabdomyolysis consist of compartment syndrome and peripheral nerve injury. The associated muscle swelling may exert pressure on peripheral nerves, resulting in neuronal ischemia and causing paresthesias or paralysis. Nerve injury is often proximal, and multiple nerves may be involved in the same extremity.[15] Compartment syndrome occurs secondary to marked swelling and edema of the involved muscle groups and is discussed in chapter 278, Compartment Syndrome.

DISPOSITION AND FOLLOW-UP

The majority of healthy patients with *exertional rhabdomyolysis* and *without comorbidities* (i.e., heat stress, dehydration, trauma) can usually be treated with oral or IV rehydration, observed in the ED, and then released.[6] Otherwise, patients should be admitted for IV hydration, diuresis, management of complications, and treatment of the underlying cause. For at least the initial 24 to 48 hours, admission should be to a monitored bed to identify dysrhythmias. The nephrology service should be consulted to evaluate the need for dialysis, especially for patients with hyperkalemia unresponsive to therapy.

PRACTICE GUIDELINES

No internationally recognized organization has published validated guidelines for the management of rhabdomyolysis, but the Finnish Medical Society has issued nonvalidated literature-based guidelines that are available on the Internet (see Useful Web Resource).

CHAPTER 90

End-Stage Renal Disease

Mathew Foley
Ninfa Mehta
Richard Sinert

INTRODUCTION AND EPIDEMIOLOGY

End-stage renal disease (ESRD) is the irreversible loss of renal function, resulting in the accumulation of toxins and the loss of internal homeostasis. Uremia, the clinical syndrome resulting from ESRD, is universally fatal without some form of renal replacement therapy. At present, renal replacement therapy consists of two basic modalities: renal transplant and dialytic therapy, either hemodialysis or peritoneal dialysis (PD).

Hemodialysis is the initial therapy in the vast majority of new cases of adult ESRD, with a few starting PD and an even smaller number receiving predialytic renal transplants. The proportions are reversed in children, with most children receiving transplants. More than 90,000 Americans await a renal transplant, with a median time of 2.6 years on a transplant wait list.

Approximately half of hemodialysis and PD patients will be alive 3 years after starting therapy, with cardiac causes accounting for about half of all deaths. Infections trigger death in up to a quarter of patients, with cerebrovascular events and malignancy being other causes.

PATHOPHYSIOLOGY

Uremia, contamination of the blood with urine, differs from azotemia, the buildup of nitrogen in the blood. Renal failure assumes many forms, often co-existing.

Excretory failure leads to elevated levels of >70 chemicals in uremic plasma, which gives rise to the hypothesis that these toxins, individually or in combination, cause uremic organ dysfunction and produce the symptoms of uremia. Urea is not the major toxin, and potential uremic toxins include cyanate, guanidine, polyamines, and β2-microglobulin.[1] If uremia were simply a toxidrome, then dialysis would reverse all its untoward effects; however, it does not, in part because many toxins are highly protein bound and nondialyzable.[2] Because many uremia-related organ dysfunctions persist after dialysis, other processes are clearly important.

Biosynthetic failure refers to the aspects of uremia caused by loss of the renal hormones $1,25(OH)_2$-vitamin D_3 and erythropoietin. The kidneys are primarily responsible for the secretion of erythropoietin and 1α-hydroxylase, which is necessary to produce the active form of vitamin D_3. Because 85% of erythropoietin is produced in the kidneys, ESRD patients have depressed levels of erythropoietin, which contributes to anemia. Vitamin D_3 deficiency results in decreased GI calcium absorption, inducing secondary hyperparathyroidism, leading to renal bone disease.

Regulatory failure results in an oversecretion of hormones, leading to uremia by disruption of normal feedback mechanisms. The uremic state produces excess free oxygen radicals, which react with carbohydrates, lipids, and amino acids to create advanced glycation end products, linked to atherosclerosis and amyloidosis in ESRD patients.[3] This may explain the progressive nature of the atherosclerosis and amyloidosis seen in ESRD patients.[4]

TABLE 90-1 Clinical Features of Uremia and Dialysis

Neurologic
Uremic encephalopathy: cognitive defects, memory loss, decreased attentiveness, slurred speech, reversal of sleep-wake cycle, asterixis, seizure, coma, symptomatic improvement with dialysis
Dialysis dementia: progressive neurologic decline, failure to improve with dialysis, fatal
Subdural hematoma: headache, focal neurologic deficits, seizure, coma
Peripheral neuropathy: singultus (hiccups), restless leg syndrome, sensorimotor neuropathy, autonomic neuropathy
Cardiovascular
Coronary artery disease
Hypertension: essential hypertension, glomerulonephritis, renal artery stenosis, fluid overload
Heart failure: fluid overload, uremic cardiomyopathy, high-output arteriovenous fistula
Pericarditis: uremic, dialysis related, pericardial tamponade
Hematologic
Anemia, decreased red blood cell survival, decreased erythropoietin levels
Bleeding diathesis
Immunodeficiency (humoral and cellular)
GI
Anorexia, metallic taste, nausea, vomiting
GI bleeding
Diverticulosis, diverticulitis
Ascites
Renal bone disease
Metastatic calcification (calciphylaxis)
Hyperparathyroidism (osteitis fibrosa cystica)
Vitamin D_3 deficiency and aluminum intoxication (osteomalacia)

CLINICAL FEATURES OF UREMIA

Uremia is a clinical syndrome, and no single symptom, sign, or laboratory test result reflects all aspects of uremia. Although a correlation exists between the symptoms of uremia and low glomerular filtration rate (8 to 10 mL/min/1.73 m^2), BUN and serum creatinine levels are inaccurate markers of the clinical syndrome of uremia. The decision to start long-term dialysis is based on the severity of the patient's symptoms related to uremia (**Table 90-1**). The most common reasons for emergency dialysis are hyperkalemia, severe acid-base disturbances, and pulmonary edema resistant to usual therapy.

NEUROLOGIC COMPLICATIONS

Stroke occurs in approximately 6% of hemodialysis patients, with about half being hemorrhagic and half ischemic. Subdural hematomas occur 10 times more frequently in dialysis patients than in the general population.

Uremic encephalopathy is a constellation of nonspecific central neurologic symptoms associated with renal failure. Uremic encephalopathy is best diagnosed after eliminating structural, vascular, infectious, toxic, and metabolic causes of neurologic dysfunction. Neurologic findings of uremic encephalopathy improve with dialysis.

Dialysis dementia is nonspecific in presentation from other encephalopathies. This manifestation of ESRD and treatment is progressive, with the 2- to 4-year survival for these patients being 24%. This disorder usually becomes evident after at least 2 years of dialysis therapy and fails to respond to increases in dialysis frequency or renal transplantation.

Peripheral neuropathy is one of the most frequent neurologic manifestations of ESRD, with greater lower than upper limb involvement. The most frequent clinical features reflect large-fiber involvement, with paresthesias, reduction in deep tendon reflexes, impaired vibration sense, muscle wasting, and weakness. Autonomic dysfunction results in impotence, postural dizziness, gastric fullness, bowel dysfunction, and reduced sweating. Reduced heart rate variability and baroreceptor control impairment occur.

Nerve conduction studies demonstrate findings consistent with a generalized neuropathy of the axonal type. No single pathologic correlate has been identified for peripheral uremic neuropathy. Conventional hemodialysis does not seem to improve autonomic dysfunction; however, daily short hemodialysis and long nocturnal hemodialysis may reduce the elevated sympathetic activity.

CARDIOVASCULAR COMPLICATIONS

The mortality from cardiovascular disease is 10 to 30 times higher in dialysis patients than in the general population. Coronary artery disease, left ventricular hypertrophy, and congestive heart failure are common. The etiology of cardiovascular disease in ESRD patients is multifactorial, related to preexisting conditions (e.g., hypertension, diabetes), uremia (e.g., uremic toxins, hyperlipidemias, homocysteine level, hyperparathyroidism), and dialysis-related conditions (e.g., hypotension, dialysis membrane reactions, hypoalbuminemia).[5]

The diagnosis of ischemic cardiovascular disease in ESRD patients often has been clouded by the misconception that the traditional serum protein markers of myocardial damage (troponins I and T) are unreliable in dialysis patients. Elevated levels of **troponin I and T** are common even in asymptomatic hemodialysis patients and probably reflect left ventricular hypertrophy and microvascular disease. Asymptomatic elevations of cardiac biomarkers are, however, associated with long-term risks of coronary artery disease.[6] To account for higher baseline levels of troponin T and I, many define myocardial infarction only by a 20% or more dynamic rise and with at least one value above the 99th percentile (see chapter 48, "Chest Pain").

Hypertension is present in most patients starting dialysis. Maintenance of hypertension depends mostly on increased total peripheral resistance. Increases in blood volume, decreased vascular compliance, the vasopressor effects of native kidneys, the renin-angiotensin system, and the sympathetic nervous system also play roles in ESRD hypertension.[7]

Management of hypertension in ESRD patients begins with control of blood volume. If that is unsuccessful, most cases can be controlled with adrenergic blocking agents, angiotensin-converting enzyme inhibitors, or vasodilating agents, such as hydralazine or minoxidil. Bilateral nephrectomy is rarely necessary for blood pressure control.

Heart failure most commonly results from hypertension, followed by coronary artery disease and valvular defects. Causes unique to ESRD include uremic cardiomyopathy, fluid overload, and arteriovenous fistula–related high-output failure (see section "Complications of Vascular Access" later in the chapter). **Natriuretic peptide levels** are elevated in hemodialysis patients, often from concomitant left ventricular hypertrophy and systolic dysfunction. Elevation of natriuretic peptides in hemodialysis patients correlates with higher short-term mortality rates, but there are no reliable thresholds to identify fluid overload.

Uremic cardiomyopathy is a diagnosis of exclusion when all other causes of congestive heart failure have been excluded. In most uremic patients, left ventricular dysfunction is related to ischemic heart disease, hypertension, and hypoalbuminemia. Dialysis rarely improves left ventricular function in uremic patients with congestive heart failure.

Pulmonary edema in ESRD patients is commonly ascribed to fluid overload, but acute myocardial ischemia can also trigger depressed left ventricular function. Cornerstones of therapy are supplemental oxygen if needed, bilevel positive airway pressure, nitrates, and angiotensin-converting enzyme inhibitors. Loop diuretics, such as furosemide (60 to 100 milligrams IV), may aid even in those with minimal urine output from their short-lived vasodilatory actions. **Hemodialysis is the ultimate treatment for fluid overload** in ESRD patients. Preload reduction by inducing diarrhea with sorbitol or by phlebotomy may help in low-resource situations. Removing as little as 150 mL of blood is safe and effective in some with pulmonary edema. Improved oxygenation

produced by phlebotomy offsets the decrease in oxygen-carrying capacity due to the decrease in hemoglobin. Blood withdrawn during phlebotomy should be collected in transfusion bags, so plasma can be extracted by the blood bank and the red blood cells transfused back to the patient later during dialysis. PD does not remove volume fast enough to have a significant impact on pulmonary edema.

Cardiac tamponade is a concern in any critically ill ESRD patient, often presenting without classic findings. Instead, signs of cardiac tamponade in these patients include changes in mental status, hypotension, or shortness of breath. Increased interdialytic weight gain, increased edema, and intradialytic hypotension are other warning signs suggesting the diagnosis of tamponade. In addition to hypotension, an increased heart size on chest radiograph suggest effusion and potential tamponade. Bedside US is the best method to detect pericardial effusion and tamponade. Hemodynamically significant pericardial effusions require pericardiocentesis under fluoroscopic or US guidance. Bedside pericardiocentesis (see chapter 34, "Pericardiocentesis") is used only in hemodynamically unstable patients because of its high complication rate.

Pericarditis is usually due to uremia. Uremic pericarditis is linked to fluid overload, abnormal platelet function, and increased fibrinolysis and inflammation. Pericardial contents are sterile unless infected and are abundant with fibrin and inflammatory cells.

Uremic pericarditis causes pericardial friction rubs, which are louder than in most other forms of pericarditis, often palpable, and frequently persist for some time after metabolic abnormalities have been corrected. BUN level is nearly always >60 milligrams/dL. One of the unique features of uninfected uremic pericarditis is that the inflammatory cells do not penetrate into the myocardium, so typical ECG changes of acute pericarditis are absent. Most often, the ECG demonstrates associated abnormalities, such as left ventricular hypertrophy, ischemia, and metabolic abnormalities (e.g., hyperkalemia and hypocalcemia). When the ECG has features typical of acute pericarditis, infection should be suspected.

Dialysis-related pericarditis is most common during periods of increased catabolism (trauma and sepsis) or inadequate dialysis due to missed sessions or vascular access problems. The pathophysiology of dialysis-related pericarditis is the buildup of middle molecules and hyperparathyroidism. Dialysis-related pericarditis is more common during hemodialysis than during PD, although now somewhat less frequent because of improved dialysis techniques. Fever and malaise are more common and severe than in uremic pericarditis. Pericardial effusion is the most important complication and tends to be recurrent. Due to the recurrent nature of dialysis pericarditis, adhesions and fluid loculations are common, which complicates the interpretation of echocardiographic scans and images obtained using other modalities.

Management of uremic and dialysis-related pericarditis in patients in hemodynamically stable condition is intensive dialysis. Hemodialysis is preferred over PD because of the higher clearance rates of the former, recognizing the risks of tamponade from heparin and rapid fluid shifts. Hemodialysis is effective in the majority of cases of dialysis-related pericarditis, usually after 10 to 14 days. Indomethacin, colchicine, and steroids are not useful for ESRD pericarditis. If pericardial effusion persists for longer than 10 to 14 days with intensive dialysis, anterior pericardiectomy is often used, with total pericardiectomy reserved for constrictive pericarditis.

HEMATOLOGIC COMPLICATIONS

Anemia is multifactorial, caused by decreased erythropoietin, blood loss from dialysis, frequent phlebotomy, and decreased red blood cell survival times. In addition, the wide fluctuations in plasma blood volume seen in dialysis patients often cause factitious anemia. Without treatment, the hematocrit should stabilize at 15% to 20%, with normocytic and normochromic red blood cells. Bone marrow shows erythroid hypoplasia, with little effect on leukopoiesis or megakaryocytopoiesis. Anemia is treated with regular infusions of human recombinant erythropoietin. Erythropoietin replacement therapy improves the quality of life for ESRD patients by increasing exercise capacity and tolerance.

The **bleeding diathesis** of ESRD patients increases the risks of GI tract bleeding, subdural hematomas, subcapsular liver hematomas, and intraocular bleeding. Several mechanisms, including decreased platelet function, abnormal platelet-vessel wall interactions, altered von Willebrand factor, anemia, and abnormal guanidinosuccinic acid–dependent production of nitric oxide, create uremic bleeding. The skin bleeding test is the best predictor of clinically important defects in hemostasis. Patients receiving aspirin or warfarin are at greater risk of major bleeding. **Improvement in bleeding times with infusions of desmopressin (benefit in 1 h), cryoprecipitate (benefit in 4 h), or conjugated estrogens (benefit in 6 h) is an option** (see chapter 233, "Acquired Bleeding Disorders" for further discussion).

Immunologic deficiency in ESRD patients results in high morbidity and mortality from infectious diseases. Depressed leukocyte chemotaxis and phagocytosis from many causes is the key feature, along with abnormal T-cell activation. Dialysis does not improve the immune function and may exacerbate immunodeficiency by complement activation after exposure to the hemodialysis filter membrane.

GI COMPLICATIONS

Anorexia, nausea, and vomiting are common symptoms of uremia and used to initiate and monitor dialysis adequacy. There is an increased incidence of gastritis and upper GI bleeding in ESRD patients, but the incidence of gastric and duodenal ulcers is similar in ESRD patients and the general population.

Chronic constipation is common secondary to decreased fluid intake and the use of phosphate-bonding gels. ESRD patients have an increased incidence of diverticular disease and colonic perforation, especially patients with polycystic kidney disease.

Dialysis-related ascites is secondary to fluid overload, portal hypertension from polycystic liver disease, and osmotic disequilibrium. Treatment of refractory ascites is possible with peritoneovenous shunts.

RENAL BONE DISEASE

As the glomerular filtration rate falls, phosphate excretion decreases, which results in increased serum phosphate levels. When the calcium-phosphate product [Ca^{2+} (milligrams/dL) × PO_4 (milligrams/dL)] is higher than 70 to 80, **metastatic calcification** can ensue. Joint pain from **pseudogout** develops from calcification of synovial membrane–lined joints. Metastatic calcification in small vessels results in skin and finger necrosis, and life-threatening calcifications can occur in the cardiac and pulmonary systems. Short-term mortality rate is higher in ESRD patients with a calcium-phosphate product of >72. Treatment consists of the use of low-calcium dialysate and phosphate-binding gels.

As ESRD progresses, the combination of calciphylaxis and vitamin D_3 deficiency results in depressed ionized calcium levels and stimulation of the parathyroid gland, causing **hyperparathyroidism**. The increased production of parathyroid hormone results in high bone turnover and weakened bones susceptible to fracture. Bone pain and muscle weakness are other symptoms. High alkaline phosphatase and parathyroid hormone levels make the diagnosis. Treatment consists of control of serum phosphate levels with binding gels, vitamin D_3 replacement, and, if necessary, subtotal parathyroidectomy.

A subset of ESRD patients develops **osteomalacia**, a defect in bone calcification. The signs and symptoms are weakened bones, bone pain, and muscle weakness, similar to those of hyperparathyroidism. Osteomalacia is characterized by low to normal alkaline phosphatase levels and low parathyroid hormone levels. Elevated serum aluminum and bone aluminum levels are useful for confirming the diagnosis. Treatment with desferrioxamine helps aluminum bone disease.

β_2-MICROGLOBULIN AMYLOIDOSIS

Dialysis-related amyloidosis (β_2-microglobulin amyloidosis) can occur in dialysis patients >50 years of age and on dialysis for >10 years. Advanced glycation end products appear central to the chronic inflammatory condition, leading to amyloidosis. Amyloid deposits are found in the GI tract, bones, and joints. Complications include GI perforation, bone cysts with pathologic fractures, and arthropathies, including carpal

tunnel syndrome and rotator cuff tears. Patients with amyloidosis have higher mortality rates than do those without this disorder.

HEMODIALYSIS

TECHNICAL ASPECTS OF HEMODIALYSIS

Hemodialysis substitutes a filter for the glomerulus to produce an ultrafiltrate of plasma. Small amounts of IV heparin, 1000 to 2000 units, are used to prevent thrombosis at the vascular access site. Hemodialysis sessions typically take 3 to 4 hours. Adjustment of the pressure gradient across the hemodialyzer filter during hemodialysis controls the amount of fluid removal (ultrafiltration). Solute removal (clearance) during hemodialysis depends on the filter pore size, the amount of ultrafiltration (solute drag), and the concentration gradient across the filter (diffusion). During hemodialysis, blood is removed from the vascular access site by large-bore needles (typically 15 gauge), circulated through the dialysis machine at rates of 300 to 500 mL/min, and returned to the patient. The dialysate usually flows at a rate of 500 to 800 mL/min through the dialysis filter in the direction opposite to blood flow.

COMPLICATIONS OF VASCULAR ACCESS

In cases in which a native artery or vein is not suitable for arteriovenous fistula creation, an interposing vascular graft made of an autologous vein, polytetrafluoroethylene, or bovine carotid artery must be used for vascular access. Such grafts generally are associated with a higher complication rate and shorter functional life expectancies than are natural arteriovenous fistulas. The third form of vascular access for hemodialysis is the use of tunneled-cuffed catheters. The most common site for tunneled-cuffed catheter placement is the right internal jugular vein. Because of the cuff, tunneled-cuffed catheters should not be removed by pulling.

Complications of vascular access account for more inpatient hospital days than any other complication of hemodialysis. The most common complications of hemodialysis vascular access are failure to provide adequate flow (300 mL/min) and infection.[8] If referred to the ED for inadequate access flow that impairs dialysis, missing a single session should not result in uremic encephalopathy, allowing emergency dialysis for those with hyperkalemia and fluid overload in the ED (see chapter 88, "Acute Kidney Injury").

Thrombosis and stenosis of the vascular access are the most common causes of inadequate dialysis flow. Grafts generally have a higher rate of stenosis than do fistulas. Stenosis or thrombosis presents with loss of bruit and thrill over the access. Stenosis and thrombosis can be treated within 24 hours by angiographic clot removal or angioplasty. Thrombosis of vascular access can also be treated with direct injection of alteplase, usually in conjunction with a vascular surgeon.[9]

Vascular access infections occur in 2% to 5% of arteriovenous fistulas and approximately 10% of grafts over their functional lifetimes. Patients with an infected access often present with fever, hypotension, or an elevated WBC count. The classic signs of infection of pain, erythema, swelling, and discharge from an infected vascular access are often missing. Dialysis catheter–related bacteremia is a very common and potentially life-threatening. After 6 months with a dialysis catheter, approximately half of patients develop bacteremia, with a serious complication (death, endocarditis, osteomyelitis, septic arthritis, epidural abscess) occurring in 5% to 10% of patients with bacteremia. Most authorities prefer a trial of IV antibiotics in an attempt to maintain the dialysis access before removal, the latter often done if there is ongoing fever after 2 to 3 days of antibiotics. To narrow the potential source of bacteremia, peripheral and catheter blood samples for culture are drawn simultaneously. A four-fold higher colony count in the catheter blood culture than in the peripheral blood culture suggests the catheter as the source of bacteremia.

The most common infecting organism is *Staphylococcus aureus*, followed by gram-negative bacteria. Patients with access infections usually require hospital admission, and vancomycin is the drug of choice (15 milligrams/kg or 1 gram IV) because of its effectiveness against methicillin-resistant organisms and long half-life (5 to 7 days) in dialysis patients. An aminoglycoside (gentamicin 100 milligrams IV initially and after each dialysis treatment) is added if gram-negative organisms are suspected, but the patient is monitored closely because of toxicity. Alternatives or adjuncts to IV antibiotics include removal and delayed replacement of the catheter, catheter exchange over a guidewire, and the use of antimicrobial/citrate lock solutions, although limited controlled data exist.

TABLE 90-2 Treatment Options for Control of Vascular Access Hemorrhage

Technique	Comments
Direct pressure to hemorrhage site using gloved finger initially	Hold for 5–10 min minimum, longer if needed.
Absorbable gelatin sponges soaked in reconstituted thrombin, or chemical thrombotic [HemCon® (chitosan; HemCon Medical Technologies, Inc., Portland, OR) or QuikClot (1% zeolite; Z-Medica Corp., Wallingford, CT; with water, thermal injury may occur; see package directions)], placed directly on hemorrhage site	Apply pressure after application for 10 min minimum.
Protamine given at a dose of 0.01 milligram per unit of heparin dispensed during dialysis	If the dose of heparin is unknown, protamine, 10 to 20 milligrams, will be sufficient to reverse the typical 1000 to 2000 units of heparin given at dialysis.
Desmopressin acetate, 0.3 microgram/kg IV	Use as an adjunct; consult nephrologist or vascular surgeon as needed.
Tourniquet proximal to vascular access	Temporizing measure only while awaiting urgent vascular surgery consultation.

Hemorrhage from a vascular access is a rare but life-threatening complication. Hemorrhage can result from aneurysms, anastomosis rupture, or overanticoagulation. Control bleeding immediately with manual pressure applied to the puncture sites for 5 to 10 minutes, and observe the patient for 1 to 2 hours if ceased. **Table 90-2** lists further options for control of hemorrhage. Consult a vascular surgeon when simple methods fail to control hemorrhage or large-volume bleeding occurs.

Vascular access aneurysms result from repeated punctures; true aneurysms are very rare. Most aneurysms are asymptomatic, with patients occasionally complaining of pain or an associated peripheral impingement neuropathy. Aneurysms rarely rupture.

Vascular access pseudoaneurysms result from subcutaneous extravasation of blood from puncture sites. Signs are bleeding and infection at the access site. Arterial Doppler US studies identify any aneurysm or pseudoaneurysm, and if detected, a vascular surgeon should be consulted.

Vascular insufficiency of the extremity distal to the vascular access occurs in approximately 1% of all patients. This "steal syndrome" is the result of preferential shunting of arterial blood to the venous side of the access. Signs and symptoms are exercise pain, nonhealing ulcers, and cool, pulseless digits. Doppler US or angiography is the best diagnostic approach, and treatment is surgical.

High-output heart failure can occur when >20% of the cardiac output is diverted through the access. The Branham sign, a drop in heart rate after temporary access occlusion, is useful for detecting this complication. Doppler US can accurately measure access flow rate and establish the diagnosis. Surgical banding of the access is the treatment of choice to decrease flow and treat heart failure.

COMPLICATIONS DURING HEMODIALYSIS

Hypotension is the most frequent complication of hemodialysis, occurring during 50% of treatments (**Table 90-3**). Fluid removal during hemodialysis averages 1 to 3 L over a 4-hour session, but removal of up to 2 L/h is possible. Maintenance of a normal blood pressure during ultrafiltration depends on cardiovascular compensatory mechanisms and refilling of the vascular space by fluid shifts from the interstitial and intracellular compartments. Excessive ultrafiltration due to underestimation of the patient's ideal blood volume (dry weight) is the most common cause of intradialytic hypotension. Optimal dry weight is often clinically defined when hypotension prevents further fluid removal.

TABLE 90-3 Differential Diagnosis of Peridialytic Hypotension

Excessive ultrafiltration
Predialytic volume loss (GI losses, decreased oral intake)
Intradialytic volume loss (tube and hemodialyzer blood losses)
Postdialytic volume loss (vascular access blood loss)
Medication effects (antihypertensives, opiates)
Decreased vascular tone (sepsis, food, dialysate temperature >37°C or 98.6°F)
Cardiac dysfunction (left ventricular hypertrophy, ischemia, hypoxia, arrhythmia, pericardial tamponade)
Pericardial disease (effusion, tamponade)

Myocardial dysfunction from ischemia, hypoxia, arrhythmias, and early pericardial tamponade are in the differential diagnosis of intradialytic hypotension. Abnormalities of vascular tone from sepsis or antihypertensive medications also contribute to hypotension. Vascular refilling can be enhanced by improving nutrition, performing ultrafiltration before dialysis, and increasing the sodium concentration of the dialysate solution.

The timing of intradialytic hypotension is often helpful in formulating a differential diagnosis. **Hypotension early in the dialysis session** is usually due to preexisting hypovolemia. Predialysis losses should be suspected when the patient starts hemodialysis at a weight below his or her dry weight; consider GI bleeding, sepsis, vomiting, diarrhea, or decreased intake of salt and water. Intradialytic blood loss can occur from blood tubing or hemodialyzer filter leaks. Hypotension near the end of dialysis is usually the result of excessive ultrafiltration, but pericardial or cardiac disease is possible.

Intradialytic hypotension produces nausea, vomiting, and anxiety. Orthostatic hypotension, tachycardia, dizziness, and syncope may occur. Treatment of intradialytic hypotension includes halting hemodialysis and placing the patient in the Trendelenburg position. If hypotension persists, the patient is given salt by mouth (broth) or normal saline, 100 to 200 mL IV. If these conservative measures fail, a more extensive evaluation is the next step.

When the patient is transferred to the ED for further evaluation, assess for adequacy of volume status, impairment of cardiac function, pericardial disease, infection, and GI bleeding. Further volume expansion or the administration of vasopressors to support blood pressure may require invasive hemodynamic monitoring in an intensive care setting.

Dialysis disequilibrium is a clinical syndrome occurring at the end of dialysis and is characterized by nausea, vomiting, and hypertension, which can progress to seizure, coma, and death. Dialysis disequilibrium occurs when large solute clearances occur during hemodialysis, as during the patient's first dialysis session or during hypercatabolic states. The cause of dialysis disequilibrium is believed to be cerebral edema from an osmolar imbalance between the brain and the blood. During high solute removal, the blood has a transiently lower osmolality than the brain, which favors water movement into the brain and causes cerebral edema. This condition can be prevented by limiting solute clearance when initiating hemodialysis. Treatment is stopping dialysis and administering mannitol IV to increase serum osmolality.

Air embolism is always a risk when blood is pumped through an extracorporeal circuit. The clinical presentation depends on the patient's body position at the time of the incident. If the patient was sitting, air passes retrograde through the internal jugular vein to the cerebral circulation, causing increased intracranial pressure and neurologic symptoms. In a recumbent position, air goes into the right ventricle and pulmonary circulation, causing pulmonary hypertension and systemic hypotension. The passage of air through a right-to-left shunt (e.g., patent foramen ovale) creates an arterial air embolism, which can lodge in the coronary or cerebral circulation, causing myocardial infarction or stroke.

Symptoms of an air embolism are acute dyspnea, chest tightness, and loss of consciousness, and sometimes full cardiac arrest. Signs include cyanosis and a churning sound in the heart from air bubbles in the blood. If air embolism is suspected, **clamp the venous blood line and place the patient supine.** Give 100% oxygen to aid reabsorption of the air. Other therapies for vascular air embolism include percutaneous aspiration of air from the right ventricle, IV administration of steroids, full heparinization, and hyperbaric oxygen treatment.

TABLE 90-4 Key Historical Elements for Hemodialysis Patients

Cause of end-stage renal disease
Dialysis schedule: any missed dialysis sessions?
Recent complications of hemodialysis
Dry weight, baseline laboratory values, and vital sign values
Average intradialytic weight gain
Does patient usually make dry weight by end of hemodialysis?
Does patient experience intradialysis hypotension? (Timing of hypotension?)
Which vascular access is currently functioning?
Symptoms of uremia
Retention of native kidneys?
Still producing urine?

Electrolyte abnormalities can occur due to errors in mixing the dialysate concentrate with water, which results in rapid osmolar shifts and hemolysis. In some communities, water contains high concentrations of calcium and magnesium and produces a final dialysate high in these minerals. Use of this dialysate can result in the "hard water syndrome," characterized by significant hypercalcemia and hypermagnesemia. Patients develop nausea, vomiting, headaches, burning skin, muscle weakness, lethargy, and hypertension. Treatment consists of properly filtering the dialysis water to lower calcium and magnesium concentrations.

Hypoglycemia occurs in diabetic and nondiabetic ESRD patients. In addition to drugs, malnutrition and sepsis are important causes of hypoglycemia.

ED EVALUATION OF HEMODIALYSIS PATIENTS

Patients treated with hemodialysis may develop complications related to ESRD or hemodialysis, or these conditions may be incidental to the reason for the ED visit. The medical history is very important, because many of the same diseases that caused ESRD (e.g., hypertension, diabetes) persist after the patient's kidneys have failed. The patient should be asked about the ESRD and hemodialysis (**Table 90-4**). Repeated episodes of intradialytic hypotension may provide important early clues to pericardial tamponade or myocardial ischemia. Repeated access infections may represent a worsening immunologic status.

Identify the hemodialysis schedule; most patients in the United States are on an every-other-day schedule (Monday, Wednesday, and Friday or Tuesday, Thursday, and Saturday), with each session lasting approximately 4 hours. Certain centers use high-flux hemodialysis machines with higher blood flows, allowing shorter sessions. Note all missed sessions and reasons, allowing identification about medical or social issues that need to be addressed.

Dialysis patients are often knowledgeable about their dry weights and baseline laboratory test results. If not, the center the patient uses should be contacted and asked about the dry weight, average interdialytic weight gains, and any recent complications. Ask about uremic symptoms as markers of inadequate hemodialysis, and ask if the native kidneys are retained since these can be sources of hypertension, infection, and nephrolithiasis.

Examine the access site (**Table 90-5**), looking for the presence of flow by identifying a bruit and thrill. The classic signs of infection—erythema, swelling, tenderness, and purulent discharge—are often

TABLE 90-5 Key Elements of Physical Examination of Hemodialysis Patients

Vital signs
Vascular access: bruit, thrill, erythema, warmth, swelling, tenderness, discharge, bleeding, Branham sign
Cardiac: signs of heart failure, murmurs, muffled (distant) heart sounds
Neurologic: mental status changes, peripheral neuropathy, asterixis

limited until the infection is far advanced. Look for congestive heart failure, effusion, or high-output fistula-related heart failure; peripheral edema, hepatojugular reflux, and jugular venous distention can be present in both fluid overload and pericardial tamponade. A loud cardiac murmur may just represent increased flow secondary to anemia or the arteriovenous access. Neurologic dysfunction in hemodialysis patients is generally diffuse and nonfocal. Any focal neurologic findings require neuroimaging. Seek GI bleeding with rectal examination and occult blood testing, and obtain Doppler US examination if any question about vascular insufficiency, aneurysm, or pseudoaneurysm exists.

PERITONEAL DIALYSIS

TECHNICAL ASPECTS OF PERITONEAL DIALYSIS

In PD, the peritoneal membrane is the blood–dialysate interface. The amount of ultrafiltration is determined by osmotic pressure differences between the blood and dialysate, which are manipulated by changing the dialysate glucose concentration. Similarly to hemodialysis, PD relies on the separate processes of clearance (solute removal) and ultrafiltration (fluid removal) to replace the functions of the nephron. Most solute removal occurs via diffusion down chemical gradients established by altering dialysate electrolyte concentrations. Dialysate is supplied in 1.5% and 4.25% glucose formulations, which can be alternated to increase or decrease ultrafiltration.

Typical PD regimens use four exchanges daily, with 2 L of dialysate infused and left in place for several hours before draining. During the day, approximately 8 L is infused and about 10 L is drained, for a removal of approximately 2 L/d of fluid. PD can be accomplished in an acute setting, over the long term via exchanges of solution throughout the day (continuous ambulatory PD), or through multiple exchanges at night while the patient sleeps (continuous cyclic PD).

COMPLICATIONS OF CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

Peritonitis is the most common complication of PD, with an incidence of about one episode every 15 to 18 patient care-months. Mortality rates from peritonitis range between 2.5% and 12.5%. Symptoms and signs of peritonitis in PD patients are fever, abdominal pain, and rebound tenderness. Cloudy effluent suggests peritonitis, confirmed by Gram stain, cell count, and culture. **The cell count in PD-related peritonitis is usually >100 leukocytes/mm,[3] with >50% neutrophils.** Results of the Gram staining are positive in only 10% to 40% of cases of culture-proven PD-related peritonitis. Organisms isolated in PD-related peritonitis are *Staphylococcus epidermidis* (approximately 40% of cases), *S. aureus* (10%), *Streptococcus* species (15% to 20%), gram-negative bacteria (15% to 20%), anaerobic bacteria (5%), and fungi (5%).[10]

Empiric therapy begins with a few rapid exchanges of fluid lavaged to decrease the number of inflammatory cells in the peritoneum, with added heparin (500 to 1000 units/L dialysate) to decrease fibrin clot formation. A first-generation cephalosporin (e.g., cephalothin) can be mixed with the dialysate, 500 milligrams/L with the first exchange and 200 milligrams/L with subsequent exchanges. In penicillin-allergic patients, use vancomycin 500 milligrams/L and maintenance doses of 50 milligrams/L per exchange. If seeking gram-negative coverage, add gentamicin 100 milligrams/L and maintenance doses of 4 to 8 milligrams/L per exchange. Most recommend treating for 7 days after the first negative culture results, usually resulting in a total of 10 days of therapy. Admission decisions are based on the patient's clinical appearance. Parenteral antibiotics are not used.

Infections around a PD catheter present with pain, erythema, swelling, and discharge around the catheter exit site. The most common causative bacteria are *S. aureus* and *Pseudomonas aeruginosa.* Empiric therapy consists of an oral first-generation cephalosporin or ciprofloxacin for outpatient therapy. Refer patients to their continuous ambulatory PD centers for follow-up the next day.

TABLE 90-6 Key Historical Elements for Peritoneal Dialysis Patients

Cause of end-stage renal disease
Type of peritoneal dialysis (continuous ambulatory peritoneal dialysis vs continuous cyclic peritoneal dialysis)
Peritoneal dialysis parameters: concentration, number of exchanges per day
Recent complications of peritoneal dialysis
Baseline weight, laboratory values, and vital sign values
Symptoms of uremia
Retention of native kidneys?
Still producing urine?

TABLE 90-7 Key Elements of Physical Examination of Peritoneal Dialysis Patients

Abdominal examination: inspection for hernia, auscultation of bowel sounds, test for rebound tenderness
Peritoneal catheter: examination of surrounding skin, palpation of tunnel

Abdominal wall hernias occur in 10% to 15% of PD patients. Immediate surgical repair of pericatheter hernias is common because of the high risk of incarceration.

ED EVALUATION OF PERITONEAL DIALYSIS PATIENTS

Table 90-6 lists important elements of patient history for PD patients. As with hemodialysis patients, the disease that caused the renal failure frequently persists.

The physical examination focuses on the abdomen: signs of infection of the peritoneum, tunnel, and exit site should be identified (**Table 90-7**).

CHAPTER 91

Urinary Tract Infections and Hematuria

Kim Askew

URINARY TRACT INFECTIONS

In 2010, urinary tract infection (UTI) was the sixth most common diagnosis in women age 15 to 64 years and the fourth most common diagnosis in women age 65 years and older presenting to the ED.[1] The self-reported annual incidence of UTI in women is 12%, and by the age of 32 years, half of all women report having had at least one UTI. Although younger women are more likely to be affected than men by a ratio of 35:1, the gender gap decreases to 2:1 by age 66, most likely due to prostatic hypertrophy and need for instrumentation in elderly men.[2] All age groups from neonates to the elderly are affected, carrying risks in special populations.[3] (See chapters 132, "Urinary Tract Infection in Infants and Children" and 99, "Comorbid Diseases in Pregnancy").

PATHOPHYSIOLOGY AND DEFINITIONS

UTIs can be grouped based on the anatomic site involved as well as patient characteristics. These classifications are important when determining treatment modalities.

ASYMPTOMATIC BACTERIURIA

Asymptomatic bacteriuria is the presence of >100,000 (>10^5) colony-forming units (CFU)/mL of a single pathogen on two successive urine cultures in a patient without symptoms.[4]

Prevalence of asymptomatic bacteriuria is up to 10% in pregnant woman, 40% in male and 50% in female residents of nursing homes, and up to 100% in patients with indwelling catheters for more than 1 month. There is evidence to suggest that asymptomatic bacteriuria may provide some protection against symptomatic infection with invasive organisms in patients with indwelling catheters[5] and in patients with recurrent UTIs.[6] Treatment of asymptomatic bacteriuria is recommended only in pregnant woman (see chapter 99) and in patients immediately prior to invasive urinary procedures.[4]

URETHRITIS AND CYSTITIS

Infections of the lower urinary tract include urethritis and cystitis. *Acute cystitis* is an infection isolated to the bladder. Acute cystitis without coexisting pyelonephritis in otherwise healthy, nonpregnant young females with no obstruction is a benign illness with a 24% spontaneous cure rate; less than 1% of patients go on to develop pyelonephritis.[7] Competent ureteral valves prevent ascent of the bacteria into the kidneys in most cases. The diagnostic criterion in acutely symptomatic patients is a positive urine culture of ≥10^2 to >10^3 CFU/mL.[8] *Urethritis,* commonly associated with sexually transmitted diseases, presents with similar symptoms but typically is associated with a vaginal discharge or irritation.

PYELONEPHRITIS

Pyelonephritis is an infection of the upper urinary tract. *Acute pyelonephritis* involves the renal parenchymal and pelvicalyceal system. Pyelonephritis is differentiated from cystitis primarily by clinical findings: a syndrome of flank pain or costovertebral angle tenderness, with or without fever, in the setting of a positive urine culture of 10^5 CFU/mL, and frequently other systemic symptoms such as nausea or vomiting. Infections of the upper urinary tract can progress into three patterns of renal infection not commonly considered part of the UTI spectrum: acute bacterial nephritis, renal abscess, and emphysematous pyelonephritis. These diagnoses are made based on imaging studies performed in patients who have an inadequate or atypical response to treatment for presumed acute pyelonephritis.

UNCOMPLICATED URINARY TRACT INFECTION

***Uncomplicated UTI* is a UTI in a patient without structural or functional abnormalities within the urinary tract or kidney parenchyma, without relevant comorbidities that place the patient at risk for more serious adverse outcome, and not associated with GU tract instrumentation.**[9,10] This classification is thus limited to young, healthy, nonpregnant women with normal anatomic and functioning urinary tracts. Women are more susceptible than men to UTI due to a shorter urethra for uropathogenic bacteria to ascend. The traditional diagnostic criterion dating from 1960 had been a positive urine culture of 10^5 CFU/mL; however, in symptomatic patients, low-colony-count infections with ≥10^2 to 10^3 CFU/mL are clinically valid.[8-10]

COMPLICATED URINARY TRACT INFECTION

***Complicated UTI* is infection involving a functional or anatomically abnormal urinary tract or infection in the presence of comorbidities that place the patient at risk for more serious adverse outcomes.**[11] Risk factors for complicated UTI, including UTI in males, are listed in **Table 91-1**.[9] The diagnostic criterion is the isolation of 10^5 CFU/mL of urine culture. Unfortunately, patients with complicated UTIs are a very heterogeneous group, and few clinical trials have been conducted to guide management. In general, patients in this group are more likely to be infected with resistant organisms.[11] Although older literature categorized pyelonephritis as a complicated UTI, current guidelines do not.[10-12] *Uncomplicated pyelonephritis* refers to the clinical syndrome of fever and flank pain or tenderness with or without vomiting in a patient with an anatomically normal urinary tract without comorbidities. However, the recommended management of patients with uncomplicated pyelonephritis is similar to recommendations for patients with complicated UTI and differs from the management of patients with uncomplicated cystitis (see "Treatment" later in the chapter).

TABLE 91-1 Risk Factors for Complicated Urinary Tract Infection (UTI)

Risk Factor	Comments
Male sex	In young males, dysuria is more commonly secondary to sexually transmitted disease; suspect underlying anatomic abnormality in men with culture-proven UTI.
Anatomic abnormality of the urinary tract or external drainage system	Indwelling urinary catheter, ureteral stent, nephrolithiasis, neurogenic bladder, polycystic renal disease, or recent urinary tract instrumentation.
Recurrent UTI plus additional risk factor(s)	Recurrent UTI is common in patients with anatomic or functional abnormalities of the urinary tract; however, recurrent infection alone is not a criterion for complicated UTI.
Advanced age in men	Presence of prostatic hyperplasia, recent instrumentation, or recent prostatic biopsy.
Nursing home residency	With or without indwelling bladder catheter.
Neonatal state	See chapter 132.
Comorbidities	Diabetes mellitus, sickle cell disease, others.
Pregnancy	See chapter 99.
Immunosuppression	Active chemotherapy, acquired immunodeficiency syndrome, immunosuppressive drugs.
Advanced neurologic disease	Spinal cord injuries, stroke with disability, others.
Known or suspected atypical pathogens	Non–*Escherichia coli* infections.
Known or suspected resistance to typical antimicrobial agents for UTI	Resistance to ciprofloxacin predicts multidrug resistance.

RECURRENT URINARY TRACT INFECTION

Recurrent UTI is defined as two uncomplicated UTIs in 6 months or three or more uncomplicated UTIs in the preceding 12 months.[13,14] Recurrent UTIs can be classified into two different categories that affect treatment decisions: relapse and reinfection. **Relapse of UTI is a recurrence of a UTI within 2 weeks of treatment completion caused by the same organism** from a focus within the urinary system, and represents treatment failure. **Reinfection is a recurrent UTI caused by a different bacterial isolate** or by the previously isolated bacteria after a negative intervening culture or a period of 2 weeks between infections.[13] Reinfection is more common than relapse. Behavioral factors can lead to increased risk for uncomplicated UTIs. The concentration of bacteria in the female bladder may increase 10-fold after sexual intercourse, whereas the use of a diaphragm and spermicide is also associated with recurrent UTI, probably because the spermicide enhances vaginal colonization with *Escherichia coli*.[15]

MICROBIOLOGY

UTIs typically arise from ascending infection from the urethra to the bladder, although hematogenous and lymphatic spread can occur. Uropathogenic organisms often have adhesins, fibrillae, or pili that allow the bacteria to adhere to and invade the uroepithelium.[15,16] *E. coli* remains the most common pathogen by a large margin (**Table 91-2**).

First reported in 1983, but with an increase since 2000,[17] community-acquired extended-spectrum β-lactamase–producing *E. coli* has emerged as a small but growing source of antibiotic resistance, affecting approximately 4% to 6% of outpatients with UTI.[17,18] Emergence of this resistant isolate of *E. coli* has important implications for treatment (see

TABLE 91-2 Etiologic Agents in Uncomplicated Urinary Tract Infection

Organism	Incidence (%)
Escherichia coli	>80
Klebsiella species	5–20
Proteus species	
Enterobacter species	
Pseudomonas species	
*Chlamydia trachomatis**	<5
*Staphylococcus saprophyticus**	
Mycobacterium tuberculosis (in human immunodeficiency virus infection)	

*Much more common in the "dysuria-pyuria" syndrome in which sterile or low-colony-count culture results are obtained. *S. saprophyticus* may account for up to 15% of acute lower tract infections in young, sexually active females, but rarely progresses to involve the upper tract.

"Treatment" later in the chapter)[19] and can increase mortality in those affected.[20]

Several anatomic, genetic, and age-related factors increase risks for bacterial invasion of the urinary tract. Select women have specific uroepithelial cell *E. coli*–binding glycolipids that promote fecal coliform colonization of the vagina.[2] In postmenopausal women, decreased estrogen has been associated with a conversion of vaginal flora from lactobacillus to *E. coli* and other Enterobacteriaceae.[2] Incomplete bladder emptying disrupts the bladder's ability to eradicate bacteria from its mucosal surface, increasing its susceptibility to infection, especially in patients with neurogenic bladder, women with uterine prolapse, and men with prostate hypertrophy.

CLINICAL FEATURES

Clinical features of UTI vary by anatomic site involved and the patient's risks for complicated UTI. Asymptomatic bacteriuria is a laboratory-based diagnosis (see "Pathophysiology and Definitions" discussed earlier).

URETHRITIS

In males, dysuria with a urethral discharge indicates urethritis (see chapter 149, "Sexually Transmitted Infections"). UTI is uncommon in healthy young adult males, but if the clinical diagnosis does not suggest urethritis or prostatitis in a male with dysuria, bacteriuria is likely due to UTI. In women, *Chlamydia* infection should be suspected in the following settings: a new sexual partner, a partner with urethritis, examination findings of cervicitis, or low-grade pyuria with no bacteria seen on urinalysis. Concurrent gonorrhea is common with *Chlamydia* infections.

CYSTITIS

Symptoms and signs of cystitis are frequency, urgency, hesitancy, suprapubic pain, visible (gross) hematuria, and/or suprapubic tenderness. The nature and severity of symptoms are determined by the etiologic organism(s), the portions of the urinary tract involved, and the patient's ability to mount an immune and inflammatory response.[12] **A history of vaginal discharge or irritation is more often associated with vaginitis, cervicitis, or pelvic inflammatory disease than with UTI.** Fever is uncommon with simple cystitis.

PYELONEPHRITIS

Flank pain, costovertebral angle tenderness, or specific renal tenderness to deep palpation may be associated with cystitis because of referred pain. However, when these findings occur, especially in association with fever, chills, nausea, vomiting, or prostration, the clinical diagnosis is *acute pyelonephritis*. Patients with pyelonephritis may or may not have coexistent symptoms of cystitis. The presentation of pyelonephritis may be subtle, and it might be difficult to distinguish lower from upper UTI, especially in patients who do not experience pain normally (those with spinal cord injury), immunocompromised patients, and the aged. A missed diagnosis of cystitis is unlikely to lead to patient deterioration[7,9]; in contrast, missed pyelonephritis could lead to untreated sepsis.

UROSEPSIS

Patients with urosepsis may or may not exhibit the symptoms listed above for cystitis or pyelonephritis. As graded by the European Section for Infections in Urology,[10,21] simple urosepsis presents with temperature change (>38°C or <36°C), rising heart rate (>90 beats/min), elevated respiratory rate (>20 breaths/min), and commonly leukocytosis. Severe urosepsis includes hypotension, and/or organ dysfunction, and/or hypoperfusion as evidenced by lactic acidosis, oliguria, or acute altered mental status. Uroseptic shock adds the criteria of hypotension or ongoing evidence of hypoperfusion despite adequate fluid resuscitation (see chapter 150, "Toxic Shock Syndromes").

COMPLICATED URINARY TRACT INFECTION

For patients at risk for complicated UTI (Table 91-1), the clinical features and the classic presenting signs and symptoms of UTI may vary widely or be entirely absent. Fever, pain, and an inflammatory response may be absent. Suspect UTI in more complicated cases involving patients with atypical and diverse signs and symptoms, including weakness, malaise, altered mental status, fever, and flank or abdominal pain. Guidelines suggest the following criteria be used to define symptomatic catheter-associated UTI: new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with no other identified cause; flank pain; costovertebral angle tenderness; acute hematuria; pelvic discomfort; and in those whose catheters have been removed, dysuria, urgent or frequent urination, or suprapubic pain or tenderness.[22,23] In patients with spinal cord injury, increased spasticity, autonomic dysreflexia, and sense of unease are also compatible with catheter-associated UTI.[22]

DIAGNOSIS

A definitive diagnosis of UTI combines appropriate historical findings with laboratory confirmation.[9,24] However, a clinical diagnosis of acute uncomplicated cystitis can be made with a moderate probability based on a history of dysuria, frequency, and urgency, in the absence of vaginal discharge or irritation, in women who have no other risk factors for complicated UTIs.[10] However, the false-positive rate for the diagnosis of UTI based on history alone has been reported to be 33% in outpatients[24,25] and as high as 43% in ED patients. Although empiric treatment of uncomplicated cystitis based on history alone in select women continues to be advocated by some experts,[10] three systematic reviews do not recommend history-based diagnosis due to inaccuracy,[26-28] and other authors advocate laboratory confirmation to reduce the growing problem of antibiotic resistance.[19,29,30]

URINALYSIS

The *clean-catch, midstream voiding specimen* is as accurate as urine obtained by catheterization if the patient follows instructions carefully. If the sample is properly collected, it should contain no or few epithelial cells. **Bacteria in urine double each hour at room temperature, so urine should be refrigerated if not sent directly to the laboratory.** Catheterization is indicated if the patient cannot void spontaneously, is too ill or immobilized, or is extremely obese. **Avoid unnecessary catheterization, because 1% to 2% of patients develop a UTI after a single catheter insertion.**

Visual inspection or assessment of the odor of the urine is generally not helpful in determining infection because cloudiness and odor are caused by noninfectious etiologies. **Table 91-3** lists normal reference values for urinalysis. UTI often results in positive dipstick test for protein in the urine, but this finding is not specific enough to be useful in diagnostic decision making to rule in infection.

Values for individual laboratories may differ from the listed norms in Table 91-3. Dipstick testing is performed on a fresh uncentrifuged urine specimen and is quick and easy to perform at the bedside. Urine for

TABLE 91-3 Normal Urinalysis Results

Value	Normal Range	Specimen Type
RBCs, female	0–5/HPF	Centrifuged specimen
RBCs, male	0–3/HPF	Centrifuged specimen
WBCs	0–4/HPF	Centrifuged specimen
Bacteria	None/HPF	Centrifuged specimen
Leukocyte esterase	None—dipstick test	Fresh urine
Nitrite	None—dipstick test	Fresh urine

Abbreviations: HPF = high-power field; RBCs = red blood cells.

microscopic analysis is routinely centrifuged prior to analysis. If examination of uncentrifuged urine is desired, make a specific request to the laboratory to account for different normal values between centrifuged and uncentrifuged specimens.

NITRITE REACTION BY DIPSTICK TEST

The urine nitrite reaction has a very high specificity (>90%), and a positive result is very useful in confirming the diagnosis of a UTI caused by bacteria that convert nitrates to nitrite, primarily the coliform bacteria, including *E. coli*. ***Enterococcus***, ***Pseudomonas*****, and *Acinetobacter* species do not convert nitrates to nitrites in the urine and therefore are not detected by the nitrite test.** Unfortunately the urine nitrite reaction has a low sensitivity (~50%), so it is not always useful as a screening examination because a negative result does not exclude the diagnosis of UTI.

LEUKOCYTE ESTERASE REACTION BY DIPSTICK TEST

Using positive culture results as the criterion standard, the leukocyte esterase urine dipstick test has an overall sensitivity of 48% to 86% and a specificity of 17% to 93% for identifying infection. Performance varies by clinical setting. In the ED, using culture findings of 10^5 CFU/mL as the criterion, a positive leukocyte esterase reaction result has a sensitivity of 77% and a specificity of 54%. The sensitivity of positive leukocyte esterase reaction result for detecting infection decreases for specimens with less bacterial growth at culture, ranging from a sensitivity of 79.5% when culture growth is >10^5 CFU/mL to 50.4% when culture growth is 10^3 CFU/mL. Therefore, if the clinician uses a lower culture threshold to define infection, the leukocyte esterase test performs with lower sensitivity to detect infection. **In summary, a positive urinary dipstick nitrite or leukocyte esterase test result supports the diagnosis of UTI, but a negative test result does not exclude it.**

URINE WBC COUNT OR PYURIA BY MICROSCOPY

The assessment of pyuria using standard centrifuged urine is imperfect due to variable specimen preparation techniques. A WBC count of >5 cells/high-power field (HPF) in a centrifuged specimen from a symptomatic patient is abnormal. Although the combination of pyuria and bacteriuria is likely to be found with typical coliform infection, lower degrees of pyuria with or without bacteriuria may be clinically significant, especially in the presence of UTI symptoms.

In a symptomatic patient who has <5 WBCs/HPF in a centrifuged specimen, other causes of false-negative pyuria should be considered such as dilute precentrifuged urine, systemic leukopenia, or patient self-treatment with leftover antibiotics. Pyuria may be intermittent or absent if the patient has an obstructed and infected kidney. **In men, >1 or 2 WBCs/HPF in a centrifuged specimen can be significant when bacteria are present.** Urethritis and prostatitis are far more likely causes of pyuria in young males who are sexually active and complain of dysuria, regardless of the presence or absence of urethral discharge.

BACTERIURIA BY MICROSCOPY

Bacteriuria is a sensitive tool for detection of UTI in the symptomatic patient. **The presence of any bacteria on a Gram-stained specimen of uncentrifuged urine (>1 bacterium/HPF or 1000×) is significant and highly correlates with culture results of >10^5 CFU/mL.** For Gram-stained centrifuged specimens, >1 bacterium/HPF (1000×) is 95% sensitive and >60% specific to predict a culture with 10^4 CFU/mL. Both of these methods of looking for bacteria under the microscope fail to detect low-colony-count UTI or infection caused by *Chlamydia*. False-positive results can occur when vaginal or fecal contamination is present. Female patients with symptoms suggestive of UTI *and* vaginal discharge or dyspareunia should have a pelvic examination to investigate for pelvic inflammatory disease.

COMBINED RESULTS OF DIPSTICK TESTING, URINE CELL COUNTS, AND HISTORICAL INFORMATION

Two meta-analyses found that classic historical findings of cystitis were weak predictors of positive culture or failed to predict cystitis.[27,28] Vaginal discharge weakly decreased the likelihood of cystitis; however, in both studies, diagnostic accuracy was significantly improved using dipstick testing, particularly a positive test for nitrites.[27,28] A 2013 systematic review of four ED-based studies pooled 948 patients using a reference culture threshold of 10^4 to 10^5 CFU/mL and found that no single historical variable of cystitis could rule in or rule out infection, but a dipstick test positive for nitrates, moderate pyuria, and/or bacteriuria were accurate predictors of a UTI,[26] effectively ruling in the diagnosis of UTI. However, **no single test or combination of testing results can effectively rule out UTI in women presenting to the ED with symptoms of cystitis.** Therefore, there will be a subset of women for whom test results are equivocal who should either be treated empirically or receive phone-in treatment based on culture, if follow-up cannot be assured in 2 to 3 days.

URINE AND BLOOD CULTURE

For the patient with typical symptoms of *cystitis* or an *uncomplicated UTI* and "positive" findings on urinalysis—pyuria on microscopic examination, bacteria in a Gram-stained specimen, positive leukocyte esterase test result, and/or positive urine nitrite test result—urine culture is not required. The vast majority of patients respond to empiric therapy. Urine culture should be performed for the following patients: those with complicated UTI, pregnant women, adult males, patients with relapse or reinfection, and septic patients. If the patient is symptomatic, a single positive culture result is significant.

Results of blood cultures in patients admitted for clinical pyelonephritis are positive in 25% to 29% of cases; organisms in blood culture match those in urine culture in 97% of cases, and blood culture results usually do not alter management. The primary indication for blood cultures in patients with suspected UTI is clinical sepsis.

IMAGING

Renal imaging studies are not indicated in otherwise healthy patients with acute pyelonephritis who can be managed as outpatients. Male, elderly, diabetic, or severely ill patients with acute pyelonephritis should be considered for imaging, particularly if there is a renal stone or a poor initial response to antibiotic therapy. The kidneys can be imaged with bedside US to evaluate for obstruction and focal parenchymal abnormalities. Plain film radiography and US have poor sensitivity for detection of intrarenal gas formation in emphysematous pyelonephritis. If kidney or ureteral stones or emphysematous pyelonephritis are suspected, CT is the best imaging modality.[9]

Table 91-4 lists the differential diagnoses for dysuria.

TREATMENT

ACUTE CYSTITIS AND UNCOMPLICATED URINARY TRACT INFECTION

Selection of antibiotics depends on the organism suspected of causing the infection, the patient's ability to adhere to the treatment regimen, local resistance patterns, potential drug toxicity, and cost. The Infectious Disease Society of America and the European Society for Microbiology

TABLE 91-4 Differential Diagnosis for Dysuria

Disorder	Comments
Urinary tract infection	Cystitis and pyelonephritis
Vaginitis/cervicitis	Infections (STD), atrophy, allergy
Urethritis	Infections (STD), allergy
Trauma	Trauma involving vagina, urethra, or bladder
Allergy	Typically a reaction to a hygienic product or spermicide
Bladder/urethral cancer	—
Nephrolithiasis	—
Urethral stricture or obstruction	—
Uterine/bladder/vaginal prolapse	—
Fistulas	Ileovesicular, urethral, urethrorectal, bladder
Urethral foreign body	Includes urethral stone disease
Urethral diverticulum	—
Cystocele	—
Chemical irritation	Spermicides, cleansing douches, feminine hygiene products
Behavioral symptom without detectable pathology	Consider previous rape, sexual abuse
Chronic disorders	Chronic cystitis, chronic urethritis

Abbreviation: STD = sexually transmitted disease.

and Infectious Disease published updated recommendations on antibiotics for uncomplicated UTI in 2010 (**Table 91-5**).[12] Other guidelines have been incorporated.[10]

Table 91-5 contains treatment recommendations for three separate groups of patients with UTI: (1) uncomplicated lower tract disease, (2) complicated UTI or pyelonephritis, and (3) women with UTI symptoms in whom coexistent urethritis cannot be excluded.[10,12]

Three-day regimens are recommended for uncomplicated infections in nonpregnant women.[12] A total of 3 to 6 days of therapy is sufficient for treating uncomplicated UTIs in elderly women; however, patient selection guidelines must be strictly adhered to because most elderly women have comorbidities that exclude them from the classification of "uncomplicated UTI."[31] Trimethoprim-sulfamethoxazole continues to be recommended because it is inexpensive and has limited side effects. Rates of resistance to trimethoprim-sulfamethoxazole are reported to be over the 20% threshold for treatment exclusion in the western and southern United States;[32] however, hospital culture data primarily reflect complicated UTI, and trimethoprim-sulfamethoxazole treatment may be successful for uncomplicated UTI.[33] Fosfomycin has less efficacy than short courses of other regimens. Within regions, local resistance patterns vary widely and change rapidly. Currently, recommendations are to avoid trimethoprim-sulfamethoxazole as the first-line empiric agent of choice when local resistance rate exceeds 20%, unless treating based on the results of urine culture with sensitivity testing.

Nitrofurantoin is indicated for treatment of UTI in pregnancy, although it is not effective against *Staphylococcus saprophyticus*. A 5-day course of extended-release nitrofurantoin is as effective as 3 days of trimethoprim-sulfamethoxazole therapy.[34] A single 3-gram dose of **fosfomycin** is a first-line choice for uncomplicated UTI[12] because the resistance rate is only 2%.[35] Both nitrofurantoin and fosfomycin are recommended oral agents in the event of extended-spectrum β-lactamase–producing *E. coli* infection, because resistance is reported to be only 6% and 3%, respectively.[36]

Because of bacterial resistance to traditional antibiotics used for UTI, use local sensitivities to guide the substitution of alternative agents such as cephalosporins. Third-generation cephalosporins are highly effective against enterobacteria, whereas first-generation cephalosporins are more effective against staphylococci. Amoxicillin-clavulanate is less effective than fluoroquinolones or oral cephalosporins for UTI due to enterobacteria. It also often leads to selection of *Klebsiella*. Aminopenicillins are therefore not recommended as first-line therapy in uncomplicated UTI.

If the patient has UTI symptoms and there is also suspicion of *Chlamydia* or *Neisseria gonorrhoeae* infection (cervicitis and/or salpingitis), antibiotic treatment is more complex. The patient should be tested[37]

TABLE 91-5 Guidelines for Outpatient Management of Urinary Tract Infection (UTI) Including Pyelonephritis

Patient	UTI Type	Antimicrobial Regimens	Culture/Treatment Comments
Adult female	Lower (cystitis) Uncomplicated	Nitrofurantoin monohydrate/macrocrystals, 100 milligrams twice a day × 5 d or TMP-SMX DS (160/800 milligrams), 1 tab twice a day × 3 d or Fosfomycin, 3 grams in single dose *or* (where available) Pivmecillinam, 400 milligrams bid × 5 days (lower efficacy than some other recommended agents; avoid if early pyelonephritis suspected)	No initial culture is required. Consider community resistance; if >20%, use another agent. Amoxicillin-clavulanate, cefpodoxime-proxetil, cefdinir, and cefaclor, in 3- to 7-d regimens are appropriate choices for therapy when other recommended agents cannot be used. The fluoroquinolones should be reserved for important uses other than acute uncomplicated cystitis.
Adult female or male	Lower (cystitis), upper (pyelonephritis) Complicated	Ciprofloxacin, 500 milligrams twice a day × 7 d *or* Levofloxacin, 750 milligrams once a day × 5 d *or* Cefpodoxime, 400 milligrams twice a day × 7–14 d *or* Only if susceptibilities are known, consider: TMP-SMX DS (160/800 milligrams), 1 tab twice a day, 14 d minimum *or* Amoxicillin-clavulanate, 875/125 milligrams twice a day	Urine culture is advised. Consider community resistance; if >20%, use another agent. Coliforms are common. Treat for at least 7 d (mild symptoms) or 14 d (more severe symptoms, clear pyelonephritis). Admit if patient is significantly ill, unable to retain fluids or medications, or pregnant. Consider IV dose of ceftriaxone if sensitivity uncertain.
Adult female	Lower (urethritis)	Ceftriaxone, 250 milligrams IM *plus* Azithromycin, 1 gram single dose *or* Doxycycline, 100 milligrams twice a day × 7 d	Culture for *Chlamydia*, and *Neisseria gonorrhoeae*. Fluoroquinolones no longer recommended for treatment of *N. gonorrhoeae* and *Chlamydia*. Consider adding a regimen listed above for cystitis if coexistent infections are strongly suspected.

Abbreviations: DS = double strength; TMP-SMX = trimethoprim-sulfamethoxazole.

TABLE 91-6 Empiric Initial Treatment for Inpatient Management of Pyelonephritis and Complicated Urinary Tract Infection

Ciprofloxacin, 400 milligrams IV every 12 h
Ceftriaxone, 1–2 grams IV once daily
Cefotaxime, 1–2 grams IV every 8 h
Gentamicin or tobramycin, 3 milligrams/kg/d divided every 8 h, ± ampicillin, 1–2 grams every 4 h
Piperacillin-tazobactam, 3.375 grams IV every 6 h
Cefepime, 1–2 grams IV every 8 h
Ertapenem, 1 gram IV every day
Imipenem, 500 milligrams IV every 8 h
Meropenem, 1 gram IV every 8 h

Note: Alternatives include ceftazidime, 1–2 grams IV every 8–12 h; amikacin, 7.5 milligrams/kg IV loading dose, then 15 milligrams/kg/d or divided dose every 8 h; and others based on local resistance and sensitivity patterns.

and empirically treated[38] for *Chlamydia* and *N. gonorrhoeae* (see Table 91-5; also see chapter 149. Fluoroquinolones were formerly recommended in this setting as a treatment for both cystitis and urethritis, but the Centers for Disease Control and Prevention no longer recommend them due to *N. gonorrhoeae* resistance. If coexistent cystitis is suspected in a patient with clinical urethritis, add a recommended treatment for cystitis (Table 91-5) to the treatment for urethritis; alternatively, culture the urine and treat for cystitis pending results.

ACUTE PYELONEPHRITIS AND COMPLICATED URINARY TRACT INFECTION

Recommendations for antibiotic therapy and cultures for patients whose condition is stable enough for outpatient treatment are listed in Table 91-5. Antibiotics for inpatient management are listed in **Table 91-6**.[10,12,] For patients whose vital signs are unstable, see chapter 150, "Toxic Shock Syndromes." After clinical improvement has been achieved with parenteral antibiotics, treatment should be changed to oral agents as listed in Table 91-5. Patients may require fluid resuscitation with crystalloids to replace fluid losses due to vomiting or sweating. Although treatment courses as short as 5 days have been studied in patients with pyelonephritis and catheter-associated infections,[9,10] guidelines recommend a total of 7 to 14 days of therapy for the majority, regardless of whether or not parenteral therapy is used.[10] Men with UTI without immunocompromise may have improved outcomes with therapy for 7 days, rather than 14 days.[39,40] For patients with sepsis syndrome, a total of 21 days of treatment may be required to eradicate bacteriuria.[10]

RECURRENT INFECTION

Women presenting to the ED with an acute UTI and a history of greater than two UTIs in 6 months or greater than three UTIs in 12 months should be cultured, treated empirically, and referred to a primary care physician in 1 to 2 weeks for repeat culture and possible prophylaxis.[41-43] The patient can be treated with recommended treatments for uncomplicated cystitis from Table 91-5 including 3-day regimins,[41] unless the recurrence is a relapse (see "Pathophysiology and Definitions" discussed earlier). Treat relapse with an alternative agent, such as one of those recommended for complicated UTI (Table 91-5).[41] Prophylaxis may take the form of continuous, postcoital, or intermittent self-treatment during symptomatic episodes.[41-43] Woman with recurrent UTI using spermicide with contraception should be encouraged to inquire about an alternative method of contraception.[41-43]

DISPOSITION AND FOLLOW-UP

The decision to admit a patient with UTI is based on age, host factors, and response to initial ED interventions. Admit patients who are unable to retain fluids and medication or those with systemic signs of UTI and a stone (see chapter 94, "Urologic Stone Disease"), and choose antibiotics as listed in Table 91-6**.** Eighty-four percent of patients are discharged.[44] Healthy females tolerating fluids and medication with uncomplicated pyelonephritis are candidates for outpatient management.[45] Adjunctive therapies at discharge include increased fluids and frequent voiding to diminish tissue contact with bacteria. An oral bladder analgesic, such as phenazopyridine (200 milligrams PO three times daily), reduces dysuria. Cranberry juice appears to be mildly effective in reducing the incidence of recurrent infection. There is no conclusive evidence that postcoital voiding prevents cystitis.[43] Ask patients to return to the ED if they experience increasing pain, fever, or vomiting. Consider systemic analgesics and antiemetics for patients with pyelonephritis.

Overall, approximately 1% to 3% of patients with acute pyelonephritis die from the infection, with younger patients experiencing the fewest complications. Factors associated with an unfavorable prognosis are advanced age and general debility, renal calculi or obstruction, a history of recent hospitalization or instrumentation, diabetes mellitus, evidence of chronic nephropathy, sickle cell anemia, underlying carcinoma, and immunocompromised state (e.g., chemotherapy, human immunodeficiency virus infection/acquired immunodeficiency syndrome [HIV/AIDS]).

Dangerous complications of acute pyelonephritis include acute papillary necrosis with possible ureter obstruction, septic shock, perinephric abscesses, and emphysematous pyelonephritis.

SPECIAL POPULATIONS

PREGNANCY

See chapter 99 for a detailed discussion.

PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION/ ACQUIRED IMMUNODEFICIENCY SYNDROME

In HIV/AIDS patients, resistance to TMP-SMX is increased due largely to its use in *Pneumocystis jiroveci* prophylaxis. Fluoroquinolones should be the initial antibiotic used for UTI in these patients unless urine culture and sensitivity test results are available to guide therapy. Most UTIs in HIV/AIDS patients are caused by typical pathogens or common sexually transmitted disease organisms. *Mycobacterium tuberculosis* is an infrequent cause of UTI in the HIV/AIDS population. Close outpatient follow-up (recheck in 1 week) and possible infectious disease consultation are warranted when treating UTI in this population (see chapter 154, "Human Immunodeficiency Virus Infection").

PRACTICE GUIDELINES

The European Association of Urology updates its "Guidelines on Urogenital Infections" yearly.[10] The Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases updated its "International Clinical Guidelines for the Treatment of Acute Uncomplicated Cystitis and Pyelonephritis in Women" in 2010.[12] "Complicated Urinary Tract Infection in Adults" guidelines were published by the Canadian Association of Medical Microbiology and Infectious Diseases in 2005.[11]

HEMATURIA

INTRODUCTION AND EPIDEMIOLOGY

Gross hematuria is visible to the eye, whereas microscopic hematuria is a laboratory diagnosis. Other pigments, particularly myoglobin, may discolor the urine and simulate gross hematuria. UTI is the most common cause of hematuria associated with urgency, dysuria, and nocturia[26,27]; however, these symptoms are also common in the much smaller group of patients who ultimately are diagnosed with cancer of the urinary tract.[46,47] Painless hematuria is more often due to neoplastic, hyperplastic, and vascular causes.

It takes approximately 1 mL of whole blood per liter of urine to result in visible hematuria. Gross hematuria may also result in false proteinuria.

The incidence of gross hematuria in the general population and in patients presenting to the ED is unknown. However, gross hematuria is more common in premenopausal women due to UTIs and contamination with menstrual blood.[48] The incidence of bladder cancer associated with gross hematuria rises with increasing age.

The American Urological Association recently redefined *microscopic hematuria* as ≥3 red blood cells (RBCs)/HPF (400×) on a properly collected and centrifuged urinary specimen in the absence of an obvious benign cause,[48] removing the prior American Urological Association requirement for a positive repeat specimen (one of the next two) as part of the definition. Hematuria from malignant causes is frequently intermittent.[48] Normal urine contains a small number of RBCs, usually too few to be detected by routine chemical dipstick testing or microscopic urinalysis. Population-based studies have found at least one episode of transient microscopic hematuria in 4% to 13% of individuals.

PATHOPHYSIOLOGY

Any process that results in infection, inflammation, or injury to the kidneys, ureters, bladder, prostate, male genitalia, or urethra may result in hematuria (**Tables 91-7 and 91-8**).[49]

In men >50 years old, tumors of the prostate or elsewhere in the ejaculatory system and benign prostatic hypertrophy are considerations when hematuria is present. In patients <40 years, common causes are infections and inflammatory conditions, including prostatitis, urethritis, sexually transmitted diseases, epididymo-orchitis, calculi with inflammation, and tuberculosis. Testicular tumors may occur in men younger than 50 years old.

False hematuria occurs when the urine appears bloody but dipstick test results are negative for blood and there are no RBCs on microscopic evaluation, or blood has been added to a previously blood-free specimen by the patient (**Table 91-9**). Free hemoglobin, myoglobin, or porphyrins in the urine result in a positive urine test strip reaction for blood.

CLINICAL FEATURES

A careful history, including information regarding sexual activity, recent urologic procedures, medications used, and HIV and tuberculosis risk factors, should be obtained. The patient's general health and condition, vital signs, abdomen, external genitalia, and prostate in males should be evaluated.

Initial hematuria is the appearance of blood at the beginning of micturition, with subsequent clearing, and suggests urethral disease including cancer. Gross hematuria more often indicates a lower tract cause.[26] In younger patients, microscopic hematuria is most often caused by nephrolithiasis or UTI.[26] In older patients, infections and nephrolithiasis remain common causes of hematuria; however, hematuria in patients >50 years old warrants follow-up because renal, bladder, and prostate cancer increase in frequency and may coexist with UTI or kidney stones.[46,48] Risk factors for uroepithelial cancer are age >50 years, male sex, smoking, family history of bladder cancer, occupational exposures in the chemical, rubber, or leather industries (e.g., exposure to dyes, benzenes, or aromatic amines), and excessive analgesic use.[46] Hematuria in a patient taking oral anticoagulants should not be attributed to the anticoagulant alone, because the incidence of underlying disease is up to 80% in patients referred to urology for evaluation.[46] Expanding abdominal aortic aneurysms may erode into the urogenital tract or cause inflammation or obstruction from direct pressure.

TABLE 91-7 Most Common Causes of Hematuria

Cause	Associated Age
Urinary tract infections	Any age
Nephrolithiasis	Usually >20 years
Neoplasms	Typically >50 years (except Wilms')
Benign prostatic hypertrophy	Males >40 years
Glomerulonephritis*	Mostly young patients and children
Schistosomiasis†	Any—underdeveloped country inhabitant

*See chapter 134, "Renal Emergencies in Children."

†See chapter 161, "Global Travelers."

  - Primary coagulopathy (e.g., hemophilia)
  - Pharmacologic anticoagulation
  - Sickle cell disease
- **Miscellaneous**
  - Eroding abdominal aortic aneurysm
  - Malignant hypertension
  - Loin pain–hematuria syndrome
  - Renal vein thrombosis
  - Exercise-induced hematuria
  - Cantharidin (Spanish fly) poisoning
  - Bites or stings by insects and reptiles having venom with anticoagulant properties

Abbreviation: NSAID = nonsteroidal anti-inflammatory drug.

TABLE 91-9 Causes of False Hematuria on Visual Inspection

Munchausen's syndrome, malingering, drug seeking
Patients may add blood to voided urine for secondary gain
Medications
NSAIDs, phenytoin, phenothiazines, quinine, rifampin, sulfasalazine, others
Foods and dyes
Beets, berries, rhubarb
Serratia marcescens infection
Amorphous urates
Hemoglobinuria, myoglobinuria, porphyrins

Abbreviation: NSAID = nonsteroidal anti-inflammatory drug.

Malignant hypertension, embolic renal infarction, and renal vein thrombosis are other serious diagnoses that can cause hematuria. In pregnancy, hematuria can be associated with UTI, nephrolithiasis, or pre-eclampsia. Recent instrumentation of the urinary tract may produce hematuria.

The reported incidence of hematuria in HIV-infected patients is 18% to 50%. Causes include UTI, chlamydial and gonococcal urethritis, glomerulonephritis, neurogenic bladder, thrombocytopenia, subclinical uroepithelial Kaposi's sarcoma, and urethral trauma. However, in up to 80% of patients, no specific cause is found.

The physical examination should note the vital signs and the patient's appearance. Hypertension and edema imply nephrotic syndrome. A new heart murmur (endocarditis) or atrial fibrillation increases the likelihood of embolic disease and renal infarction. A full genital-urinary examination is essential for both males and females. Systemic signs need to be correlated to potential diseases that cause hematuria (Table 91-8).

DIAGNOSIS

Potential causes of hematuria are often suggested by considering the patient's age, sex, demographic characteristics, habits, potential risk factors, history of recent GU instrumentation, and comorbidities.[48]

LABORATORY TESTING

A clean-catch midstream urine collection is appropriate for most patients. Catheter-collected specimens are recommended for women with a vaginal discharge or menstrual or vaginal bleeding; however, urethral catheterization induces hematuria in 15% of patients. Brown or smoke-colored urine, along with dysmorphic RBCs, cellular casts, and proteinuria, suggests a glomerular source.[48] Red, clotted blood in the urine indicates a source below the kidneys.

A urine dipstick test for blood can detect as little as 150 micrograms/L of free hemoglobin, corresponding to 5 to 20 intact RBCs/mL on microscopic analysis. False-negative results may be obtained with urine dipstick tests for blood if the urine has a high concentration of ascorbic acid (>5 milligrams/dL) or a high specific gravity. False-positive results occur in the presence of free hemoglobin, myoglobin, or porphyrins.

For patients with a clinical picture that does not provide a clear cause of hematuria on dipstick analysis (or indication for an urgent evaluation), urinalysis with microscopy should be performed to confirm hematuria before further work-up.[48] Hemorrhagic cystitis with invasive infection of the bladder wall by bacteria resulting in shedding and bleeding is a common cause of hematuria and resolves with appropriate antibiotic treatment.

For patients taking anticoagulants, obtain appropriate coagulation studies in the ED, with imaging at follow-up for older patients to exclude malignancy.

The finding of normal RBCs on microscopic examination of the urine together with bacteriuria and leukocytes in a young healthy patient supports UTI as the probable cause of hematuria. Additional laboratory studies may be needed depending on the results of the history, physical examination, and presumptive differential diagnosis. The presence of normal RBCs without evidence of infection should prompt further urologic evaluation to determine the site of bleeding; however, in stable patients without an urgent cause suggested by history and physical examination, an outpatient evaluation is appropriate.

TABLE 91-10 Risk Factors for Significant Disease in Patients with Microscopic Hematuria

Age >50 y
Male sex
History of gross hematuria
Smoking history
Occupational exposure to chemicals or dyes (benzenes or aromatic amines)
Analgesic abuse
History of pelvic irradiation
Cyclophosphamide use
Pregnancy
Known malignancy
Sickle cell disease
Renal insufficiency

IMAGING

Initial upper and lower urinary tract imaging for hematuria is now typically done with noncontrast helical CT or renal US.[48,50] Helical CT clearly delineates most renal tumors, obstructions, or stones and their precise location.[48,50]

Renal US is useful when screening for obstruction, hydronephrosis, or abdominal aortic aneurysm. It is the study of choice in pregnant patients with suspected nephrolithiasis. However, renal US rarely identifies or locates stones in the ureters that are not large enough to give findings of obstruction. Renal US also does not provide any assessment of renal function—normal enhancement and excretion of contrast by both kidneys. Helical CT with contrast provides this important information.

Gross hematuria in patients with blunt or penetrating trauma to the abdomen, flank, or back warrants an aggressive approach to identify the source of bleeding and to guide management (see chapter 265, "Genitourinary Trauma").[48]

TREATMENT, DISPOSITION, AND FOLLOW-UP

Treatment of hematuria is directed at the cause (Tables 91-7 and 91-8). Outpatient management and referral for follow-up are appropriate for patients in hemodynamically stable condition without an apparent life-threatening cause of the hematuria. The urgency for follow-up depends on the presence of gross hematuria or risk factors for significant disease (**Table 91-10**).[48,50] Patients with gross hematuria or listed significant risk factors should ideally be reevaluated at follow-up within 2 weeks.

The American Urological Association guideline recommends referral to urology to assess for urinary tract malignancy in all patients with microscopic hematuria without an obvious benign cause.[48,] Follow-up within 1 month is acceptable for patients with microscopic hematuria without significant risk factors.

Gross hematuria may lead to intravesical clot formation and bladder outlet obstruction. See chapter 92, "Acute Urinary Retention" for management.

Patients with intractable pain, intolerance of oral fluids and medications, significant comorbid illness, bladder outlet obstruction, evidence of hemodynamic instability, or possible life-threatening causes of hematuria should be admitted, and the appropriate specialist should be consulted.

PRACTICE GUIDELINES

Practice guidelines include those from the American Urological Association.[48]

CHAPTER 92

Acute Urinary Retention

David Hung-Tsang Yen
Chen-Hsen Lee

INTRODUCTION AND EPIDEMIOLOGY

Acute urinary retention is a common painful urologic emergency characterized by a sudden inability to pass urine, with lower abdominal distention or pain. Most patients with urinary retention are elderly men with benign prostatic hyperplasia.[1,2] The incidence and risk increase with age. There is a 20% recurrence within 6 months after an episode of urinary retention.[2] Few data are available for women. In men with spontaneous urinary retention, the mortality rate at 1 year increases from 4.1% in patients age 45 to 54 years to 32.8% in those age 85 years and older.[3]

PATHOPHYSIOLOGY

The voiding process, or micturition, involves the complex integration and coordination of high cortical neurologic (sympathetic, parasympathetic, and somatic) and muscular (detrusor and sphincter smooth muscle) functions. As the sensory impulse of bladder distention transmits to cortical centers, these areas of the brain smoothly coordinate voluntary urination. Continent urine storage in the bladder requires both relaxation of the detrusor muscle (through β-adrenergic stimulation and parasympathetic inhibition) and contraction of the bladder neck and internal sphincter (through α-adrenergic stimulation). The contraction of bladder detrusor muscle (by cholinergic muscarinic receptors) and relaxation of both the internal sphincter of bladder neck and the urethral sphincter (through α-adrenergic inhibition) contribute to smooth urination.[6]

Any causes that interfere with the neurologic control of the voiding process can result in voiding dysfunction. Urinary retention is the inability to void voluntarily despite a distended bladder and results from the dysfunction of the detrusor muscle and its coordination with the control of the bladder outlet. As bladder outlet obstruction progressively increases, the urine stream decreases in strength and size despite forceful and prolonged detrusor contraction. In chronic decompensation of urination, diminished detrusor muscle contractility is more pronounced, with a large amount of residual urine volume, compared to acute decompensation.

CLINICAL FEATURES

The causes of urinary retention (**Tables 92-1** to **92-3**) are categorized into several domains: obstructive, neurogenic, traumatic, infectious, operative, psychogenic, childhood, extraurinary, and pharmacologic.[4-7] A detailed history of the present illness and physical examination, especially the neurologic examination, supported by imaging and urodynamic studies, reveal the cause in the majority of patients.

The most common presentation is an elderly male with inability to void for several hours and lower abdominal distention or pain, secondary to benign prostatic hyperplasia.

TABLE 92-1 Gender-Specific Causes of Acute Urinary Obstruction

Men	Women
Obstructive Causes	**Obstructive Causes**
Benign prostatic hypertrophy*	Cystocele
Prostate cancer	Ovarian tumor
Phimosis	Uterine tumor
Paraphimosis	**Operative Causes**
Meatal stenosis	Incontinence surgery
Urethral strangulation	**Infectious Causes**
Infectious Causes	Pelvic inflammatory disease
Prostatitis	

*Most common cause.

TABLE 92-2 Causes of Acute Urinary Retention in Both Sexes

Obstructive Causes	**Extraurinary Causes**
Urethral stricture	Perirectal or pelvic abscesses
Bladder calculi	Rectal or retroperitoneal masses
Bladder neoplasm	Fecal impaction
Foreign body, urethral or bladder	Abdominal aortic aneurysm
Neurogenic Causes	**Psychogenic Causes**
Multiple sclerosis	Psychosexual stress
Parkinson's disease	Acute anxiety
Shy-Drager syndrome	**Infectious Causes**
Brain tumors	Cystitis
Cerebral vascular disease	Herpes simplex (genital)
Cauda equina syndrome	Herpes zoster involving pelvic region
Metastatic spinal cord lesions	Local abscess
Intervertebral disk herniation	**Operative Causes**
Neuropathy (diabetes, other causes)	Postoperative bleeding (clots)
Nerve injury from pelvic surgery	Epidural anesthesia
Postoperative retention	**Childhood Causes**
Traumatic Causes	Posterior urethral valves
Urethral injury	Rhabdomyosarcoma of the bladder
Bladder injury	Urethral atresia
Spinal cord injury	**Pharmacologic Agents (Table 92-3)**

Collect past medical history to look for a history of prostatism, prostate or urinary bladder cancer, bladder calculi, indwelling urethral catheter or injury to urethra, prostate surgery, or pelvic radiation therapy. Ask about history of urinary urgency, frequency, or hesitancy; decreased force and caliber of stream; terminal dribbling; nocturia; and incontinence (typically due to overflow phenomena). Gross hematuria may indicate infection, bladder calculi, or urinary tract neoplasm. A patient with urethral stricture may have a history of Foley catheter insertion, cystoscopy, trauma, or previous radiation therapy or infection. Collect any history of new medications, including common cold preparations, anticholinergics (including bronchodilators), sympathomimetic agents, and psychogenic and other potential agents (Table 92-3). Obtain a detailed neurologic history, looking for a causative lesion from high cortical function down to peripheral nerves that determine end-organ function. Identify possible spinal cord injury by determining recent activities including any remote trauma.

Fever, tachycardia, tachypnea, and hypotension suggest infection or sepsis. Hypertension or tachycardia may be transient and may resolve after bladder decompression. Consider urinary retention in patients complaining of lower abdominal pain, even if they do not offer urinary complaints. On abdominal examination, palpitate or percuss from the epigastric area to the lower abdomen to identify a painful mass (distended

TABLE 92-3 Pharmacologic Agents Associated with Urinary Retention

α-Adrenergic agents	Carbamazepine
Amphetamines	Decongestants
Androgens	Estrogens
Anesthesia agents	Hydralazine
Anticholinergics	Muscle relaxants
Antihistamines	Nonsteroidal anti-inflammatory drugs
Antiparkinsonian agents	Opiates
Antipsychotic agents	Progesterones
Antispasmodics	Selective serotonin reuptake inhibitors
Benzodiazepines	Tetracyclic antidepressants
β-Adrenergic agents	Tricyclic antidepressants
Calcium channel blockers	

bladder) in the lean patient. Examine the external genitalia to identify phimosis, paraphimosis, meatal stenosis or stricture, or evidence of urethral or penile trauma.

Perform digital rectal examination (either before or after relief of obstruction, depending on patient comfort) to evaluate the anal-rectal area and prostate, assessing anal tone, perineal sensation, prostate enlargement, stool impaction, and any possibility of malignancy. A nodular or rock-hard prostate may suggest prostate cancer, which must be confirmed at a later date. Women with urinary retention should receive a pelvic examination to detect possible inflammatory lesions or pelvic or adnexal masses. Perform a neurologic examination to determine any neurogenic cause. After successful drainage of the distended bladder, a repeat physical examination of the lower abdomen is indicated to help exclude an unresolved extraurinary bladder problem (e.g., appendicitis) needing further management.

DIAGNOSIS

Bedside US can easily identify urinary retention. However, the need for further diagnostic tests will depend on the nature of the clinical presentation, precipitating factors, and the patient's comorbidities. Obtain a urine culture to identify urinary tract infection. Hematuria secondary to the physical trauma of catheter insertion that clears over time is common (see chapter 91, "Urinary Tract Infections and Hematuria"). A CBC should be checked for patients with suspected severe infection, massive hematuria with possible hypovolemia, or hematologic diseases. Prolonged obstruction may result in impaired renal function and electrolyte imbalance, so obtain renal function studies and serum electrolytes. Formal abdominal US or CT may be indicated to identify pelvic or abdominal masses, bladder stones, or hydronephrosis, but are not routinely needed if symptoms resolve after catheter placement. Neuroimaging or spinal imaging is needed if examination identifies neurologic deficits. Cystourethrography may be required eventually to evaluate the pathology in the lower urinary tract; however, this is not an ED procedure.

TREATMENT

The goal of ED management is outlined in **Table 92-4**. Bladder decompression is by urethral or suprapubic catheterization. Difficult catheterization in males can result from urethral stricture, prostatic enlargement, or postsurgical bladder neck contractures. **If the patient recently underwent urologic surgery (e.g., radical prostatectomy or complex urethral reconstruction), consult the urologist before attempts at catheter placement.**

TABLE 92-4 Steps in Evaluation and Management of Acute Urinary Retention

Recognition	Recognize a patient with possible acute urinary retention.
Initial assessment	Obtain complete history and physical examination to identify underlying diseases and precipitating factors: obstructive, pharmacologic, infectious, neurogenic, traumatic, childhood, or psychogenic causes. Assess bladder volume with bedside US.
Initial stabilization	Place a urethral or suprapubic catheter.
Risk assessment	Assess for risk of recurrence, need for surgical intervention, and morbidity: age, severity of clinical presentation, causes, comorbidity, prostate size, postvoid residual, and maximum urine flow rate.
Need for inpatient care	Admit for treatment of significant underlying medical illness or precipitating factors. Consider malignancy, spinal cord compression or injury, unresolved hematuria, or urinary tract infection with possible sepsis.
Need for urologic consultation	Discuss with urology consultant in the event of urethral stricture, meatal stenosis, urethral injury, suspected prostate cancer, acute prostatitis, or urologic postoperative complications.
Outpatient management	Acute urinary retention without significant comorbidities and without evidence of complications, such as bleeding, infection, or renal function impairment: discharge with Foley catheter, leg bag, α-adrenergic receptor blocker, (i.e., alfuzosin, 10 milligrams daily, or tamsulosin, 0.4 milligram daily) and follow up with urology in 3–7 d.

URETHRAL CATHETERIZATION TECHNIQUE

Most catheters are made of latex, but silicone catheters are available for patients with latex allergy. The retrograde injection of 10 to 15 mL of water-soluble anesthetic lubricant (e.g., 2% lidocaine jelly) 5 to 10 minutes before inserting the catheter can alleviate patient discomfort (**Figure 92-1**). Retract the foreskin when inserting the catheter, and remember to reduce the foreskin once the catheter is in place. The catheter is in place when urine is freely draining. Do not inflate the retention balloon until urine begins to flow through the catheter into the clear extension tube. **The urethra can be injured from inflation of the retention balloon within the urethra.** If the catheter balloon is inflated in the prostatic urethra and not the bladder, urine may or may not drain freely, and balloon inflation causes extreme pain[8] (**Figure 92-2**). Forceful attempts at catheter removal with the balloon still inflated can cause edema and tears to the urethra.

If attempts at passage of a straight 14- to 18-French Foley catheter fail, use a firm angulated coudé catheter, positioned so the tip points anteriorly. The curved tip adjusts to the course of the prostatic urethra. A modification of the standard catheterization technique was reported in a small convenience sample, using US guidance while applying transrectal pressure to help smooth out the course of the prostatic urethra and simultaneously gently advancing the catheter.[9] Applying this technique requires two healthcare providers—one using US and applying rectal pressure, and another advancing the catheter.

During insertion, a false lumen can be created, or the catheter may kink in the urethra, especially in patients with underlying urethral strictures or prostate enlargement. Consult urology for management. If catheterization produces gross blood, deflate the balloon, remove the catheter, and do not attempt reinsertion because a false passage (through the penile soft tissue instead of the urethra) may have been produced. Management may require urology consultation for the use of a guidewire, flexible filiforms, and dilation followers for progressive dilation of the urethra to place a catheter.

SUPRAPUBIC CATHETERIZATION TECHNIQUE

Suprapubic catheterization can be performed in patients after failure of several attempts of urethral catheterization and as long as there is no obvious pelvic trauma or abnormal anatomy in the lower abdomen. This may be the only option to decompress an extremely painful, distended bladder when urethral catheterization is not possible. US-guided suprapubic catheterization has a low complication rate.[10] Prepare the suprapubic area with betadine and local anesthesia. Visualize the distended bladder with US. While monitoring with US, advance a 22-gauge spinal needle with 10-mL syringe posteriorly and caudally at a 30-degree angle from the true vertical and 60 degrees from the horizontal plane of the abdomen, 3 to 4 cm above the pubic symphysis in the midline. Advance the needle while withdrawing on the syringe. US visualization of the needle in the bladder and urine return indicates correct placement. Use the depth and position of this attempt to direct the placement of the obturator. Make a small skin incision in the midline at the point of prior needle removal. The cystostomy catheter and obturator assembly are then placed in similar manner as the spinal needle, again aspirating for urine (**Figures 92-3** and **92-4**).

After inflating the retention balloon, withdraw the obturator and leave the catheter in the bladder. Secure the catheter with a suture. If a guidewire is used for catheter insertion, remove the pull-apart sheath after successful bladder placement.

POSTCATHETERIZATION CARE

Patients with long-standing obstruction are at risk for postobstructive diuresis and postobstructive renal failure. Monitor for 4 hours minimum for significant hourly urinary output (>200 mL/h over input)

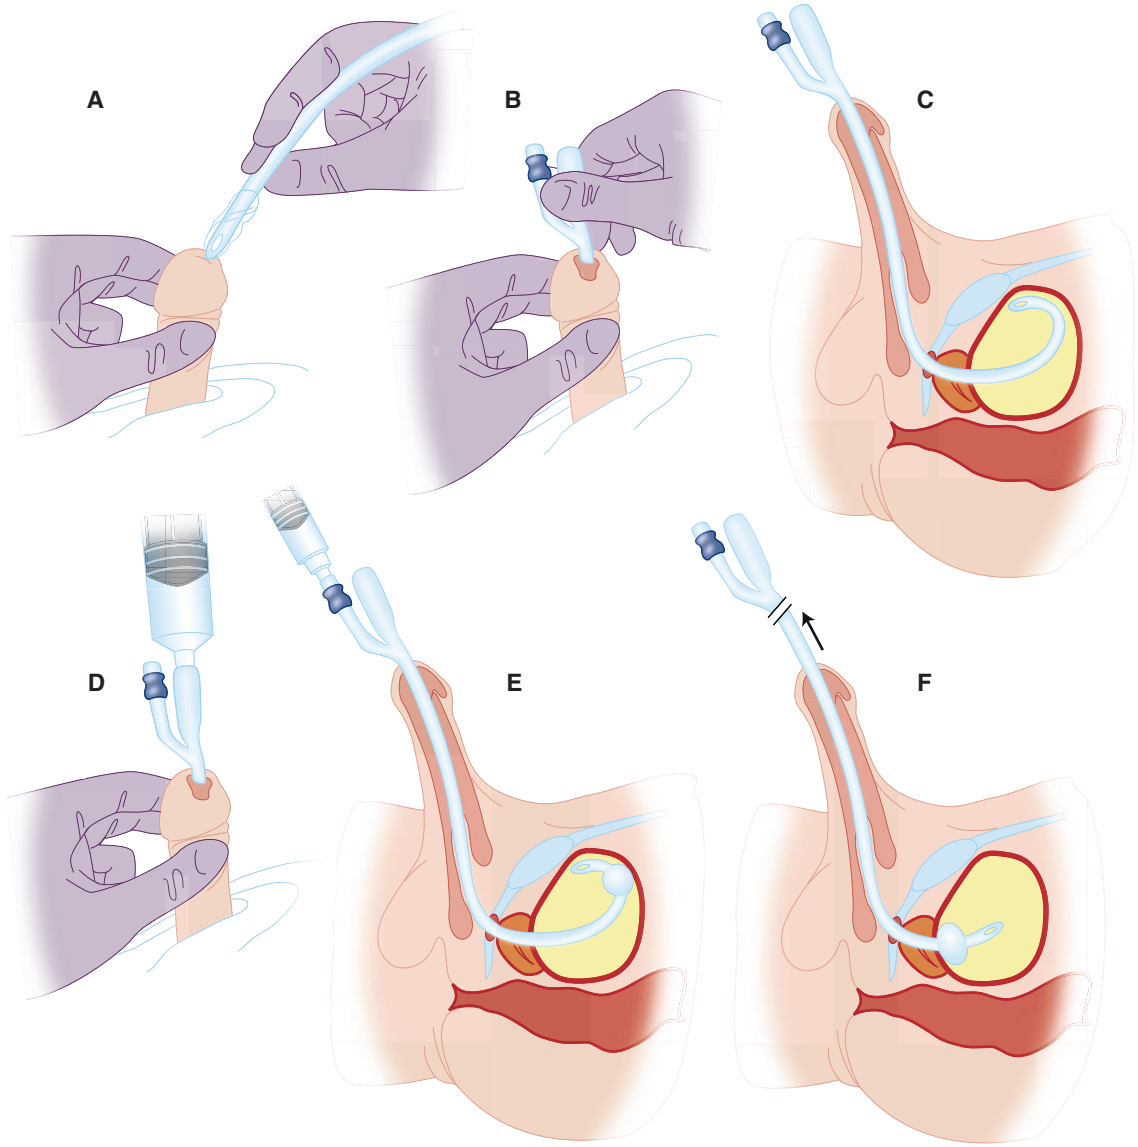

FIGURE 92-1. Urethral catheter insertion. **A.** Insert the lubricated catheter into the urethra. **B.** Advance the catheter until the ports are at the meatus. **C.** Cross-section of the male pelvis showing the distal catheter and cuff positioned within the bladder. **D.** Urine aspiration confirms proper placement of the catheter. **E.** If urine is flowing freely, inflate the balloon at the tip of the catheter. **F.** Gently withdraw the catheter to lodge the cuff against the bladder neck. after initial return. If this degree of output continues, admit the patient with volume replacement adjusted hourly according to urine output. Patients with significant elevations of BUN or creatinine should be admitted. Patients should be reassessed after Foley insertion for resolution of symptoms.

Routine use of antibiotics for the prevention of bacteriuria or for the treatment of asymptomatic bacteriuria is not suggested. Antibiotics are reserved for symptomatic urinary tract infection[4] (see chapter 95, "Complications of Urologic Procedures and Devices").

Pharmacologic therapy with an α-adrenergic receptor blocker, which exerts its effects on the bladder neck and prostate, may relax bladder smooth muscle, reducing outlet resistance to urinary flow (**Table 92-4**). α-Adrenergic blockers such as alfuzosin, 10 milligrams daily, or tamsulosin, 0.4 milligram daily, increase the success of spontaneous voiding after the catheter is removed.[11] Warn patients, especially the elderly, about possible postural hypotension. α-Adrenergic blockers may also shorten the interval of time before a successful voiding trial and prevent recurrent episodes.[12]

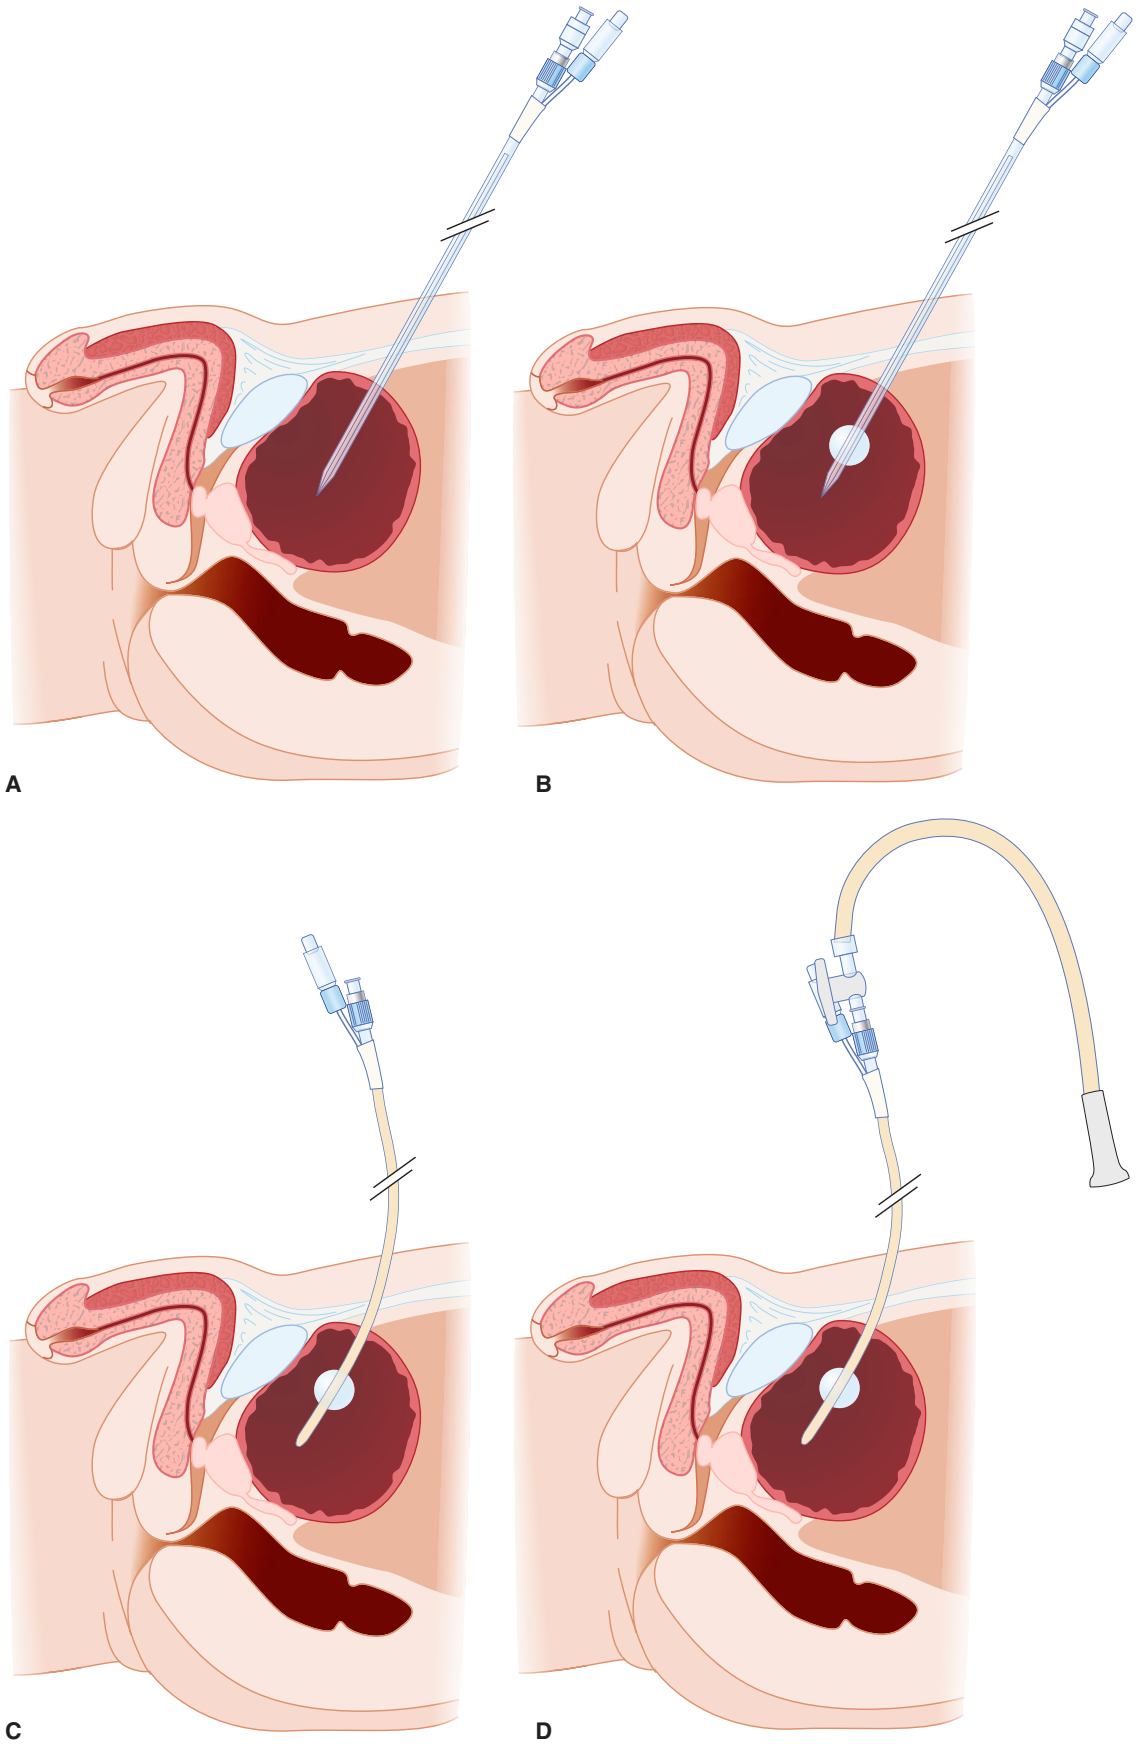

FIGURE 92-3. The obturator technique. **A.** The obturator is within the catheter. The system is inserted 60 degrees to the skin and advanced into the bladder. **B.** The balloon is inflated. **C.** The obturator is removed while the catheter remains within the bladder. **D.** The collecting tube is attached to the catheter. DISPOSITION AND FOLLOW-UP

The majority of patients with urinary retention are discharged home with a catheter connected to a leg bag and wait for further surgical intervention after the urology clinic visit. Patients should be educated in Foley catheter care and bag drainage and given a list of alarm symptoms that should prompt return to the ED. These include fever, return of symptoms, repeated vomiting, abdominal pain, catheter blockage, or penile pain. Penile pain suggests migration of the balloon into the proximal urethra. Feelings of urgency or bladder spasm can be treated with oxybutynin, 2.5 milligrams PO two or three times a day. Oxybutynin has anticholinergic properties and can cause the same adverse effects as any anticholinergic agent. There is no satisfactory treatment for urinary leakage around the catheter. Placement of a larger catheter is not typically effective.

α-Adrenergic blockers can be prescribed as needed (Table 92-4). Recommend urology follow-up within 3 to 7 days. A longer period of Foley drainage is encouraged in patients with retention volumes >1.3 L to improve chances of successful voiding. The serum prostate-specific antigen assay and long-term use of a 5α-reductase inhibitor could be evaluated at urology follow-up.

For precipitated urinary retention, remove the catheter in the ED and allow a voiding trial. Discontinue offending medications. Patients with clot retention, hematuria and coagulopathy, sepsis, possible neurologic cause of urinary retention, or other significant comorbidities should be admitted.[12]

SPECIAL CONSIDERATIONS

FEMALES WITH URINARY RETENTION

Urinary retention in women is uncommon. The obstructive causes of urinary retention in women are usually related to gynecologic problems (Table 93-1), but neurogenic causes can develop in both men and women.[13]

The management of urinary retention in females involves catheterization and attending to any treatable cause. The ideal selection of catheterization method, including in and out catheterization, short-term indwelling urethral catheter followed by a trial of voiding, or clean intermittent self-catheterization, depends on the clinical assessment of precipitating factors and underlying conditions. α-Adrenergic blockers do not appear to be helpful in women with urinary retention. If there is no apparent cause, refer to a gynecologic urologist for urodynamic studies.[13]

GROSS HEMATURIA AND CLOT RETENTION

Gross hematuria can lead to clot retention, resulting in pain and hypertension and tachycardia from acute bladder distention. Management of gross hematuria is placement of a 20- to 24-French triple-lumen catheter (one port for urine drainage, one port for balloon inflation, one port for bladder irrigation) and irrigation with saline until clear to evacuate clots.[14] Patients with clot retention may require admission, because clot retention may reoccur and may require cystoscopic clot removal. Patients with gross hematuria from coagulopathy (i.e., warfarin) should have clotting parameters corrected as appropriate and be admitted.

POSTOPERATIVE URINARY RETENTION

Treatment is discussed in chapter 87, "Complications of General Surgical Procedures." For patients with retention after GU or pelvic procedures, consult with the operating surgeon. Otherwise, for patients with normal renal function and no obstruction, bladder catheterization to relieve symptoms and then removal of the catheter and a trial of voiding are usually all that is necessary.

CHAPTER 93

Male Genital Problems

Jonathan E. Davis

INTRODUCTION

This chapter reviews the common acute infectious and structural or anatomic GU disorders. There are five GU emergencies: testicular torsion, Fournier's gangrene, paraphimosis, priapism, and significant GU trauma (see chapter 265, "Genitourinary Trauma"). Related emergencies include strangulated inguinal hernia (see chapter 84, "Hernias") and ruptured abdominal aortic aneurysm (see chapter 60, "Aneurysmal Disease"), which may present with scrotal pain.

ANATOMY

PENIS

Three cylindrical bodies—the corpus spongiosum, which surrounds the urethra, and the paired corpora cavernosa—form the shaft of the penis (**Figure 93-1**). The corpora cavernosa are the major erectile bodies,

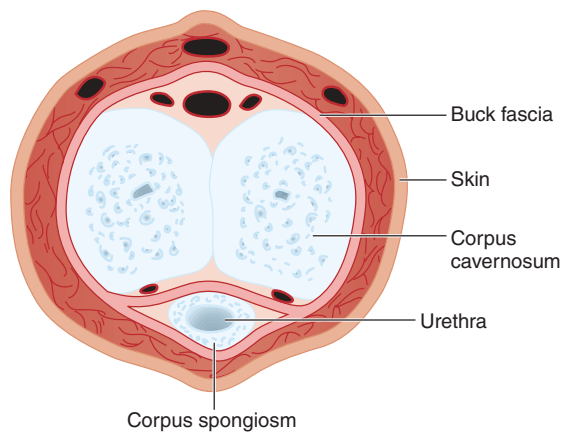

FIGURE 93-1. Cross-section of the penis.

extending distally from the pubic rami and capped by the glans penis. These cylindrical structures are encased in a thick tunic of dense connective tissue, the tunica albuginea. External to the tunica albuginea is Buck's fascia, which fuses with Colles' fascia at the level of the urogenital diaphragm. The internal pudendal artery provides the blood supply, which branches to form the deep and superficial penile arteries. Lymphatics drain from the penis into the deep and superficial inguinal nodes.

SCROTUM

The prepubertal scrotal skin is thin and thickens with subsequent hormonal stimulation during puberty. Immediately beneath the skin are the smooth muscle and elastic tissue layers of Dartos' fascia, similar to the superficial fatty layer (Camper's fascia) of the abdominal wall. The deep membranous layer (Scarpa's fascia) of the abdominal wall extends into the perineum, where it is referred to as *Colles' fascia*, and forms part of the scrotal wall (**Figure 93-2**). The blood supply is derived primarily from branches of the femoral and internal pudendal arteries. Lymphatics from the scrotum drain into the inguinal and femoral nodes.

TESTES

The testes average in size between 4 and 5 cm in length and 3 cm in width and depth, and usually lie in an upright position, with the superior portion tipped slightly forward and outward. Each testis is encased in a thick fibrous tunica albuginea except posterolaterally, where it is in tight apposition with the epididymis. The enveloping tunica vaginalis covers the anterior and lateral aspects of the testes and attaches to the posterior scrotal wall. Superiorly, the testes are suspended from the spermatic cord; inferiorly, the testis is anchored to the scrotum by the scrotal ligament (gubernaculum). Maldevelopment with lack of firm posterior fixation of the tunica vaginalis leaves the testes and epididymis at risk for torsion about the spermatic cord. The posterior (visceral) leaf of the tunica vaginalis is adherent with the tunica albuginea of the anterior testicular surface. A potential space exists between this visceral leaf and the anterior (parietal) tunica vaginalis. Any traumatic or inflammatory event can impede the normal parietal tunica vaginalis from absorbing viscerally secreted fluid, resulting in hydrocele formation anterior to the testes (**Figure 93-3**). Hematocele results from accumulation of blood in the potential space.

The internal spermatic and external spermatic arteries provide the blood supply, traveling together in the spermatic cord. Venous return is primarily by the internal spermatic, epigastric, internal circumflex, and scrotal veins. The lymphatics drain toward the external, common iliac, and periaortic nodes.

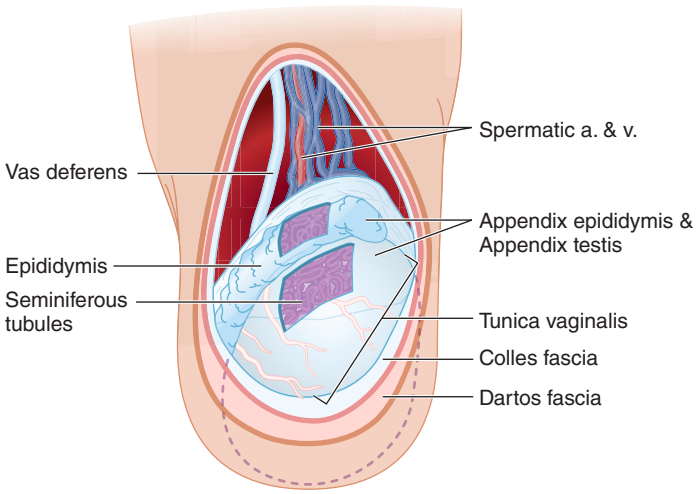

FIGURE 93-2. Anatomy of the scrotum and the testis. a. = artery; v. = vein.

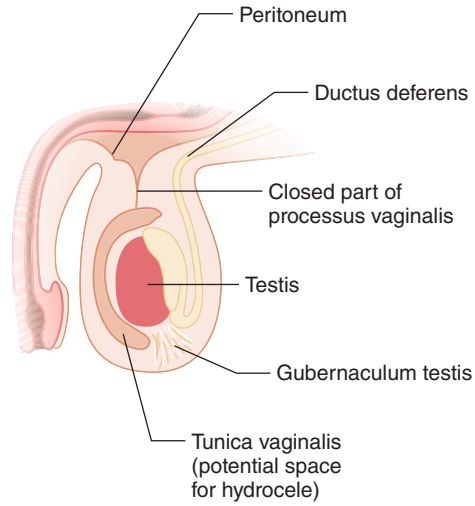

FIGURE 93-3. Embryonic retroperitoneal testis descends into the scrotum and invaginates into the tunica vaginalis, which anchors it to the posterior scrotal wall. Note the potential space in the tunica vaginalis for development of a hydrocele.

EPIDIDYMIS AND VAS DEFERENS

The epididymis is a single, fine, tubular structure approximately 4 to 5 m long compressed into an area of about 5 cm. It serves to promote sperm maturation and motility. Vestigial embryonic structures, the appendix epididymis and the appendix testis, which have no known physiologic function, are often associated with the testes and epididymis. The appendix epididymis is found attached to the head of the epididymis, or globus major. The appendix testis, a pear-shaped structure, is usually situated on the uppermost portion of the testis at the junction of the testis and the globus major of the epididymis, although anatomic variation exists.

The vas deferens is a distinct muscular tube that is easily palpable within the scrotal sac. It extends cephalad in the spermatic cord from the tail of the epididymis (globus minor), traverses the inguinal canal, and crosses medially behind the bladder over the ureters to form the ampullae of the vas, where it joins with the seminal vesicles to form the paired ejaculatory ducts in the prostatic urethra.

PROSTATE

The prostate originates from the urogenital sinus at approximately the third month of embryonic life. It is continually enlarging and, in the young male, is often not definable on rectal examination. As a man matures, the prostate may enlarge dramatically, resulting in significant bladder outlet obstruction. The anterior, median, posterior, and lateral lobes define the divisions of the prostate.

PHYSICAL EXAMINATION

The GU examination should be performed with the male patient in both the supine and upright positions in a well-illuminated, warm room if feasible. In uncircumcised males, fully retract the foreskin to inspect the glans, coronal sulcus, and preputial (foreskin) areas for ulceration or lesions. Note the location of the urethral meatus and presence of discharge. Replace the foreskin to its native position following examination to prevent iatrogenic paraphimosis. Carefully palpate the penile shaft for skin or subcutaneous lesions.

Testicular nodularity or firmness should be considered carcinoma until proven otherwise. The epididymis usually lies on the posterolateral aspect of the testis and has a soft, fleshy feel similar to that of the earlobe. Many males experience pain and tenderness with palpation of a normal globus major (head), body, and globus minor (tail) of the epididymis. Males experience some discomfort during palpation of a normal prostate, and a lateral supine position helps prevent an infrequent vasovagal response.

The prostate has a heart-shaped contour, with its apex located more distally, abutting the urogenital diaphragm. The consistency of the normal prostate has the same resiliency as the cartilaginous tip of the nose, whereas suspicious carcinogenic areas feel more like the bony prominence of the chin. The posterior lobe is small and thin, allowing palpation of the median raphe that distinguishes the two lateral lobes. A rectal prostate examination cannot assess the anterior or median lobes. The seminal vesicles, lying just superior to the prostate, cannot normally be distinguished unless there is inflammation, induration, or enlargement.

Examination of the inguinal canals for hernias and the scrotal spermatic cords for varicoceles is best done in the upright position, with the patient straining at the designated time. When the patient is upright, it should be determined whether the testes are aligned along a vertical or horizontal axis. Horizontally aligned testes are at greater risk for torsion. Likewise, an elevated, horizontally aligned testis may be the result of torsion.

DISORDERS OF THE SCROTUM

An acute scrotum is defined as acute pain or painful swelling of the scrotum or its contents, accompanied by local signs or general symptoms. Testicular torsion and Fournier's gangrene are the most time-sensitive diagnoses of the acute scrotum; the first priority in the evaluation of patients with scrotal pain is differentiation these life- or testicular-threatening disorders from other entities.

SCROTAL EDEMA

Insect bites, human bites, and contact dermatitis may cause scrotal edema, or it may be idiopathic in young boys.[1] In the setting of hypoalbuminemia, or anasarca from any cause, contiguous scrotal and penile edema may occur. Idiopathic scrotal edema presents as unilateral or bilateral pain with scrotal, perineal, and inguinal swelling and erythema in boys between 3 and 9 years of age. US findings include an easily compressible thickened scrotal wall (mean 11.2 mm), increased peritesticular blood flow, and in some cases, a reactive hydrocele.[2,3] Episodes resolve in 1 to 4 days with scrotal elevation, rest, and nonsteroidal anti-inflammatory drugs, although recurrences occur.[4] Antibiotics are sometimes used, but are not typically needed unless fever, increased warmth, or purulence is noted.

SCROTAL ABSCESS

Management of a scrotal abscess depends on its depth. In the case of a simple hair follicle abscess, the phlegmon is localized to the scrotal wall. A superficial abscess should be differentiated from a deeper abscess involving or originating from infection in one of the primary intrascrotal organs (i.e., testis, epididymis, or bulbous urethra). This distinction is difficult late in the course of the infection when a general scrotal mass may be the only physical finding. US can determine contiguous involvement of an inflammatory mass in the testis or epididymis with the scrotal skin. When in question, a retrograde urethrogram will delineate the integrity of the urethra.

A simple hair follicle scrotal wall abscess is managed by incision and drainage. Frequently, wound care can be simplified by circumferential excision of the entire roof of the abscess. This allows access for wound care and sitz baths and assures healing from the base outward.[1] Antibiotics are rarely needed in an immunocompetent male unless there are signs of cellulitis or systemic involvement. Definitive care of deep-seated or complex abscesses require consultation with urology.

FOURNIER'S GANGRENE

Fournier's gangrene is a polymicrobial, synergistic, infective necrotizing fasciitis of the perineal, genital, or perianal anatomy. This process typically begins as a benign infection or simple abscess that quickly becomes virulent, especially in an immunocompromised host, and results in microthrombosis of the small subcutaneous vessels, leading to the development of gangrene of the overlying skin. (**Figure 93-4**).[5]

FIGURE 93-4. A patient with Fournier's gangrene of the scrotum. Note the sharp demarcation of gangrenous changes (black portion) and the marked edema of the scrotum and the penis.

Patients with diabetes and alcohol abuse are disproportionately affected with Fournier's gangrene.[6] Mortality rates have varied from 3% to 67%,[7] but contemporary estimates range from 20% to 40%.[8-13] Age over 60 and complications during treatment are the most important predictors of death.[12,13]

In advanced Fournier's gangrene, the local signs and symptoms are usually dramatic, with marked pain and swelling. Crepitus and ecchymosis of the inflamed tissues are common features. Prompt recognition of Fournier's gangrene in its early stages may prevent extensive tissue loss that accompanies delayed diagnosis or treatment. Treat with aggressive fluid resuscitation, gram-positive, gram-negative, and anaerobic antibiotic coverage (see also chapter 151, "Sepsis"). Recommended agents include piperacillin-tazobactam, 3.375 to 4.5 grams IV every 6 hours, or imipenem, 1 gram IV every 24 hours, or meropenem, 500 milligrams to 1 gram IV every 8 hours, plus vancomycin.[7-9] Urgent urologic consultation is required for wide surgical debridement.[7] The addition of clindamycin, 600 to 900 milligrams IV every 8 hours, or metronidazole, 1 gram IV, then 500 milligrams IV every 8 hours, to the antimicrobial regimen may be of benefit.[7] Hyperbaric oxygen therapy in the pre- and postoperative setting is a treatment option but does not improve mortality.[14] Admission to the intensive care unit postoperatively is typically required.[7]

DISORDERS OF THE PENIS

Ischemic priapism, paraphimosis, and entrapment injuries are priority diagnoses that, if left untreated, can result in necrosis of the penis.

BALANOPOSTHITIS

Balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin), and balanoposthitis (inflammation of the glans and the foreskin) are primarily caused by inadequate hygiene or external irritation with subsequent colonization with *Candida* species, *Staphylococcus* species, *Streptococcus* species,[15] and less commonly, *Mycoplasma genialium*.[16] Infections are frequently mixed flora.[15] On examination, when foreskin retraction is attempted, the glans and apposing prepuce appear purulent, excoriated, malodorous, and tender. **Balanoposthitis can be the sole presenting sign of diabetes.**[17] Consider *Candida*, *Gardnerella*, and anaerobes as potential causes.[15] Treatment consists of cleansing the area with saline, ensuring adequate dryness after cleaning, application of antifungal creams (nystatin or clotrimazole), treatment with an oral

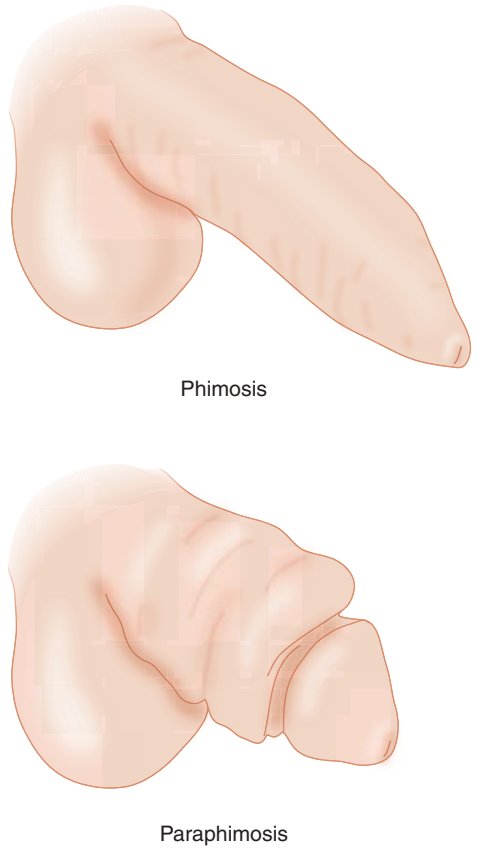

FIGURE 93-5. Phimosis and paraphimosis.

azole in severe cases (fluconazole 150 milligrams orally), and circumcision for recurrent cases.[15] Soap may increase inflammation during the acute phase, but routine hygiene is essential to prevent reoccurrence. Bacterial infection is suggested by warmth, erythema, and edema of the glans, foreskin, and penile shaft; anaerobic organism is suggested by foul smell.[15] If these signs are present, oral clindamycin, 300 milligrams three times per day for 7 days, or metronidazole, 500 milligrams two time per day for 7 days, is recommended.[15,18] Cases that persist warrant culture for potential infective causes or biopsy and follow-up with urology.

PHIMOSIS

Phimosis is the inability to retract the foreskin proximally and posterior to the glans penis (**Figure 93-5**). Physiologic phimosis occurs naturally in uncircumcised newborns. By 3 years of age, fewer than 10% of foreskins remain nonretractile, with nearly all becoming retractile by late adolescence. Infection, poor hygiene, and previous preputial injuries with scarring are common causes of pathologic phimosis. Scarring at the tip of the foreskin can occlude the preputial meatus, infrequently causing urinary retention. Hemostatic dilation of the preputial ostium will temporarily relieve the urinary retention. Circumcision is curative. Alternatively, topical steroid treatment (such as betamethasone, 0.05% to 0.10% twice daily) applied from the tip of the foreskin to the glandis corona for 1 to 2 months, along with daily manual preputial retraction, has been shown to be an effective nonsurgical management option for phimosis.[19]

PARAPHIMOSIS

Paraphimosis, a true urologic emergency, is the inability to reduce the proximal edematous foreskin distally over the glans penis into its natural position (Figure 93-5). The resulting glans edema and venous engorgement can progress to arterial compromise and gangrene.

Paraphimosis can often be reduced by compression of the glans for several minutes to reduce edema and allow for successful reduction of the now smaller glans through the foreskin. **Tightly wrapping the glans with a 2-inch elastic bandage for 5 minutes will reduce edema.** A local anesthetic block of the penis can help the patient tolerate the pain of compression but also adds fluid to an already swollen penis. The patient may require an anxiolytic before the injection of a "ring" of local anesthetic at the base of the penis. If these methods are unsuccessful, local infiltration of the constricting band with 1% lidocaine without epinephrine followed by superficial dorsal incision of the band will allow foreskin reduction.[20] Use of an iris scissor may help prevent damage to underlying tissue. The examining provider should perform this procedure in cases of impaired perfusion to the glans, unless a urologist is immediately available.

ENTRAPMENT INJURIES

Circumferential objects surrounding the penis can occlude the veins and, subsequently, the arterial blood supply. Hair, string, metal rings, and wire have been wrapped around the penis for accidental, experimental, or sexual reasons. Removing the offending object requires care and ingenuity.[21] Removal techniques include compression and cooling the penis, cutting the object, and urologic surgical removal.[21] Lubrication with petroleum jelly may assist. Ice packs can help decrease inflammation and edema, but take care to avoid cooling injury. The compression technique uses the same modified string method recommended for removing finger rings, with the addition of inserting an 18-gauge needle into the end of one of the two corpora cavernosa through the glans to allow edema and blood to be pushed out by the proximal to distal compression of the penis. Start by inserting the short end of the tape under the constriction device to be left proximally, while the long end is used to compress the penis winding in a proximal to distal direction.[21] Cutting devices can remove penile rings. Protect underlying skin with a hard object, preferably metal. Also avoid overheating the surrounding tissues. Urologic consultation may be required depending on the entrapment complexity and physiologic concerns.[21]

The **penile hair-tourniquet syndrome** (**Figure 93-6**) seen in young males presents with swelling of the glans. The offending hair may be

FIGURE 93-6. Hair is entrapped behind the coronal sulcus (*arrow*), constricting and progressively amputating the glans.

invisible within the edematous coronal sulcus. Several common techniques for removal consist of unwinding the hair, lancing the hair when easily accessible, or surgical removal when circumferential edema prevents access to the constricting source.[22]

Another common entrapment injury is penile or scrotal entrapment in a zipper. The reported interventions include dismantling the zipper with wire cutters or trauma shears and surgical interventions like circumcision. First, cleanse the affected area with povidone-iodine and provide local anesthesia with 1% to 2% lidocaine. Next, try coating the zipper and affected area with mineral oil or other nontoxic lubricant. If this does not free the zipper, cut the zipper away from clothing to make the zipper easier to handle. Next, try cutting the sliding bar of the zipper and the zipper teeth.[23] The bottom bar of the zipper apparatus can also be cut and then unzipped from below.

FRACTURE OF THE PENIS

A penile fracture occurs when the tunica albuginea of one or both corpus cavernosa ruptures due to direct trauma to the erect penis.[24] It can be associated with partial or complete urethral rupture (18%) or deep dorsal vein injury.[24] The most common cause is sexual intercourse, but other causes include animal bites, stabbing, bullet wounds, and self-mutilation.[24,25] On examination, the penis is acutely swollen but flaccid, discolored, and tender. A retrograde urethrogram may be necessary to assure urethral integrity, but radiologic evaluation rarely influences surgical managment.[25] Surgical treatment consists of hematoma evacuation and suture apposition of the disrupted tunica albuginea.

PEYRONIE'S DISEASE

Peyronie's disease produces progressive penile deformity, typically curvature with erections, that is painful and may result in erectile dysfunction or preclude successful vaginal penetration during intercourse.[26] Examination of the penile shaft will disclose a thickened plaque, typically on the dorsum, involving the tunica albuginea of the corpora bodies. Urologic referral is warranted. Peyronie's disease of the penis has been noted in association with Dupuytren's contractures of the hand.

PRIAPISM

Priapism is a urologic emergency that is characterized by persistent, usually painful, pathologic erection in which both corpora cavernosa are engorged with stagnant blood.[27] Even though the glans penis and the corpus spongiosum are characteristically soft and uninvolved, urinary retention may develop. Impotence can result in 35% of cases with sustained erections for prolonged periods, so emergency urologic consultation is needed.

Many cases of priapism in adults are pharmacologically related to intracavernosal injection of vasoactive substances for impotence (papaverine, prostaglandin E_1), use of oral agents for hypertension (hydralazine, prazosin, calcium channel blockers), neuroleptic medications (chlorpromazine, trazodone, thioridazine), or oral agents related to erectile dysfunction.[27] Most cases of priapism in children are due to hematologic disorders, usually sickle cell disease.

Priapism is classified into high-flow (nonischemic) priapism and low-flow (ischemic) priapism. High-flow (nonischemic) priapism is rare, most often painless, and usually results from traumatic fistulae between the cavernosal artery and the corpus cavernosum. Blood gas analysis of the first corporal aspirate is recommended to differentiate arterial (high-flow) from ischemic priapism.[27] High-flow priapism may be further delineated by color Doppler US and is treated by embolization. Low-flow (ischemic) priapism is more common, is usually quite painful, and is diagnosed by the aspiration of dark acidic intracavernosal blood from the corpus cavernosum.

Provide adequate narcotic analgesia. Corporal aspiration followed by irrigation (with plain saline or α-adrenergic agonists [i.e., phenylephrine]) is the primary treatment method for persistent priapism. The urologic consultant usually performs this procedure, but if one is not readily available, the examining provider may need to intervene. On each lateral side of the proximal penis, raise a wheal with 1% lidocaine using a 27-gauge needle. After local anesthesia, insert a 19-gauge butterfly needle into the corpora cavernosa on each side, approximately 0.5 cm deep. The needle must penetrate the skin, subcutaneous tissue, and the tunica albuginea in order to enter the corpus cavernosum. The needles can be supported in place by using a combination of small gauze pads on either side of the "butterfly wings" and roller gauze around the penis to secure its position. Aspirate blood from each side.[27] If medical treatment or phenylephrine irrigation fails to produce detumescence, surgery may be required.[27] If priapism due to sickle cell crisis fails to respond to adequate analgesia and hydration, consult both urology and hematology. The role of exchange transfusion has been reexamined; penile aspiration and irrigation, with or without instillation of α- or β-adrenergic agonists, is recommended for acute ischemic episodes in sickle cell patients.[28]

PENILE CARCINOMA

Carcinoma of the penis is rare, usually appearing in the fifth or sixth decade in an uncircumcised male. Carcinoma may appear as a nontender ulcer or warty growth beneath the foreskin in the area of the coronal sulcus or glans penis and is often hidden by an inflamed phimotic foreskin.

DISORDERS OF THE TESTES AND EPIDIDYMIS

TESTICULAR TORSION

The differential diagnosis of acute scrotal pain includes testicular torsion, torsion of the testicular appendages, epididymitis, incarcerated hernia, and trauma, among others. Frequent causes of acute scrotal pain include testicular torsion or epididymitis in adults, with the added possibility of appendage torsion in children (**Table 93-1**). Because of the potential for infarction and infertility, testicular torsion must be the primary consideration in acute scrotal pain. The annual incidence of testicular torsion is 3.8 in 100,00 males under the age of 18.[29] Testicular torsion presents in a bimodal age distribution, with extravaginal torsion occurring in the perinatal period and intravaginal torsion peaking during puberty,[29] although this may occur at any age.

Torsion of the testis or spermatic cord results from abnormal fixation of the testis within the tunica vaginalis. This allows the testis to twist, especially after episodes of minor trauma and during periods of testicular growth such as puberty. Torsion usually occurs in the absence of a preceding event; only a small percentage occurs due to associated trauma. Torsion may occur during sleep, when unilateral cremasteric muscle contraction results in twisting of the testis. Inadequate fixation of the tunica vaginalis to the posterior scrotal wall (bell-clapper deformity) places the testis at risk for torsion. A testis aligned along a horizontal rather than a vertical axis is at particular risk.

Patients usually complain of acute severe pain, usually felt in the lower abdominal quadrant, the inguinal canal, or the testis. Although the pain may be constant or intermittent, it is not positional in nature, because testicular torsion is primarily an ischemic event that becomes inflammatory only after the testis has infarcted. The presence of vomiting makes the diagnosis of testicular torsion more likely.[30]

When examined early, the involved testis is firm, tender, and often higher than the contralateral testis and frequently with a transverse lie.[31] The epididymis may be displaced and not found in its normal posterolateral position. The most sensitive finding in excluding testicular torsion is the unilateral presence of the cremasteric reflex. Testicular torsion has, however, been reported in the setting of an intact cremasteric reflex. Although commonly associated with testicular torsion, the absence of an ipsilateral cremasteric reflex is a nonspecific finding and may be associated with scrotal inflammation from any cause. In addition, some healthy young males may have an underdeveloped reflex, particularly in the first few years of life. Relief of pain with elevation of the affected testicle (Prehn sign–positive for epididymitis) does not reliably distinguish torsion from epididymitis.

TABLE 93-1 Differential Diagnosis of Acute Scrotal Pain

	Testicular Torsion	Epididymitis	Appendage Torsion
Historical Features			
Peak incidence	Neonates, adolescents	Adolescents, young adults	Prepubertal
Risk factors	Undescended testicle (neonate), rapid increase in testicular size (adolescent), failure of prior orchiopexy	Sexual activity/promiscuity, GU anomalies, GU instrumentation	Presence of appendages
Pain onset	**Sudden**	Gradual, progressive	Variable
Nausea/vomiting	**More likely**	Less likely	Less likely
Dysuria	Less likely	**More likely**	Less likely
Physical Findings			
Fever	Less likely	**More likely**, particularly in advanced disease (epididymo-orchitis)	Less likely
Location of swelling/tenderness (early)	Testicle, progressing to diffuse hemiscrotal involvement	Epididymis, progressing to diffuse hemiscrotal involvement	Localized to head of affected testicle or epididymis
Cremasteric reflex	Testicular torsion less likely if present	May be present or absent	May be present or absent
Testicle position	High riding, transverse alignment	Normal position, vertical alignment	Normal position, vertical alignment

In obvious cases of testicular torsion, emergent urologic consultation and surgical exploration are essential. With acute torsion, testicular salvage is related to the duration of symptoms before surgical detorsion. Excellent salvage rates are expected with <6 hours of symptoms, but salvage declines rapidly thereafter. There are no readily available clinical or laboratory parameters to judge the degree or duration of testicular ischemia. Therefore, no matter how long the patient has been symptomatic, a rapid evaluation, including emergency scrotal exploration if necessary, should be performed. Doppler US and radionuclide scintigraphy are two imaging modalities used to evaluate patients with equivocal clinical presentations. Both may be useful, but their routine clinical use is limited by timely availability and operator experience in interpreting the images, particularly for radionuclide scintigraphy. These studies are considered "positive" for testicular torsion when they demonstrate absent or clearly reduced ipsilateral intratesticular blood flow, and "negative" when flow is normal or increased. Older duplex US studies report sensitivities ranging from 69% to 90% and specificities ranging from 98% to 99% for testicular torsion[1]; however, a 2013 prospective study found a sensitively of only 83%.[32] Importantly, partial torsion may reveal falsely reassuring blood flow in an ischemic testicle. Likewise, normal or increased flow may be seen in a high-risk testicle following spontaneous detorsion. Gray-scale US imaging of the spermatic cord itself assessing for coils or kinks may aid in diagnosis. US findings need to be interpreted with caution in the context of the overall clinical picture. US has the advantage of demonstrating scrotal anatomy, which may indicate an alternative diagnosis. Within these limitations, testicular imaging modalities, when used in equivocal cases, can be very helpful tools.[1]

For emergency or preoperative treatment, consider manual detorsion of the affected testis. Explain to the patient that detorsion is a painful procedure but successful detorsion will help to relieve the presenting pain. Most testes twist in a lateral to medial fashion (two thirds of cases); therefore, detorsion initially should be done in a medial to lateral motion.[33] **Detorsion is typically done in a manner similar to opening a book (Figure 93-7A).** If one were to stand at the patient's feet, the patient's right testis would be rotated in a counterclockwise fashion and the patient's left testis in a clockwise fashion (**Figure 93-7B**). The initial attempt should include one and one-half rotations (540 degrees). Any relief of pain is a positive end point, and the success of the maneuver can be assessed with Doppler US, demonstrating restoration of blood flow. An occasional patient will require manipulation beyond the initial one and one-half rotations. A worsening of the patient's pain suggests that detorsion should then be done in the opposite direction (one third of cases). Successful detorsion converts an emergent procedure to an elective one. The timing of the elective surgical correction should depend on the patient's compliance and responsibility.

Young boys may present to the ED with nonspecific abdominal pain suggestive of gastroenteritis only to return 1 to 2 days later with a diagnosis of testicular torsion. Whether these patients had undisclosed testicular torsion at their initial evaluation is not known, but **consider testicular torsion in the differential diagnosis of any male presenting with abdominal pain or vomiting**.

APPENDAGEAL TORSION

The four testicular appendages—appendix testis, appendix epididymis, paradidymis (organ of Giraldes), and vas aberrans—have no known physiologic function. These pedunculated structures are capable of torsion and, in prepubertal boys, probably twist more often than the testes, with the appendix epididymis and appendix testes accounting for approximately 8% and 90% of appendage torsion, respectively. Presenting symptoms, although similar to testicular torsion, classically lack the

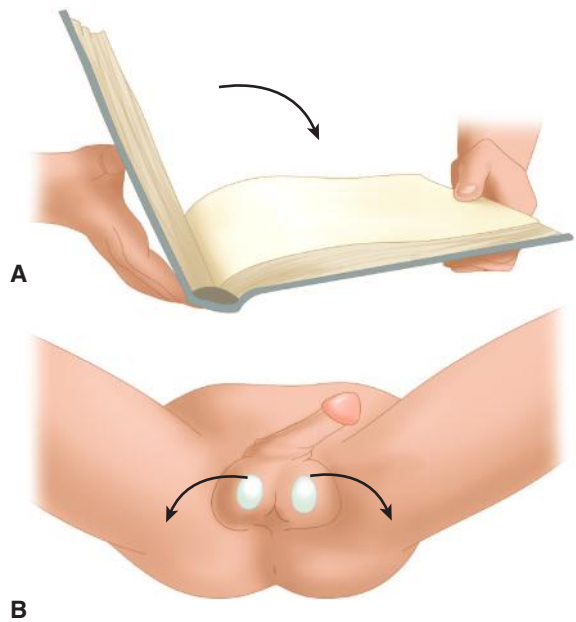

FIGURE 93-7. Testicular detorsion. This procedure is best done standing at the foot of or on the right side of the patient's bed. **A.** The torsed testis is de-torsed in a fashion similar to opening a book. **B.** The patient's right testis is rotated counterclockwise, and the left testis is rotated clockwise. [Reproduced with permission from Strange GR, Ahrens WR, Schafermeyer RW, et al: *Pediatric Emergency Medicine*, 3rd ed. © 2009, McGraw-Hill, Inc., New York, NY, p. 679.]

systemic symptoms of nausea and vomiting. If the patient is seen early, with the pain localized to the upper pole of the testis or epididymis, a blue spot may be observed through the scrotal skin—the "blue dot sign." This "sign" is pathognomonic for torsion of the appendix testis or epididymis. If the diagnosis can be assured and normal intratesticular blood flow to the involved testis is confirmed by color Doppler US, surgical exploration is not necessary. Torsion of an appendage is usually self-limiting and best managed with analgesics, bed rest, supportive underwear, and reassurance, with the expected symptom resolution within 3 to 5 days. If late in the process and testicular swelling is present, or if the color Doppler US is equivocal, then urologic consultation and surgical exploration are needed to exclude testicular torsion.[1]

EPIDIDYMITIS

The onset of pain in epididymitis or epididymo-orchitis is usually gradual. Bacterial infection is the most common cause, and the type of infection tends to depend on age. In young boys, epididymitis or epididymo-orchitis is commonly associated with sterile reflux of urine, but may be due to coliform bacteria, often associated with congenital anomalies of the lower urinary tract. Other considerations include increases in abdominal pressure from lifting or straining, which promote urinary reflux into the tail of the epididymis and subsequent inflammation. In young men <35 years old, epididymitis is due primarily to sexually transmitted diseases or associated complications (i.e., urethral stricture). Consider fungal or coliform infection of the lower urinary tract in addition to the more common sexually transmitted disease organisms in the setting of anal insertive intercourse. In men >35 years old, epididymitis is more commonly caused by common urinary pathogens, such as *Escherichia coli* and *Klebsiella*, or sexually transmitted diseases. In elderly men with epididymitis and urinary tract infection, consider associated benign prostatic hypertrophy or urethral stricture. Large residual urine volume (>50 to 100 mL urine) suggests outlet obstruction as the cause of the patient's infection (see chapter 92, "Acute Urinary Retention"). Chemical epididymitis can occur due to reflux of sterile urine and should be considered as a cause of prolonged symptoms despite appropriate antibiotic treatment.

CLINICAL FEATURES

Epididymitis may cause lower abdominal, inguinal canal, scrotal, or testicular pain alone or in combination. The retrograde progression of infection from the prostatic urethra to the epididymis explains the location and progression of pain. Epididymitis represents a more advanced GU tract infection when compared with urethritis. Patients with epididymitis are more prone to lower urinary tract voiding discomfort and may note transient pain relief in the recumbent position with scrotal elevation. Initially, isolated firmness and nodularity of the affected globus minor are noted on examination. As the disease progresses, the sulcus between the epididymis and testis becomes obliterated, and the inflammatory epididymal mass may become contiguous with the testis, producing a large, tender scrotal mass (epididymo-orchitis) that may be difficult to differentiate from testicular torsion or abscess.

Urinalysis may show pyuria in about half of patients. Obtain a specimen for gonorrhea and *Chlamydia* if urethral discharge is present, or in patients <35 years old. Obtain urine culture in children and elderly men. Adjunctive diagnostic modalities, such as color flow duplex Doppler sonography or radionuclide scintigraphy, will demonstrate increased or preserved blood flow to the testes. A reactive hydrocele may be seen on US.

TREATMENT

Most cases of epididymitis can be managed with oral antibiotics (**Table 93-2**).[34] Admission criteria for epididymitis include fever and clinical toxicity, which can be indicative of epididymal or testicular abscess formation. The ambulatory patient should wear a scrotal supporter, being careful not to lift heavy objects or strain when having a bowel movement, both of which will increase intra-abdominal pressure and exacerbate the inflammatory cycle. A urologist will need to reevaluate the patient in 5 to 7 days and then ultimately decide when the patient may return to work based on his job description (i.e., a sedentary worker would be able to return sooner than a laborer).

TABLE 93-2 Empiric Outpatient Treatment of Epididymitis and Epididymo-Orchitis

Age <35 y
Treat for gonorrhea and *Chlamydia*[*]
Ceftriaxone, 250 milligrams IM single dose, plus doxycycline, 100 milligrams PO twice a day for 10 d
Age >35 y
Treat for gram-negative bacilli[*]
Ofloxacin, 300 milligrams PO twice a day for 10 d
Levofloxacin, 500 milligrams PO every day for 10 d

[*]Antibiotic treatment should be adjusted depending on patient risk factors for sexually transmitted disease (STD) and culture results. If age >35 y with risk factors for STD, consider ceftriaxone, 250 milligrams IM single dose, in addition to ofloxacin or levofloxacin orally.

ORCHITIS

Isolated orchitis, or inflammation of the testicle, is quite rare and usually occurs in conjunction with other systemic infections, such as mumps or other viral illnesses (coxsackie virus, Epstein-Barr virus, varicella, or echovirus). Mumps orchitis presents with unilateral involvement in 70% of cases, followed by contralateral involvement in 1 to 9 days. Bacterial orchitis is almost always associated with epididymitis. Orchitis in immunocompromised patients can be due to mycobacteriosis, cryptococcosis, toxoplasmosis, or candidiasis. Patients with orchitis usually present with testicular tenderness and swelling over a few days in duration. The diagnosis is primarily clinical using history and physical examination, but US can exclude testicular torsion or abscess. Treatment for acute episodes starts with antibiotic coverage as listed above for epididymitis; IV antibiotics should be considered for patients with abnormal vital signs.[34] Immunocompromised patients or patients with risks for tuberculosis (exposure, uncontrolled human immunodeficiency virus, or diabetes) require admission if they have abnormal vital signs or, if not, referral to urology and/or infectious disease for further management.

TESTICULAR MALIGNANCY

The hallmark of testicular carcinoma is an asymptomatic testicular mass with firmness or induration. Ten percent of tumors will present with pain secondary to acute hemorrhage within the tumor. Metastatic testicular tumors can be insidious and must be suspected in any male with unexplained supraclavicular lymphadenopathy, abdominal mass, or chronic nonproductive cough from a lung metastasis. Testicular examination may disclose a primary tumor. Any unexplained testicular mass must be approached as a possible tumor with urgent urologic referral.

ACUTE PROSTATITIS

Acute prostatitis is bacterial inflammation of the prostate gland. Patient complaints can include low back pain; perineal, suprapubic, or genital discomfort; obstructive lower urinary tract voiding symptoms; frequency or dysuria; perineal pain with ejaculation; and fever or chills. Risk factors include anatomic or neurophysiologic lower urinary tract obstruction, acute epididymitis or urethritis, anal receptive intercourse, phimosis, intraprostatic ductal reflux, and indwelling urethral catheter or condom drainage. The causative organism is *E. coli* in most cases, with other uropathogens such as *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Serratia*, or *Staphylococcus* causing the remainder. In contrast to acute prostatitis, chronic bacterial prostatitis is characterized by prolonged or recurrent symptoms and relapsing bacteriuria.

Clinical findings include perineal tenderness, rectal sphincter spasm, and prostatic tenderness or bogginess. The diagnosis is clinical, because urinalysis and urine culture may both be negative. Prostatic massage is not necessary to make the diagnosis. Obtain urethral cultures or first-void urine for gonorrhea and chlamydia testing.

Initial treatment is fluoroquinolone antimicrobial therapy for 2 to 4 weeks,[35] such as ciprofloxacin, 500 milligrams orally for 14 days, with plan for primary care revelation at 2 weeks for possible continued therapy as needed. If drug cost is an issue, trimethoprim-sulfamethoxazole double-strength, one tablet PO twice a day, is an alternative, although cure rates are lower than for the fluoroquinolones. Consider treating for sexually transmitted disease organisms in younger patients or older patients with sexually transmitted disease risk factors; give ceftriaxone, 250 milligrams IM as a single dose, plus doxycycline, 100 milligrams PO twice a day for 14 days. Provide adequate narcotic analgesia.

Most patients can be treated as outpatients. Patients with abnormal vital signs should be admitted and given a broad-spectrum antibiotic such as piperacillin-tazobactam, 3.375 to 4.5 grams IV, or cefotaxime combined with an aminoglycoside.[35] If associated with urinary retention, urology consultation is needed. Urologic follow-up should be provided for discharged patients to ensure eradication of infection and to provide continuity of care in case of relapse. Chronic prostatitis is managed with urine cultures after prostatic massage, long-term antibiotics based on culture for chronic bacterial infections, anti-inflammatory medicines plus α-blockers for nonbacterial chronic prostatitis, and urology follow-up.

DISORDERS OF THE URETHRA

URETHRITIS

Urethritis is characterized by purulent or mucopurulent urethral discharge. Diagnosis is clinical, although it can be confirmed by evidence of pyuria or bacteriuria in a first-void urine specimen. Most cases are due to *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. Herpes simplex virus, *Ureaplasma urealyticum*, or *Trichomonas vaginalis* are less frequent causes. Physical examination should exclude other disorders such as epididymitis, disseminated gonococcemia, or Reiter's syndrome. Treatment for urethritis is ceftriaxone, 250 milligrams IM, and azithromycin, 1 gram PO, or doxycycline, 100 milligrams PO twice a day, for 7 days. Failure to respond suggests reinfection or reexposure or infection with *T. vaginalis* or doxycycline-resistant *U. urealyticum*. Treatment with metronidazole or azithromycin should be considered depending on the infectious etiology. See chapter 149, "Sexually Transmitted Infections" for further discussion of sexually transmitted diseases.

URETHRAL STRICTURES

In decades past, sexually transmitted diseases caused the largest percentage of urethral strictures; however, trauma (such as pelvic fractures) and urinary instrumentation have been shown to cause the majority of strictures in recent assessment (**Figure 93-8**).[36]

If a patient requires measurement of his residual urine volume, simple bedside US can be performed. Most urologists agree that postvoid volumes of 50 to 100 mL may signify an abnormal residual urine volume. If the patient has difficulty voiding or is in urinary retention and a 14- or 16-F Foley or Coudé catheter cannot be easily placed into the bladder, the differential diagnostic possibilities include urethral stricture, voluntary external sphincter spasm, bladder neck contracture, or benign prostatic hypertrophy. If time permits, retrograde urethrography can be done, which will define the location and extent of a urethral stricture. Only cystoscopy can confirm a bladder neck contracture or the extent of an obstructing prostate gland. Suspected voluntary external sphincter spasm can be overcome by holding the penis upright and encouraging the patient to relax his perineum and breathe slowly during urinary catheter insertion. Liberal preapplication of intraurethral anesthetic lubricant jelly for male urinary catheterization is prudent.

When a urethral stricture is encountered, copious anesthetic lubrication is placed intraurethrally after the foreskin has been controlled with folded 4 × 4 gauze. This latter maneuver is especially important in uncircumcised patients. A 12- or 14-F Coudé catheter may negotiate the strictured area, because this catheter has an angled bend near its tip. If there are previous false passages from attempts at dilation or unsuccessful instrumentation, passage of the Coudé catheter may be difficult. Further urethral manipulation may create new false passages, leading to unnecessary hemorrhage and possible gram-negative bacteremia. If two or three gentle attempts to pass the catheter fail, urologic consultation is indicated. A catheter guide or urethral sound should be used only by a urologist.

For emergency bladder decompression, consider a suprapubic cystostomy using the Seldinger technique (see chapter 92, "Acute Urinary Retention").

URETHRAL FOREIGN BODIES

Patients of all ages, but especially young children, may be victims of innocent urethral exploration or attempts to heighten sexual experiences by using a variety of foreign bodies such as bobby pins; long, thin paint brushes; or ball point pens.[37] Bloody urine combined with infection and slow, painful urination should suggest a possible foreign body in the lower urinary tract. An x-ray of the bladder and urethral areas may disclose the presence of a radiopaque foreign body.

Foreign bodies often require cystoscopic removal or even open cystotomy. Occasionally a gentle milking action of the proximal end of the urethral foreign body by an experienced examiner will allow its retrieval from the distal urethral meatus. Even then, retrograde urethrography or endoscopic confirmation of an intact urethra is indicated.

HEMATOSPERMIA

Hemospermia, or hematospermia, is a disturbing symptom that produces extreme anxiety in sexually active males. The incidence and prevalence of this condition are not known. For all practical purposes, hematospermia can be regarded as gross hematospermia—that is, visually apparent to the patient—as microscopic analysis of semen is rarely performed. Most symptomatic men seek medical attention after one or two occurrences. Any process that results in trauma or other injury (e.g., tumor with erosion), inflammation, or infection of the male ejaculatory

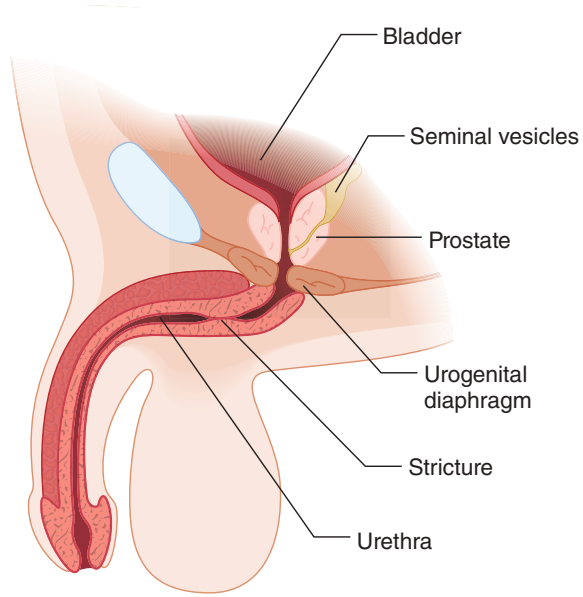

FIGURE 93-8. Stricture of the bulbous urethra.

system may result in bloody semen.[38] It is not uncommon after vigorous sexual activity. Unless the cause can be determined on physical exam, the diagnosis cannot be completed in the ED. Seventy percent of cases are diagnosed as idiopathic hematospermia after a complete outpatient urologic workup. Hematospermia should be differentiated from hematuria based on a clean catch urinalysis (see chapter 91, "Urinary Tract Infections and Hematuria"). Infection, including sexually transmitted disease, should be considered, and if suspected based on history and physical, the patient should be cultured and treated appropriately. Although all patients with hematospermia should be referred to a urologist, those >40 years are at higher risk for cancer and should be strongly advised to seek further evaluation by a urologist even when there is spontaneous resolution of hematospermia.

CHAPTER 94

Urologic Stone Disease

David E. Manthey
Bret A. Nicks

INTRODUCTION AND EPIDEMIOLOGY

Emergency medicine management is directed at relieving pain, assessing kidney function, and determining the likelihood of spontaneous stone passage. This chapter discusses renal and ureteral stones. Bladder stones are discussed in chapter 92, "Acute Urinary Retention."

The prevalence of kidney stones in the United States has risen from 5.2% in 1994[1] to 8.8% in 2010.[2] The prevalence is 10.6% in men and 7.1% in women.[2] Increasing prevalence is documented in Europe and Southeast Asia.[3] Obesity and diabetes are strongly associated with kidney stones.[2] The lifetime risk is approximated at 10% to 15% in the United States and other developed countries. Urinary calculi recur in 37% of patients in the first year, 50% of patients within 10 years, and 75% of patients in 20 years.[4] Children <16 years old constitute about 7% of all renal stone cases.[5] Unique to children is a 1:1 sex distribution.[4] The most common causes in children involve metabolic abnormalities (50%), urologic anomalies (20%), infection (15%), immobilization syndrome (5%), and idiopathic causes (10%).[5] Ethnically, whites develop stones more frequently than blacks.[2]

PATHOPHYSIOLOGY

Stone formation requires supersaturation of dissolved salts in the urine, which condense into a solid phase. Increasing the amount of solvent (urine) and decreasing the amount of solute presented to the kidney (i.e., calcium, oxalate, uric acid) can aid in prevention. Inhibitory substances, such as citrate, and magnesium can prevent crystal precipitation and stone formation.

About 80% of calculi are composed of calcium oxalate, calcium phosphate, or a combination of both. Calcium excretion is elevated in conditions that include hyperparathyroidism, absorptive and renal hypercalciuria, and immobilization syndrome. Randall's plaque, a collection of interstitial suburothelial calcium phosphate particles on the surface of the renal papillae, serves as a nucleation surface for calcium oxalate stones.[6,7] Complex interactions between the gut, kidney, and bones contribute to calcium oxalate stone formation. A diet restricting calcium paradoxically increases calcium stone formation because there is less calcium to bind oxalate in the intestinal lumen, leading to increased absorption of oxalate from the gut, recruitment of calcium from bones, osteoporosis, and symptomatic stone disease in predisposed patients.

About 10% of stones are struvite (magnesium-ammonium-phosphate). These stones are associated with infection by urea-splitting bacteria (*Proteus*, *Klebsiella*, *Staphylococcus* species, *Providencia*, and *Corynebacterium*) and are the most common cause of staghorn calculi, which are large stones that form a cast of the renal pelvis. Antibiotic penetration into staghorn calculi is poor, and the potential for urosepsis exists as long as the stones remain.

Uric acid causes about 10% of urolithiasis. Twenty-five percent of patients with gout will develop kidney stones, and they occur at a rate of approximately 1% per year after the first gout attack. Urate stones are radiolucent, and the urine is typically acidic. Cystine stones are rare, account for approximately 1% of all stones, and occur in patients with cystinuria, an autosomal recessive genetic disorder affecting amino acid transport (COLA: *c*ysteine, *o*rnithine, *l*ysine, *a*rginine). Stones can be made of many other miscellaneous substances, including indinavir, triamterene, xanthene, and silicate.

Some medications predispose to stone disease. The protease inhibitor indinavir sulfate, used to treat the human immunodeficiency virus, is associated with a 4% to 10% incidence of symptomatic urolithiasis. Pure indinavir stones are radiolucent on plain abdominal x-ray and CT scan. Carbonic anhydrase inhibitors, triamterene, and laxative abuse also increase the prevalence of renal stones.[8] With appropriate evaluation, 90% of patients will have a cause identified, and over 50% of calcium oxalate stone recurrences can be prevented.[9] **Table 94-1** lists risk factors associated with kidney stones.[2,3,10]

Pain associated with kidney stones is due to obstruction of a hollow viscus organ (ureter) and subsequent hydronephrosis creating pressure against Gerota's fascia, causing flank pain. Isolated small renal pelvis stones (not staghorn) do not cause pain unless they cause intermittent obstruction of the entrance to the ureter. A migrating but nonobstructive stone also causes pain. **During acute obstruction, most patients have no rise in serum creatinine because the unobstructed kidney functions at up to 185% of its baseline capacity.** A rise in serum creatinine in acute obstruction suggests a solitary kidney or preexisting renal disease such that the unobstructed kidney is unable to compensate completely. Fortunately, most patients have incomplete ureteral obstruction, and many patients can be safely observed over weeks. Irreversible renal damage from an obstructive kidney stone is rare if obstruction has been present for ≤1 month.[11]

The probability of spontaneous passage of stones is determined by multiple factors, including size, shape, location, and degree of ureteral obstruction. Bizarre or irregularly shaped stones with spicules or sharp edges have a lower spontaneous passage rate. With complete obstruction, there is a lower rate of spontaneous passage than if the blockage is partial. **The most common sites of obstruction include the ureteropelvic junction, where the 1-cm pelvis constricts into the 2- to 3-mm ureter; the pelvic brim, where the ureter courses over both the pelvis and the iliac vessels; and finally, the ureterovesical junction, because this is the most constricted site of the ureter due to the muscular coat of the bladder.** Based on stone size alone, 98% of stones <5 mm will pass within 4 weeks

TABLE 94-1 Kidney Stone Risk Factors

Risk Factor	Mechanisms
Obesity	May promote hypercalciuria
Low urine volume	Allows solute to supersaturate
Excess dietary meat (purine)	Creates acidic urinary milieu; depletes available citrate (inhibitor); promotes hyperuricosuria
Excess dietary sodium	Promotes hypercalciuria
Insulin resistance, metabolic syndrome	Ammonia mishandling; alters pH of urine
Family history	Genetic predisposition
Gout	Promotes hyperuricosuria
Bowel surgery, inflammatory bowel disease	Promotes low urine volume; acidic urine depletes available citrate (inhibitor); hyperoxaluria
Primary hyperparathyroidism	Creates persistent hypercalciuria
Prolonged immobilization	Bone turnover creates hypercalciuria

without intervention. Sixty percent of stones 5 to 7 mm and 39% of stones >7 mm will pass within 4 weeks. **Stone size on plain radiographs is magnified by up to 20%, and a measured stone on CT is 88% of actual stone size.**[12]

CLINICAL FEATURES

The classic symptom complex for nephrolithiasis is the acute onset of a crampy intermittent flank pain that radiates toward the groin. As pain originates from a hollow viscus (ureter), the pain is visceral in nature without associated peritoneal irritation. Patients writhe in pain, unable to find a position of comfort. However, patients with renal colic may demonstrate rebound tenderness (29%), guarding (61%), and rigidity (8%).[13] Pain is commonly accompanied by nausea and vomiting (50%). The adrenergic response to pain can result in tachycardia, hypertension, and diaphoresis. **Hematuria is present in only 85%** of patients with renal colic, and 30% have gross hematuria.

The location of the pain correlates somewhat with the location of the stone. Stones in the upper ureter refer pain to the flank, whereas those in the mid-ureter radiate to the lower anterior quadrant of the abdomen. A distal ureter stone, which is where 75% of stones are diagnosed, refers pain to the groin. Stones positioned at the ureterovesical junction can mimic a urinary tract infection by causing frequency, urgency, and dysuria in 3% to 24% of patients.[13] Extracorporeal shock wave lithotripsy fractures stones into small particles with the use of focused sound waves. The resulting "sludge" is passed in the urine. When there are large fragments, an acute episode of renal colic occurs.

In children, symptoms vary with age. Older children are more likely to present with typical adult symptoms. Younger children may complain of nonspecific abdominal or pelvic pain. Although renal colic is rare in infants, symptoms may be mistakenly attributed to intestinal colic. Overall, 20% to 30% of children may have only painless hematuria with urologic stone disease.

During the patient interview, elucidate three important items of history: assess risk factors for stone development (Table 94-1), prior stone-related outcome, and important mimickers. The risk factors for a poor outcome with stones include three categories: renal function at risk, history of difficulty with stones, and infection (**Table 94-2**). Two mimickers that are very important to exclude are abdominal aortic aneurysm and renal artery infarction. **Nephrolithiasis is the most common misdiagnosis given to patients with a rupturing or expanding abdominal aortic aneurysm.** Recall that stones do not usually present in men older than age 60 and do not cause hypotension, even transiently. Renal artery thrombosis can mimic stone symptoms due to swelling of the infarcted kidney and can also be associated with hematuria. However, early in the course, noncontrast CT will not necessarily show inflammation around the kidney, and because no contrast is used, the function of the kidney is not assessed.

Systemic illness
Urinary tract infection

DIAGNOSIS

The diagnosis of urologic stone disease is clinically suspected and supported by the presence of hematuria; imaging confirms the diagnosis with certainty.

Many diagnoses can be confused with renal colic (**Table 94-3**). History and physical examination can be difficult because the patient's discomfort may interfere with adequate information collection. The most critical diagnoses to consider are aortic dissection and ruptured abdominal aortic aneurysm. Renal colic and abdominal aortic aneurysm may have similar presentations.

LABORATORY EVALUATION

The laboratory evaluation centers on evaluating for infection, kidney dysfunction, and possibility of pregnancy. **Test all females of childbearing potential for pregnancy when considering renal colic.** With pregnancy, consider ectopic pregnancy in the differential diagnosis while minimizing radiation exposure to the fetus.

TABLE 94-3 Differential Diagnoses for Ureterolithiasis

Vascular	Aortic dissection
	Abdominal aortic aneurysm
	Renal artery embolism
	Renal vein thrombosis
	Mesenteric ischemia
Renal	Pyelonephritis
	Papillary necrosis
	Renal cell carcinoma
	Renal infarct
	Renal hemorrhage
Ureter	Blood clot
	Stricture
	Tumor (primary or metastatic)
Bladder	Tumor
	Varicose vein
	Cystitis
GI	Biliary colic
	Pancreatitis
	Perforated peptic ulcer disease
	Appendicitis
	Inguinal hernia
	Diverticulitis
	Cancer
	Bowel obstruction
Gynecologic	Ectopic pregnancy
	Pelvic inflammatory disease/tubo-ovarian abscess
	Ovarian cyst
	Ovarian torsion
	Endometriosis
GU	Testicular torsion
	Epididymitis
Other	Drug-seeking behavior
	Shingles
	Retroperitoneal hematoma/abscess/tumor

Urinalysis is needed to rule out infection. If infection is found, obtain urine culture and sensitivities to guide antibiotic therapy.[14] In suspected pediatric nephrolithiasis, a culture is often sent regardless, because identification of a urinary tract infection in children can be more difficult (see chapter 132, "Urinary Tract Infection in Infants and Children").

Hematuria (three or more red blood cells per high-power field), or even its absence, can mislead the physician. Although 10% to 15% of patients with nephrolithiasis will have no hematuria, approximately **24% of patients with flank pain and hematuria have no radiographic evidence of ureterolithiasis**.[15] Therefore, although hematuria may contribute to diagnostic decision making, it should not be used alone to exclude or confirm the diagnosis of ureterolithiasis[15] (see chapter 91, "Urinary Tract Infections and Hematuria").

Check renal function because the overwhelming majority of patients who form stones have reduced creatinine clearance.[16] Unless febrile or systemically ill, a WBC count does not aid in the evaluation; many patients will have an elevated WBC count due to stress demargination. Other laboratory studies, such as serum calcium or uric acid, are not useful in the initial evaluation or treatment but help determine stone type and long-term therapy.

IMAGING

Imaging confirms the presence of a ureteral stone, rules out other diagnoses, identifies complications, defines stone location, and assists with management if the stone fails to pass spontaneously.[17] Imaging is recommended by the American Urological Association in patients with suspected first-time stones.[18] For young, healthy, stable patients with a history of kidney stones in whom the diagnosis is clinically clear, imaging may be deferred until the follow-up visit provided that a reliable follow-up mechanism exists.[19] However, clinicians are frequently incorrect in their clinical impression in 20% to 70% of cases.[20] CT scanning reveals an alternative diagnosis in 33% of the patients.[20] Thus, the physician should determine the need for confirmation of the diagnosis based on the patient's past medical history, dangers of accumulated radiation exposure, clarity of the clinical diagnosis, and ease of follow-up and ability to return for worsening symptoms.

CT The noncontrast helical CT scan is sensitive and specific, with "diagnostic" positive and negative likelihood ratios for detection of renal stones (**Table 94-4**).[21] Images are obtained from the top of the kidney to the bladder base. Secondary signs of ureteral obstruction, such as ureteral dilatation, stranding of perinephric fat, dilatation of the collecting system, and renal enlargement, can be helpful in making the diagnosis. In combination, unilateral ureteral dilatation and perinephric stranding have a positive predictive value of 96% for stone disease.[22] If both are absent, the negative predictive value is 93% to 97%[22] (**Figures 94-1** and **94-2**).

Noncontrast helical CT has advantages over other imaging modalities, including superior speed, the avoidance of radiocontrast media, and greater ability to identify other pathologies. However, because radiocontrast is not used, the specificity and sensitivity for other diagnoses (e.g., abdominal aortic aneurysm, appendicitis, renal infarct, or perinephric abscess) are not as great as with imaging protocols using contrast, and renal function is not assessed.

Low-dose CT has been studied in small numbers. Low-dose CT is as sensitive as standard CT in detecting stones >3 mm in patients with a body mass index <30. However, it was not as sensitive for smaller stones or at higher body mass indices.[23]

IV Urography IV urography (or IV pyelogram) is rarely used, but yields information on renal function and anatomy. It detects calculi with modest sensitivity but excellent specificity[21] (Table 94-4). IV urography can be an adjunct to CT if functional information and knowledge of the degree of obstruction are required.

Plain Abdominal Radiographs Approximately 90% of urinary calculi are radiopaque because calcium phosphate and calcium oxalate stones have a density similar to that of bone. Magnesium-ammonium-phosphate (struvite) is slightly less radiodense, followed by cystine, which is only partly radiopaque. Uric acid and matrix stones are essentially radiolucent, as are most stones associated with medications such as indinavir. Unfortunately, because of small size and overlapping soft tissue and bone shadows, urinary stones are visible much less frequently on plain films. A plain kidney-ureter-bladder film is neither sensitive nor specific enough to rule in or rule out stone. However, once the location of a stone is identified on CT scan, the progression of the stone can be followed by a kidney-ureter-bladder film assuming the stone is visible.

US If patients are not candidates for CT due to concerns about radiation (e.g., during pregnancy or in children), US can assist in the diagnosis. Although useful in the detection of larger stones (**Figure 94-3**), US may miss smaller (<5 mm in diameter) ureteral stones.[24] US is helpful in diagnosing stones in the proximal and distal ureters but is insensitive for mid-ureteral stones. Overall, US has only modest sensitivity and specificity for detecting renal stones (Table 94-4) but is 78% sensitive for detecting hydronephrosis. This sensitivity for hydronephrosis goes up from 75% for stones <6 mm to 90% for stones >6 mm. However, of hydronephrosis diagnosed by US, up to 22% of studies do not represent obstruction; but rather, normal anatomic variation, full bladder, and renal cysts. Rapid bolus infusion of crystalloid can result in a false-positive finding of hydroureter.

US provides information on renal size and, with Doppler scanning, renal blood and urine flow. Obesity may interfere with obtaining good-quality scans, and US can miss early obstructive signs. Accuracy of the US study is dependent on the skill and experience of the operator.

Bedside US Although not quite as accurate as a screening examination would need to be, compared with CT, bedside US by ED physicians had a sensitivity of 80% (95% confidence interval [CI], 65% to 89%), specificity of 83% (95% CI, 61% to 94%), and overall accuracy of 81% (95% CI, 69% to 89%) in the detection of hydronephrosis.[25-27] Bedside US may be useful to detect larger stones unlikely to respond to conservative measures.

TREATMENT

PAIN AND NAUSEA

Treatment for symptomatic nephrolithiasis in the ED includes pain and nausea/vomiting control as needed, antibiotics for those with evidence of infection, and medical expulsion therapy. Forced IV hydration results in no difference in pain control or stone passage rates when compared

TABLE 94-4 Ancillary Tests in Urologic Stone Disease

Test	Sensitivity (%)	Specificity (%)	LR+	LR–	Comments
Noncontrast CT	94–97	96–99	24–∞	0.02–0.04	Advantages: speed, no RCM, detects other diagnoses Disadvantages: radiation, no evaluation of renal function
IV urogram	64–90	94–100	15–∞	0.11–0.15	Advantage: evaluates renal function Disadvantage: RCM (allergy, nephrotoxicity, metformin related acidosis)
US	63–85	79–100	10–∞	0.10–0.34	Advantages: pregnancy, no RCM, no radiation, no known side effects Disadvantages: insensitive in middle third of the ureter, may miss smaller stones (<5 mm)
Plain abdominal radiograph	29–58	69–74	1.9–2.0	0.58–0.64	Advantage: may be used to follow stones Disadvantage: poor sensitivity and specificity

Abbreviations: LR = likelihood ratio; RCM = radiocontrast media.

FIGURE 94-1. **A.** ***Red arrow*** shows 6-mm stone within the proximal third of the left ureter on noncontrast CT reformatted image of upright abdomen. **B.** From same patient as in **A**, note 6-mm stone (***arrow***) within the proximal third of the left ureter on noncontrast CT.

to minimal IV hydration.[28] Fluids should be given to correct any fluid deficit due to vomiting or limited oral intake.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the primary choice of analgesics in the treatment of stone disease, because they have a direct action on the ureter by inhibiting prostaglandin synthesis.[29,30] IV administration achieves more rapid relief than IM or PO dosing[31] (e.g., ketorolac, 30 milligrams IV). There are several U.S. Food and Drug Administration boxed warnings regarding NSAID use: do not give NSAIDS in those with aspirin or NSAID hypersensitivity; avoid in coagulopathy or patients at risk for bleeding; NSAIDS increase risk of GI bleeding at any time during therapy and without warning; and avoid in renal impairment. Urology may delay the use of lithotripsy on patients who receive any drugs affecting platelet function for 3 to 10 days. Narcotics (e.g., hydromorphone, 0.5 to 2.0 milligrams IV) are good analgesics but do not affect the cause of pain. Because both the pain of the stone and narcotics can cause nausea and vomiting, address these symptoms as well.

Metoclopramide is the only antiemetic that has been specifically studied in the treatment of renal colic. In two double-blinded studies, metoclopramide provided pain relief equivalent to narcotic analgesics in addition to relieving nausea. Metoclopramide works by blocking dopaminergic receptors in the CNS but is less sedating than other centrally acting dopamine antagonists.[32]

URINARY TRACT INFECTION

Patients with fever, renal insufficiency, and systemic signs of infection are treated with IV antibiotics and admitted. Options include gentamicin or tobramycin, 3.0 milligrams/kg/d divided every 8 hours, plus ampicillin, 1 to 2 grams every 4 hours; piperacillin-tazobactam, 3.375 grams IV every 6 hours; cefepime, 2 grams IV every 8 hours; ticarcillin-clavulanic acid,

FIGURE 94-2. CT image shows 5-mm stone (***arrow***) at left ureterovesical junction. Other calcifications are seen in the pelvis, unrelated to the urinary outflow system.

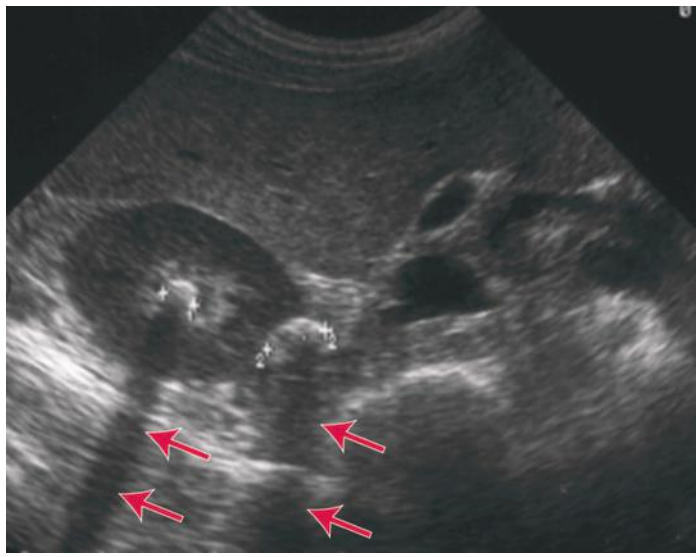

FIGURE 94-3. US of renal pelvis showing stones (marked with 1+ and 2+) with shadowing effects (***arrows***).

3.1 grams every 6 hours; or ciprofloxacin, 400 milligrams every 12 hours, if local sensitivities do not predict treatment failure.

Patients who have a ureteral stone with an associated urinary tract infection but no evidence of significant obstruction, fever, or systemic illness can be treated as outpatients, provided follow-up in 48 to 72 hours can be accomplished (see section "Disposition and Follow-Up" later in the chapter). The choice of antibiotic should cover gram-negative rods and be appropriate for antibiotic sensitivity at your institution. Resistance rates of >10% to 20% should preclude use of that antibiotic. Choices include ciprofloxacin, 500 milligrams PO twice a day for 10 to 14 days; levofloxacin, 500 milligrams PO once a day for 10 to 14 days; cefpodoxime, 200 milligrams PO twice a day for 10 to 14 days; or others predicted to be successful based on local sensitivities.

MEDICAL EXPULSION THERAPY

Medical expulsion therapy is commonly used in clinical practice and is recommended by the urologic societies.[33,34] α-Blockers are associated with increased rate of expulsion, decreased time to expulsion, and decreased pain, with a number needed to treat of 3.3 and a 2- to 6-day improvement in time to expulsion.[33,35] The benefit shown is attributable to stones in the distal third of the ureter because these were the ones most commonly included in the studies. The most commonly used agent is tamsulosin (0.4 milligram PO daily for up to 4 weeks), but terazosin (5 to 10 milligrams daily) and doxazosin (4 milligrams daily) are also as effective.[33,35] Renal colic is an off-label use of these agents; 4% of patients develop side effects including hypotension, but the drugs generally appear to be well tolerated. Calcium channel blockers, specifically nifedipine (30 milligrams PO daily up to 8 weeks), have adverse effects in approximately 15% of patients, a number needed to treat of 3.9, and time to stone expulsion reported as <28 days.[33] Some studies, including one that involved primarily ED patients, have called into question the benefit of this therapy.[36,37] One double-blinded study showed that there was no benefit in stones <6 mm.[38] Steroids are not currently recommended.[34]

DISPOSITION AND FOLLOW-UP

Most patients with stones are discharged with urologic or primary care follow-up, at which time preventive therapy may be considered based on stone type.[18] Because of lower rates of spontaneous passage, discuss disposition of patients with large (>5 mm), irregular, or proximal stones (**Table 94-5**). Also discuss with urology the disposition of patients with renal insufficiency, severe underlying comorbidities, complete obstruction, multiple ED visits associated with the stone, or associated urinary tract infection without sepsis.

Discharge is appropriate in patients with smaller stones, in the absence of infection, and when pain is controlled by oral analgesics. Give patients a urinary strainer with instructions to save any stones they pass for pathologic evaluation. **Average time for stone passage varies according to size and location but may range up to 7 to 30 days for stones 5 to 6 mm in diameter.** Patients should be counseled to return promptly for fever, vomiting, or uncontrolled pain. A prescription for an oral opiate and NSAIDs should be provided, as well as for medical expulsive therapy if used. Follow-up with a urologist within 7 days should be recommended.

TABLE 94-5 Indications for Admission in Patients with Nephrolithiasis

Absolute Indications for Admission	Relative Indications for Admission
Intractable pain or vomiting	Fever
Urosepsis*	Solitary kidney or transplanted kidney without obstruction
Single or transplanted kidney with obstruction*	Obstructing stone with signs of urinary infection
Acute renal failure	Urinary extravasation
Hypercalcemic crisis	Significant medical comorbidities
Severe medical comorbidities/advanced age	Stone unlikely to pass—large stone above the pelvic brim

*Indication for urgent decompression.

If the stone passes in the ED, no further treatment is required. Elective urologic consultation is recommended so that the etiology of the stone is evaluated and a prophylactic strategy can be arranged. **Patients with hematuria, negative imaging studies, and no other source require outpatient urologic follow-up to determine the cause of hematuria.**

SPECIAL POPULATIONS/CONSIDERATIONS

PREGNANCY

Stones occur in 1 in 1500 pregnancies, and 80% to 90% present in the second or third trimester. The presentation is the same as in nonpregnant patients with flank pain (89%) and hematuria (95%). The study of choice in pregnancy is US to identify hydronephrosis. Unfortunately, up to 90% of pregnant patients display physiologic hydronephrosis. US techniques recommended to improve sensitivity and diagnostic accuracy include endovaginal approach and looking for ureteral jets and calculating resistive indices for the kidneys.[39] If US does not provide the information necessary for management, low-dose CT[40,41] or MRI[42] should be considered in consultation with a urologist and obstetrician. **The radiation doses for various imaging modalities for stones are as follows: kidney-ureter-bladder, 0.05 to 0.15 cGy; three-film IV pyelogram, 0.15 to 0.20 cGy; and CT scan, 2.2 to 2.5 cGy.**[42] The American College of Obstetrics recognizes the use of CT scan in the evaluation of emergent conditions in pregnancy, including nephrolithiasis.[43]

With regard to treatment of pregnant patients, NSAIDS are not recommended, so narcotic pain control is most commonly used. Medical expulsive therapy with α-blockers, which are category B drugs in pregnancy, is acceptable.[41]

CHILDREN

Children with stones need investigation for metabolic disease and anatomic abnormality. Up to 30% of children with kidney stones have urinary tract anomalies. CT scans are most commonly used to identify stones in the pediatric ED, although radiation exposure remains a concern. US evaluation should be considered, especially in patients with a history of stones. Treatment includes pain and nausea control. Medical expulsive therapy is not recommended in children.

PRACTICE GUIDELINES

Practice guidelines have been issued by the European Association of Urology[34] (www.uroweb.org/gls/pdf/21_Urolithiasis_LR.pdf) and the American Urological Association (http://www.auanet.org/education/clinical-practice-guidelines.cfm).

CHAPTER 95

Complications of Urologic Procedures and Devices

Elaine B. Josephson

COMPLICATIONS OF URINARY CATHETERS

Urinary catheters should be used sparingly. Indwelling urethral catheters are the most common; suprapubic catheters require a surgical procedure but have fewer infectious complications (see chapter 92, "Acute Urinary Retention"). **Most catheters are made of latex; however, silicone catheters are available for patients with latex allergy.**[1] **Table 95-1** lists the complications of urinary catheters.

TABLE 95-1 Complications of Urinary Catheters

Indwelling Urethral Catheters	Suprapubic Urethral Catheter
Infection	Local complications
Asymptomatic bacteriuria	Hematoma formation
Urinary tract infection (UTI)	Persistent leakage
Pyelonephritis	Insertion failure
Prostatitis	Infection
Epididymitis	Asymptomatic bacteriuria
Scrotal abscess	UTI
Gross and microscopic hematuria	Pyelonephritis
Creation of false lumen	Abdominal wall cellulitis
Urethral disruption	
Bladder perforation	
Mechanical obstruction	
Nondeflating catheter balloon	
Intraluminal encrustation	

TABLE 95-2 Infectious Complications of Indwelling Urethral Catheters

Symptomatic Urinary Tract Infection Type	Diagnosis Requires Symptoms
Cystitis	New onset or worsening of fever, rigors, suprapubic pain or tenderness , altered mental status, malaise, acute hematuria (compare to prior assessment); pelvic discomfort or lethargy with no other identified cause.
Pyelonephritis	Syndrome, including fever, rigors, flank pain, or costovertebral angle tenderness.
Symptomatic urinary tract infection in patients with spinal cord injury	Fever, rigors, increased spasticity, autonomic dysreflexia, or sense of unease.
Bacteremia	Diagnosis supported by correlation between blood and urine cultures.
Sepsis syndrome	See chapter 151, "Sepsis"
Suppurative Complications	
Urethritis	See chapter 93, "Male Genital Problems."
Epididymitis	See chapter 93.
Prostatitis	See chapter 93.
Abscess, scrotal, urethral	See chapter 93.

INFECTION

Catheter-associated urinary tract infections (UTIs) are one of the most common causes of nosocomial infections. The risk of infection is approximately 1% to 2% with a catheter in place for <24 hours, with the prevalence of bacteriuria reaching almost 100% for long-term catheterization (by 30 days).[2] Comorbidities that increase the risk of catheter-associated UTI include female sex, prostatic hypertrophy, creatinine >2 milligrams/dL, diabetes, advanced age, nonsurgical disease, and debilitation.[3] Microbial factors associated with an incidence of catheter-associated UTI include the source of the organisms, the specific bacteria, the route of invasion, and the duration of catheterization.

Pathophysiology In the noncatheterized urinary tract, bacteria are efficiently eliminated. In contrast, most bacterial strains that are introduced into the catheterized urinary tract are able to multiply to high concentrations in 24 hours. Bacteria may be able to gain access to the urinary tract through the catheter lumen (intraluminal) or along the catheter surface (extraluminal). The drainage tube of a urinary catheter must be opened periodically to drain the accumulated urine. If the drainage tube lumen is colonized, bacteria may ascend the collection bag and catheter, causing an infection. An infection from the catheter lumen route begins with the formation of a biofilm on the catheter's inner surface. This biofilm extends from the uroepithelium through catheters to the drainage bag and allows adherence of bacteria to a catheter or mucosal surface. Organisms become embedded within the biofilm and gain protection from the mechanical flow of urine, host defenses, and antibiotics.[2] The microbiology of catheter-associated UTI varies according to the duration of catheter placement. During short-term catheterization, infections are usually due to single organisms, most commonly *Escherichia coli*, followed by *Klebsiella*, *Pseudomonas*, *Enterobacter*, and gram-positive cocci such as staphylococci. With long-term catheterization (≤30 days), catheter-associated UTIs are usually polymicrobial from *E. coli*, *Proteus mirabilis*, *Pseudomonas*, *Morganella morganii*, and *Candida* species. These infections are usually difficult to treat due to antibiotic resistance by the infecting bacteria.[2]

Asymptomatic bacteriuria usually occurs with short-term catheterization, and removal of the catheter clears the bacteriuria. **Antibiotic treatment of asymptomatic bacteriuria in a patient with a short-term indwelling urinary catheter is not recommended**[2-5] **(unless the patient is pregnant or immediately pending a urologic procedure).** Guidelines and reviews recommend antibiotics for symptomatic catheter-associated UTI only.[2-4]

Clinical Features Signs and symptoms include fever, rigors, altered mental status, malaise, or lethargy with no other identified cause; flank pain; costovertebral angle tenderness; acute hematuria; pelvic discomfort; and in those whose catheters have been removed, dysuria, urgent or frequent urination, or suprapubic pain or tenderness. In patients with spinal cord injury, increased spasticity, autonomic dysreflexia, and sense of unease are also compatible with catheter-associated UTI.[4]

Diagnosis Diagnoses of catheter-associated UTI symptoms are listed in **Table 95-2**.[4] **Pyuria is universal for patients with long-term (>1 month) indwelling catheters; in the absence of clinical symptoms, pyuria should not be used in the diagnosis of symptomatic infection.**[2-4] Hematuria is a better indicator of infection and also may suggest urinary obstruction. Bedside US can identify urinary obstruction.[4]

Pyelonephritis (complicated UTI; see chapter 91, "Urinary Tract Infections and Hematuria") is the most common complication of catheter-associated UTI with fever. Other related infections include prostatitis, epididymitis, and scrotal abscess. Obtain urine cultures prior to empiric antibiotic therapy, and obtain blood cultures if the patient is septic or immunocompromised.[2]

Treatment **Remove the catheter if clinically feasible, or replace the catheter if it has been in place for >7 days.**[2,4] Empiric antibiotics should be instituted promptly in most cases[4] unless the fever is low grade and the clinical condition allows for time to perform cultures and continued observation.[2] Assess local resistance patterns if available before instituting therapy. Treatment for complicated UTI is reviewed in Table 91-6. Outpatient treatment for patients without clinical toxicity is presented in Table 91-5 in chapter titled "Urinary Tract Infections and Hematuria". A total of 7 total days is the recommended duration of antimicrobial treatment for patients with catheter-associated UTI who have prompt resolution of symptoms, and a total of 10 to 14 days of treatment is recommended for those with a delayed response.[4] Alter drug regimens for renal insufficiency. If candiduria exists, remove the catheter, and consider antifungal agents in symptomatic patients.[2,4]

CATHETER OBSTRUCTION AND LEAKAGE

Urethral catheters can become obstructed for many reasons, most commonly from the formation of intraluminal encrustations during long-term placement. These concretions are composed of compounds, such as ammonium magnesium sulfate (struvite) and calcium phosphate (apatite), often with urease-splitting organisms, such as *Protease* and *Morganella*. Such encrustations can increase the risk of formation of infectious stones and cause bladder trauma, leading to blood clots. A catheter obstruction may lead to urinary leakage around the catheter and acute urinary retention. Management options include repeated bladder irrigations, methenamine treatment, and removal of the catheter if the other methods fail.

NONDEFLATION OF FOLEY RETENTION BALLOON

The Foley balloon is typically inflated with 10 mL of sterile water after successful insertion. Nondeflation of the retention balloon on the catheter can be caused by a faulty valve mechanism or crystallization of balloon fluid, yielding entrapment of the Foley catheter.[6] One noninvasive method is introduction of a flexible guidewire into the balloon inflation channel after cutting off the plastic cylindrical valve from the catheter just below its head. The guidewire dilates the channel and may allow the balloon to deflate. If unsuccessful, try step 2; a 22-gauge central venous catheter can be passed over the guidewire. When the catheter tip is into the balloon, the wire can be removed, and the balloon may drain. If step 2 is unsuccessful, instill 10 mL of mineral oil and leave for 15 minutes in an attempt to dissolve the balloon. Repeat once (10 more mL of mineral oil) if unsuccessful. If simple methods do not work, urologic consultation for intervention and potential cystoscopy is recommended.[7] Another alternative is US-guided percutaneous rupture of the balloon using a needle, typically done by the radiologist in the US suite with input from urology.

COMPLICATIONS OF PERCUTANEOUS NEPHROSTOMY

Percutaneous nephrostomy is a urinary drainage procedure used for supravesical or ureteral obstruction secondary to malignancy, pyonephrosis, GU stones, and ureteral strictures. It is also adjunctive to lithotripsy and ureteral stents. Nephrostomy tubes are also used for urinary diversion associated with vesical fistula, ureteral transection, and trauma. The percutaneous procedure to remove renal calculi is known as *percutaneous nephrolithotomy*. Nephrostomy tubes or stents are commonly left in place, but the tubeless percutaneous nephrolithotomy technique may have less risk of morbidity.[8] Patients develop postoperative complications days or months after the percutaneous nephrostomy. In general, the risk of complications is low and includes bleeding, infection, mechanical complications related to the catheter (dislodgement or obstruction), and accidental punctures of adjacent organs.[8]

During insertion, injury can occur to the renal collecting system (subintimal dissection), lungs (pneumothorax), liver, spleen, and bowel (perforation).[9] This complication usually is clinically apparent during or immediately after the procedure, but recognition may be delayed a few days.[9]

Bleeding and hemorrhage can occur, especially if the patient has a coagulopathy. Check hemoglobin, hematocrit, and renal function. Obtain coagulation studies (prothrombin time, partial thromboplastin time, and platelet count) and type and cross-match if bleeding is excessive or if coagulopathy is suspected. Most bleeding episodes are mild and can be managed with irrigation to clear nephrostomy tube blood clots. More severe bleeding can be handled by catheter tamponade, a procedure undertaken by the urologist and radiologist. Severe hemorrhage occurs from vascular injury, such as laceration of an artery, formation of an arteriovenous fistula, or bleeding from a pseudoaneurysm, and may occur in the retroperitoneal space or perirenal areas. In such cases, fluid resuscitation and blood transfusion, in addition to more definitive interventions, are required. Angiographic studies with possible embolization may be needed to ascertain the site of bleeding and effect treatment.[9] Infectious complications from nephrostomy tubes include simple bacteriuria, pyelonephritis, renal abscess, bacteremia, and urosepsis. Signs and symptoms are fever, chills, rigors, pain, and purulent drainage at the site or from the tube. Obtain urine and wound drainage (if present) cultures, and give antibiotics after consultation with the urologist.

Mechanical complications, such as catheter dislodgement, tube blockage, and residual stone fragments, can occur with these devices. CT scan may be helpful for specific diagnosis. The risk of catheter dislodgement increases with increasing duration of the nephrostomy. Dislodgement occurring in the early postoperative period usually requires creation of a new tract at a different site. Dislodgement occurring after some period may be treated by recannulation under fluoroscopic guidance. Tube blockage can occur secondary to encrustations and kinking. The urologist has several techniques available to reestablish access to an obstructed nephrostomy tube.[8,9]

URINARY DIVERSION AND ORTHOTOPIC BLADDER SUBSTITUTION

The most common method of urinary diversion in the United States is the ileal conduit. With this procedure, a section of small bowel is isolated, and the free ends of the remaining small bowel are reunited, allowing for normal bowel function. The ureters are reimplanted to the isolated section of small bowel, most commonly at the base of the conduit. A stoma is created, typically on the anterior abdominal wall, where a collecting bag is attached. Postoperative complications include bowel obstruction, pyelonephritis, skin breakdown surrounding the stoma, stenosis of the stoma, and inflammatory changes of the upper tract due to reflux of urine back into the ureters. Complications occur in 66% of patients, including deterioration in kidney function (27%), stoma stenosis or infection (24%), bowel obstruction or symptoms (24%), symptomatic UTI/pyelonephritis (23%), conduit/ureteral anastomosis dysfunction (14%), and urolithiasis (9%).[10]

There are multiple newer methods of creating a neobladder for orthotopic bladder substitution. These methods all have a goal of creating a continent reservoir for urine without reflux of the urine into the reimplanted ureters, which predisposes the patient to pyelonephritis. Options include other means of isolating portions of the small bowel (Kock pouch, T pouch, "W" shape neobladder) or large bowel (ileocecal segment). An evidenced-based evaluation of multiple methods has failed to identify a superior procedure.[11] Bacteriuria is common after the procedure (85%) and mostly involves skin flora but may occasionally include uropathogenic strains (gram-negative Enterobacteriaceae species like *E. coli*, *Proteus*, *Pseudomonas*, and *Enterococcus faecalis*).[2,3,12] Clean intermittent catheterization, frequently required after procedure, is associated with increased bacteriuria and pyuria. **Diagnosis of infection should be made on evidence of symptomatic infection based on fever, flank pain, a change in chronic symptoms, or culture of pathologic organisms.** A threshold of at least 10^4 colony-forming units/mL should be used as the criterion for a positive culture.[13] Consultation with urology may be required for optimal management.

LITHOTRIPSY

Extracorporeal shock wave lithotripsy is the application of repetitive high-intensity sound waves to fragment GU calculi so they can pass down the ureter more easily.[14] Common complications include colicky pain in 15% to 40%, gross hematuria in 32%, skin bruising in up to 26%, and steinstrasse ("street of stone," aggregate of stone fragments lining and/or impacting the ureter) in up to 24%.[15-17] Uncommon complications include spleen rupture, kidney rupture, pyelonephritis/sepsis, bowel injury, ureteric perforations, psoas abscess, vascular injury, and pancreatitis (a small rise in lipase is common).[15-18] Postlithotripsy patients may present with abdominal and flank pain, nausea, vomiting (especially 48 hours after procedure), skin ecchymosis, gross hematuria, or fever in up to 30%. Uncommonly, patient may be unstable with hypotension or sepsis. Hematuria is generally self-limited (<24 hours); however, UTI may be coexistent. Diagnosis of minor complications usually requires blood counts, basic chemistries, urinalysis, and renal US if obstruction is suspected. CT scan or MRI (only if stable) is indicated if the serious complications are suspected (consider with flank hematoma, fall in hematocrit, hypotension, syncope, or significant pain). Acute management may include IV fluid hydration, antiemetics, analgesics, monitoring, fluid resuscitation, blood transfusions, and antibiotics. Most patients are managed conservatively with close monitoring of hemodynamic status, urine output, and laboratory studies to assess for decreasing hematocrit and renal function. Consult urology early on, because specific treatments, such as embolization and nephrectomy, may be required.[14]

COMPLICATIONS OF URETERAL STENTS

Ureteral stents are used primarily in patients to relieve ureteral obstruction and maintain ureteral lumen patency. Obstruction to the ureter may result from causes such as stones, strictures, trauma, malignancies, or

TABLE 95-3 Complications of Ureteral Stents

Complication	Management
Fever with pyelonephritis or sepsis	Admission, IV antibiotics, consult urology
Simple urinary tract infection (UTI)	Oral antibiotics
Microscopic hematuria/gross hematuria	Microscopic hematuria is expected, consult urology for gross hematuria
Pyuria	Treat if coexistent bacteriuria
Irritative bladder symptoms	Analgesics, anticholinergics, rule out UTI
Dysuria/urgency/frequency	Analgesics, anticholinergics, rule out UTI
Flank pain/abdominal pain	Analgesics, anticholinergics, rule out UTI
Pain with voiding	Analgesics, anticholinergics, rule out UTI
Incontinence	Analgesics, anticholinergics, rule out UTI
Obstruction	Consult urology
Stent migration/stent fragmentation	Consult urology
Encrustation	Consult urology if obstructed
Erosion of the urinary tract	Consult urology
Vascular-ureter fistula	Consult urology, resuscitation
Malposition	Consult urology
Stent malfunction	Consult urology

retroperitoneal fibrosis. Stents can be placed during ureteroscopy, by the percutaneous nephrostomy route, during surgery involving the GU tract to maintain urinary patency and drainage, and in very specific cases as an adjunct to lithotripsy in the management of nephrolithiasis. **Table 95-3** lists the complications of ureteral stents.

Many factors contribute to stent-related UTIs. Stents induce a foreign body reaction, which increases the risk for infections. Encrustation of stents in the presence of infection with urea-splitting organisms also promotes infection. More serious infections, such as pyelonephritis and sepsis, can occur but are less common.

Most minor infections can be managed with outpatient antibiotics and do not require stent removal (see antibiotic recommendations for catheter-associated UTI in the "Infection" section above). If pyelonephritis or a systemic infection is suspected, IV antibiotics, radiologic studies to determine the position of the stent, and urologic consultation are required. Stents usually can be visualized by plain abdominal x-rays due to the presence of radiodense marking embedded within the catheters. US imaging can detect hydronephrosis, along with confirmatory CT studies if obstruction or pyelonephritis is present.[19,20]

Symptoms, such as mild flank pain, and signs suggestive of an irritative bladder, such as dysuria, urgency, frequency, incontinence, and pain during voiding, occur commonly in patients with ureteral stents. Treatment options for these symptoms can include analgesics and anticholinergic medications and obtaining urine specimen to exclude UTI. New complaints and symptoms, such as severe flank pain, require evaluation for stent migration, infection, or obstruction. Asymptomatic microscopic hematuria is usually of no clinical significance, but gross hematuria may indicate stent migration or ureteral erosion. Imaging studies are needed to identify stent position.[19,20]

Serious problems, such as stent migration and stent fragmentation—or even rarer, ureteral-arterial fistulization due to stent erosion into a nearby vessel—are usually late complications seen with long-term stent placements. Stent migration can occur upward above the ureteropelvic junction or downward below this junction. See **Figure 95-1** for a radiographic demonstration of ureteral stent migration. Such migration can lead to obstruction and infections. Stent migration results in symptoms of new-onset abdominal pain, fever, and irritative bladder symptoms and hematuria.[19,20] For new anemia without hematuria, obtain a CT without contrast to rule out a stent-caused retroperitoneal hematoma.[21] In the presence of severe gross hematuria and syncope or hypotension, assume vascular fistulization from an eroding stent exists until proven otherwise.[21] Resuscitate with IV fluids, and conduct lab studies, bladder irrigation as indicated, and possible blood transfusion. Serious complications require immediate consultation with the urologist, and depending on the case, a surgeon and radiologist may need to be consulted.

FIGURE 95-1. Ureteral stent migration. This abdominal plain film demonstrates stent migration with the distal portion of the stent coiled within the bladder. [Reproduced with permission from Cline D, Stead L: *Abdominal Emergencies*. © 2008, McGraw-Hill Inc., New York.]

PROSTATE SURGICAL PROCEDURES

Prostate surgery is commonly performed for symptomatic benign prostatic hyperplasia or prostate cancer. Surgical techniques include prostate needle biopsy, transurethral resection of the prostate, transurethral electrovaporization of the prostate, transurethral microwave thermotherapy of the prostate, transurethral needle ablation of the prostate, and visually assisted laser prostatectomy.[22,23] Complications include urinary retention (3%), clot retention (2%), UTI (1.7%), and bleeding requiring transfusion (0.4%). Less common complications include blood per rectum, urethral strictures, and urosepsis.[22,23] Patients may also experience obstructive or irritative voiding symptoms, including incontinence, dysuria, hesitancy, dribbling, urgency, and frequency.

Depending on severity of illness, appropriate laboratory studies may include urinalysis, CBC, blood type and screen, blood chemistries, and renal function. Assess for hemodynamic instability and treat with IV fluids or blood for life-threatening bleeding. Patients with outflow obstruction should be treated with a three-way Foley catheter. Start with manual irrigation to remove clots, and then initiate continuous irrigation with normal saline until clear or slight pink return.[6] If bleeding does not clear, consult urology. **Prolonged irrigation requires monitoring of serum electrolytes to assess for hyponatremia.**[6] If infection is suspected, obtain urine cultures, administer antibiotics, and consult with the urologist.

COMPLICATIONS OF ARTIFICIAL URINARY SPHINCTERS

The artificial urinary sphincter is used for urinary incontinence secondary to sphincter disturbance, postsurgical incontinence, neurogenic bladder with incontinence, trauma to the urethra, and congenital conditions associated with bladder dysfunction, such as exstrophy and epispadias. There are many different models of sphincter devices. The basic principle of the artificial sphincter is to increase the resistance around the urethra and, thus, provide urinary continence.[24,25] Mechanical parts of the artificial sphincter include a pump, an inflatable cuff that encircles the urethra, and a pressure-regulating reservoir balloon

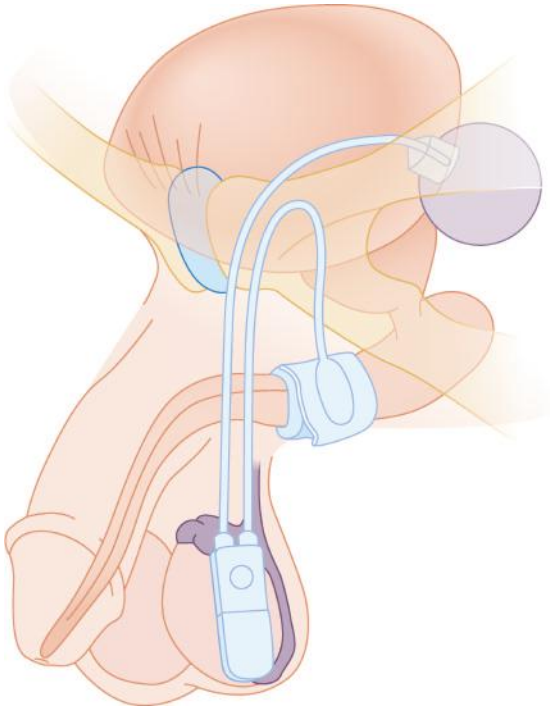

FIGURE 95-2. Diagram of artificial urinary sphincter. [Adapted with permission from James MH, McCammon KA: Artificial urinary sphincter for post-prostatectomy incontinence: a review. *Int J Urol* 21: 536, 2014. Copyright John Wiley & Sons.]

(**Figure 95-2**). These are connected by a set of two tubes. Continence occurs when fluid is moved from the balloon to the cuff. To allow urination, the cuff is emptied, and fluid moves to the reservoir. Both activities are controlled by the pump, which is implanted in the scrotum of males or the pelvis of females.[25]

Postoperative complications can include bleeding (including hematoma), infection, and malfunctions. Hematomas usually occur in the scrotum or the labia, and most resolve spontaneously. Larger hematomas may need to be drained to aid with the healing process (consult the surgeon).[24,25]

Infections are the most serious complication of the artificial sphincter. Periprosthetic infection can present early or late after surgical implantation. Infections occurring early after implantation are usually due to skin flora. Later infections are usually due to gram-negative organisms of the urinary tract. Symptoms and signs of infection can range from pain, swelling, and induration of the site to localized erythema of the pump or cuff site. More serious infections can present with fever, cellulitis, local abscess formation, drainage from incision sites, and erosion of the pump or the cuff. Infections can cause the components (e.g., cuff) to externalize out onto the skin or erode the urethra.[26] Treatment of periprosthetic infection requires antibiotics and removal of the sphincter. Patients with an artificial sphincter in place should receive antibiotic prophylaxis when undergoing procedures that may cause hematogenous seeding of the device, such as dental procedures.[26]

Retained air bubbles, tube kinking, fluid leaks, and perforation of the cuff are some of the mechanical complications that can occur with the artificial sphincter. Air bubbles can cause blockage of the pump, leading to filling defects and, thus, incontinence. Ineffective device functioning secondary to fluid leakage also can lead to sudden onset of incontinence. Tube kinking, a rare complication, can result in fluid blockage, thereby leading to urinary retention. A careful history may provide clues to malfunction. A pump that is difficult to squeeze implies blockage due to any cause, whereas a pump that remains compressed after squeezing signifies pressure loss or fluid leakage. Incorrect urinary catheterization and damage to the device components during other nonurologic surgeries may account for iatrogenic malfunction of the artificial sphincter. Plain radiographs of the pelvis and other imaging studies are used to assess continuity of the mechanical components.[24,25]

Urethral erosion secondary to infection or excessive cuff pressure around the urethra is another serious complication and one that is seen most commonly within several months after the implantation. Signs and symptoms include pain, swelling along the urethra and in the perineum, urinary incontinence, bloody urethral discharge, and infection. Cystourethroscopy and cuff removal are necessary for management of erosions.[24-26]

Recurrent incontinence after artificial sphincter placement can have many causes—infection, cuff erosion, fistulas due to surgical injuries, or mechanical failure. Evaluation requires urodynamic studies to accurately define the cause. Acute urinary retention in a patient with an artificial sphincter implant may occur as a result of bladder neck contractures, urethral strictures, or cuff erosion. Evaluation usually requires cystourethrography or cystourethral endoscopy.

Evaluation in the ED of complications related to the artificial sphincter requires a thorough history noting the model type and make; symptom assessment; a detailed physical examination; urinalysis; appropriate labs, cultures, and imaging studies; and consideration for IV antibiotics as indicated. **Never introduce a urethral urinary drainage catheter through an artificial urinary sphincter.** Consult the urologist for further evaluation and management.

COMPLICATIONS OF DEVICES FOR ERECTILE DYSFUNCTION

The most common causes of erectile dysfunction are diabetes, priapism, vascular disease, Peyronie's disease (deformity especially seen on erection due to nodules/fibrous plaques in penile tissue), pelvic trauma or surgery, spinal cord injury, and psychogenic reasons. Although oral medication and penile injectable device treatment currently exist for erectile dysfunction, some patients with erectile dysfunction fail pharmacologic therapy and are treated with nonpharmacologic interventions such as vacuum therapy, external splint devices, and the surgically implantable prostheses.[27] Two forms of injection therapy for erectile dysfunction are available: intracavernosal and intraurethral.

INTRACAVERNOSAL INJECTIONS

The intracavernosal injections are given along the lateral aspect of the penis, directly into the corpora cavernosa. The basic mechanism involves vasodilatation of arteries and veins leading to corporal smooth muscle relaxation and penile erection. Drugs used are papaverine, phentolamine, and alprostadil, a prostaglandin E_1 analog, singly or in combination. Side effects include penile pain, prolonged erections (4 to 6 hours), priapism (painful erection for longer than 6 hours), and localized hematoma. Of these, priapism is the most critical complication. Management of priapism includes emergent urology consultation for direct injection of terbutaline or α-adrenergic agonists, such as phenylephrine, and corporal aspiration of blood (see chapter 93).[28]

INTRAURETHRAL INJECTION

Intraurethral injections of alprostadil are successful in producing penile engorgement. One marketed product, the MUSE® (medicated transurethral system for erection), uses a medicated pellet via an applicator that allows insertion of the drug into the urethra. The basic mechanism of intraurethral administration is similar to intracavernosal injections. The drug is absorbed from the urethra and through the local communicating vessels and exerts its actions on the corpora. Side effects are few and can include penile pain, urethral bleeding, laceration of the cavernosal artery, and dizziness. Very rarely, priapism can occur. Intraurethral administration is usually free of any major systemic side effects, but syncope secondary to a vasovagal reaction due to the anxiety of the injection and the vasodilatory effects of the drug can occur.[29]

VACUUM DEVICES AND PENILE SPLINTS

Vacuum devices work by use of negative pressure and the use of a constriction ring to cause venous and arterial congestion, thus causing penile engorgement. The most common complaint reported is pain during application of the device and during ejaculation secondary to

inappropriate pressure rise. Both symptoms can be resolved with proper education on use of the device. Local skin cyanosis secondary to a drop in penile blood flow from the negative pressure may also be seen. Serious complications from the use of a vacuum device include penile skin necrosis, urethral bleeding, ischemia, and subcutaneous hemorrhage with ecchymosis. Peyronie's disease and Fournier's gangrene have also been reported.[30]

The external penile splint consists of two steel support rods in a silicone cover that have a support loop at the distal end, to loop around the subcoronal sulcus, and support rings at the proximal end, to position around the base of the penis. Aside from occasional dislodgement during sexual intercourse, these splints are relatively free of side effects.[27]

PENILE PROSTHESES

Surgical implantation of a penile prosthesis is reserved for men who fail pharmacologic treatment. Several different kinds of implantable penile prostheses are used: the malleable or semirigid devices, and inflatable types that contain fluid to give a more natural erection. The malleable or semirigid device consists of implanted semirigid rods and is always somewhat firm. The penis may be positioned away from the body to achieve penetration. There are self-contained and three-piece inflatable devices. The self-contained device consists of a pair of inflatable cylinders inserted in the cavernosa and a scrotal pump. The three-piece device is composed of a pair of inflatable cylinders, a scrotal pump, and an abdominal fluid reservoir. Postoperative urinary retention, penoscrotal hematoma formation, and superficial wound infections have been reported. Infection is the most devastating of all penile prosthesis complications and usually occurs soon after the primary surgery for implantation. Late infections can occur years after the procedure secondary to seeding through the bloodstream. Organisms causing penile prosthesis infection are typically *Staphylococcus epidermidis*, *Staphylococcus aureus*, and gram-negative bacilli. Infections present as pain along the device (e.g., in the scrotum or along the penis), erosion, and purulent urethral discharge. Treatment requires antibiotics and removal of the entire device by the urologist.[29,30]

Erosion of the prosthesis can occur into penile tissue and often is accompanied by an infection in the same area. Migration of the device may occur proximally or distally, presenting as extrusion through the urethral meatus. Erosion problems and device migration require consultation with the urologist for removal of the prosthesis. Penile ischemia and necrosis are rare but serious complications occurring mainly in patients with predisposing factors such as diabetes and vascular disease. Mechanical failures may occur, such as pump autoinflation or fluid leakage from tubing, cylinder, or reservoir. Evaluation of mechanical problems requires an assessment of the device by a urologist.[27,29]

VASECTOMY

With few exceptions, vasectomies are completed in the urologist's office. Complications of infection, symptomatic hematoma, and chronic scrotal pain occur in 1% to 3%.[31] Less common complications include bleeding and scrotal hematoma, local wound infections (cellulitis and abscess), epididymitis, and painful sperm granulomas. Patients may develop persistent testicular pain or congestive epididymitis (pain and testicular tenderness on the affected side) months to years later.[31]

Evaluate for infection especially if the patient is immunosuppressed, and treat accordingly; consider scrotal US and consult urology for deep abcess (see chapter 93). When there is no evidence of bleeding or wound infection, treat postvasectomy epididymitis with ice packs, scrotal support, and analgesia with nonsteroidal anti-inflammatory drugs or opiates.

ADULT CIRCUMCISION

Circumcision, or foreskin resection, is usually performed on infant males. However, the procedure is also performed in adolescents and adults.[32] Complications after circumcision include bleeding and infection (most common), pain, hematomas, swelling, suture tears, and wound dehiscence due to premature erection before completion of healing. Treat minor bleeding with direct pressure, or a topical thrombostatic agent as needed. Administer oral antibiotics (trimethoprim-sulfamethoxazole or ciprofloxacin) with local wound care for minor infections. Give analgesia as indicated. Consult urology for significant bleeding or infection.

CHAPTER 96

Abnormal Uterine Bleeding

Bophal Sarha Hang

INTRODUCTION

Abnormal uterine bleeding is an overarching term that is defined as bleeding from the uterine corpus that is irregular in volume, frequency, or duration in absence of pregnancy (**Table 96-1**).[1] Vaginal bleeding is a common complaint in the ED, and differential diagnoses include pregnancy, structural abnormalities (e.g., polyps, fibroids), endometritis, coagulopathies, trauma, and various other causes. The prevalence of abnormal bleeding is estimated at 9% to 14% in the general population. Although vaginal bleeding may present as an acute or chronic problem, this chapter will focus on the ED evaluation and management of abnormal uterine bleeding.

MENSTRUAL CYCLE

In North America, average age of menarche is 12.5 years of age, approximately 2 years after the development of thelarche (breast budding). Early cycles are often anovulatory and irregular due to the immaturity of the hypothalamic-pituitary axis. Regular ovulatory cycles develop on average 2 years after the start of menarche.

The normal menstrual cycle is 28 days and is divided into four phases: menses, follicular, ovulation, and luteal or secretory. **Figure 96-1** depicts hormonal and endometrial changes associated with a normal menstrual cycle.

In response to the rising estrogen levels, the pituitary gland secretes follicle-stimulating hormone and luteinizing hormone, which stimulates the release of the mature oocyte. The residual follicular capsule forms the corpus luteum. During the luteal phase, the corpus luteum secretes estrogen and progesterone, which maintains the integrity of the endometrium and makes it more receptive to implantation. If fertilization and implantation occur, the developing embryo secretes human chorionic gonadotropin into the bloodstream, signaling the corpus luteum to continue the production of progesterone and estrogen necessary to support early pregnancy. In the absence of human chorionic gonadotropin, the corpus luteum involutes, and estrogen and progesterone levels fall. Hormonal withdrawal causes vasoconstriction in the spiral arterioles of the endometrium. As a consequence, the ischemic endometrial lining becomes necrotic and sloughs, which leads to menses. The vaginal effluvium contains blood, endometrial tissue, and fluid. The average amount of menstrual blood loss ranges from 25 to 60 mL.

The average tampon or pad absorbs 20 to 30 mL of vaginal effluent. However, judging the amount of blood loss by usage may be unreliable because personal habits vary greatly among women. In women with heavy bleeding, there may be insufficient time for fibrinolysis, so blood clots form.

TABLE 96-1 FIGO Terminology for Bleeding*

Type	Definition
Abnormal uterine bleeding	Bleeding that is abnormal in regularity, volume, frequency, or duration. Bleeding may be acute or chronic and is present for at least 6 months.
Heavy menstrual bleeding *(heavy uterine bleeding [HUB] replaces menorrhagia)*	Excessive menstrual bleeding that interferes with a woman's physical, emotional, social, and quality of life. Note that the definition is menstrual bleeding deemed excessive by the patient regardless of duration, frequency, or timing.
Amenorrhea	Bleeding that is absent for >6 months.
Prolonged menstrual bleeding	Menstrual bleeding that is absent for >6 months.
Intermenstrual bleeding *(replaces metrorrhagia)*	Bleeding episodes between normally timed menstrual periods.
Irregular menstrual bleeding	Unpredictable onset of menses, with cycle variations >20 days over a period of 1 year.
Postmenopausal bleeding	Any bleeding that occurs >12 months after cessation of menstruation.

Abbreviation: FIGO = International Federation of Gynecology and Obstetrics.

*Discarded terms include dysfunctional uterine bleeding, menorrhagia, functional uterine bleeding, hypermenorrhea, hypomenorrhea, menometrorrhagia, metrorrhagia, oligomenorrhea, polymenorrhea, and uterine hemorrhage.[2]

CLINICAL FEATURES

HISTORY

Obtaining a focused medical history should include details of current bleeding episode, associated symptoms, and past medical history including reproductive and sexual history (**Table 96-2**). Pregnancy-related bleeding should always be considered and ruled out in reproductive-age patients. Patients may describe heavy bleeding as soaking of more than one pad or tampon within 1 hour or passing large clots. **Up to 20% of women with heavy uterine bleeding have an underlying coagulation disorder, with von Willebrand's disease being the most common.** Screening for history of heavy menstrual bleeding since menarche, postpartum hemorrhage, surgery- or dental-related bleeding, and family history may help guide further evaluation for bleeding disorders. It is also important to ask about oral contraceptive use because missed doses are a frequent cause of bleeding. Questions about drug interactions and smoking are also important in determining the cause of bleeding.

To obtain an accurate sexual history from an adolescent patient, assure physician confidentiality and maintain a nonjudgmental attitude. If a female physician is requested, try to honor the request if at all possible. Always ask the parents for an opportunity to interview the patient without the parent present. Furthermore, all states allow minors to consent to diagnosis and treatment of sexually transmitted diseases and drug abuse without parental consent.

PHYSICAL EXAMINATION

The initial assessment includes evaluation of vital signs and hemodynamic status. However, significant signs of volume depletion may not be present until bleeding is profuse. Perform a focused physical examination including pelvic (speculum and bimanual) and abdominal exam to determine the cause of bleeding and to exclude life-threatening blood loss requiring emergent surgical intervention. Look for signs of other illnesses, including hyper- and hypothyroidism, galactorrhea, obesity associated with hirsutism, and liver disease. Petechiae, purpura, and mucosal bleeding require hematologic investigation.

For pelvic examinations in the ED, both male and female physicians are equally advised to have a chaperone present. Decisions regarding parent or guardian presence during examination of adolescents depend

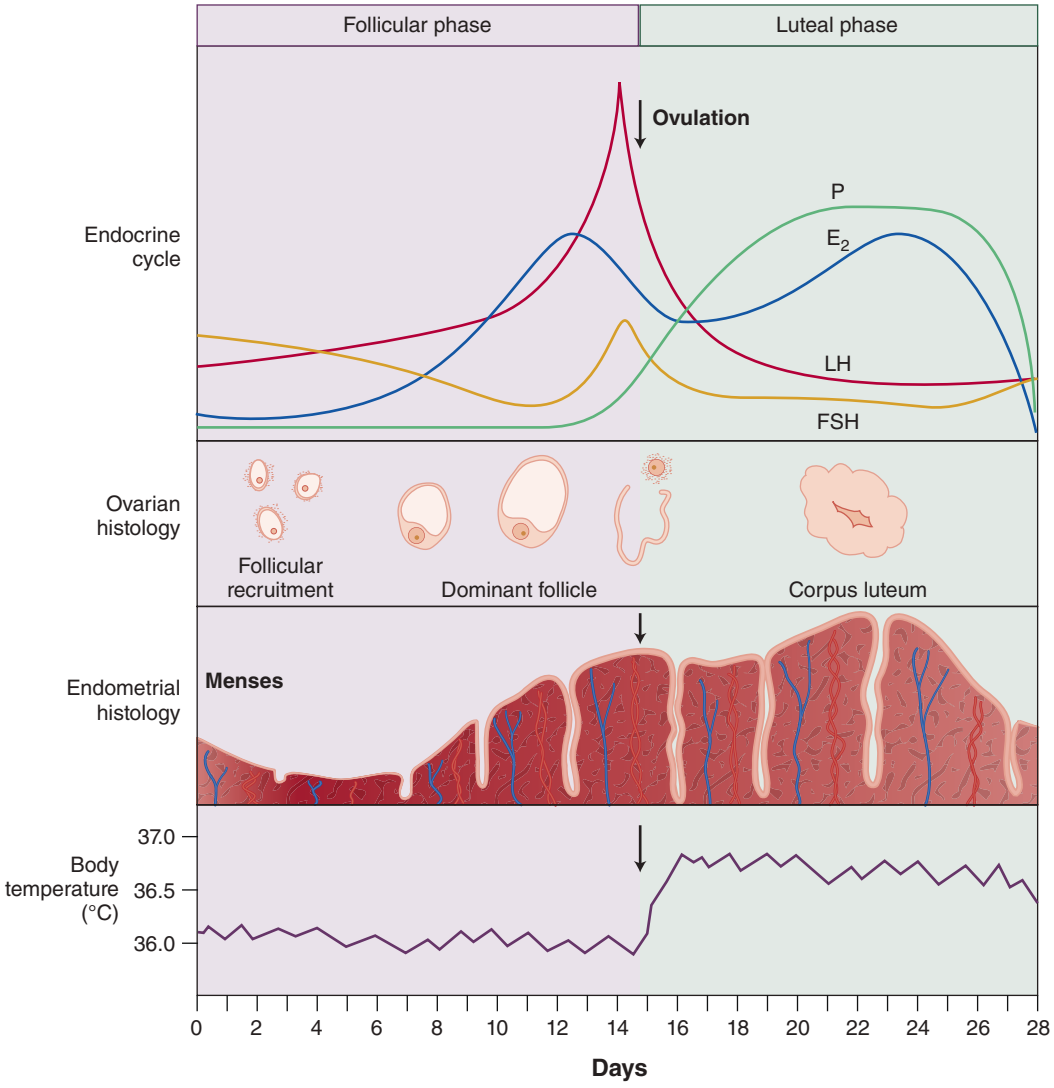

FIGURE 96-1. The hormonal, ovarian, endometrial, and basal body temperature changes and relationships throughout the normal menstrual cycle. E_2 = prostaglandin E_2; FSH = follicle-stimulating hormone; LH = luteinizing hormone; P = progesterone. on the patient's age and maturity level. Inspect the perineum, vulva, urethra, and perianal region before internal speculum exam. Evaluate the vaginal canal and cervix for lacerations, fissures, lesions, infection, tumors, and foreign bodies. On bimanual examination, determine the softness and patency of the cervical os, and ask about pain on cervical movement. Palpate the uterus and adnexa for size, consistency, tenderness, and masses.

In a virginal patient, a rectovaginal digital examination is generally sufficient. In the case of trauma, concern for sexual abuse, or vaginal foreign body, a vaginal examination is necessary. Adolescents with intact hymen can generally tolerate a speculum examination if a narrow Pederson-type adolescent or Huffman pediatric speculum is used. Conscious sedation or full anesthesia may be required, depending on the psychological response of the patient, the circumstances, and the extent of the injury or disease.

Several techniques may help facilitate performing a pelvic examination in elderly women, including using a smaller speculum with generous lubrication and proper positioning. Age, immobility, and degenerative joint disease may make it difficulty to place the patient in the dorsal lithotomy position. Patients may be positioned supine, with the head supported with a pillow, and with knees flexed and with hips externally rotated (frog-leg position). The pelvis may be elevated using padding or an upside-down bedpan. If vaginal bimanual examination cannot be performed due to vaginal atrophy, a recto-abdominal approach may be attempted. Abnormalities such as irregular nodules, masses, or thickened rectovaginal septum may suggest malignancy.

CAUSES OF VAGINAL BLEEDING

The causes of abnormal vaginal or uterine bleeding in nonpregnant females are classified into structural and nonstructural causes, using the acronym: PALM-COEIN: **P**olyp, **A**denomyosis, **L**eiomyoma, **M**alignancy and hyperplasia, **C**oagulopathy, **O**vulatory dysfunction, **E**ndometrial, **I**atrogenic, and **N**ot otherwise classified.[2] Causes of bleeding based on age are shown in **Table 96-3**. The term *abnormal uterine bleeding* encompasses all causes of abnormal bleeding in nonpregnant women, and the most likely causes are largely determined by patient age. Because the first clinical signs of heavy menstrual bleeding (heavy uterine bleeding) are noted after the onset of menses during early adolescence, structural causes are uncommon. Anovulatory and bleeding disorders are most common during this time period (ages 13 to 19). **Pregnancy-related complications become the most common cause of abnormal vaginal bleeding during the reproductive years.** Issues regarding pregnancy are covered in chapters 98, "Ectopic Pregnancy and Emergencies in the First 20 Weeks of Pregnancy" and 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period."

Abnormal uterine bleeding as a result of local structural pathology such as polyps and fibroids is not typically seen until women reach their

TABLE 96-2 Important Historical Elements in Uterine Bleeding

Category	Details
Reproductive history	Age of menarche Menstrual history Date of the last menstrual period Pattern of normal and abnormal bleeding or discharge Presence of dysmenorrhea
Sexual history	Current sexual activity Contraception Use of barrier protection Pregnant—yes/no? Gravida and para Previous abortion or recent termination History of ectopic pregnancy History of pelvic inflammatory disease, sexually transmitted diseases, human immunodeficiency virus, and hepatitis status
History of trauma	—
Possibility of retained foreign body	—

Past medical history	Signs and symptoms of coagulopathy, including nosebleeds, petechiae, and ecchymoses Endocrine disorders, including diabetes, pituitary tumors, polycystic ovary disease, hyperthyroidism, and hypothyroidism Liver disease
Associated symptoms	Urinary, GI, musculoskeletal symptoms; fever or syncope

mid 30s. Perimenopausal anovulatory bleeding is typically seen in the mid to late 40s. Postmenopausal bleeding is often related to atrophic vaginitis, exogenous hormones, and malignancy. A summary of the causes by age is provided in **Table 96-3**.

STRUCTURAL CAUSES OF VAGINAL BLEEDING

POLYPS

Endometrial and endocervical polyps are epithelial proliferations that most often are benign. Although most polyps are asymptomatic, polyps can be a cause of abnormal uterine bleeding in women older than 35 years. A common symptom is intermenstrual bleeding, and diagnosis is made on hysteroscopy.

ADENOMYOSIS

Adenomyosis is the presence of endometrial glands and stroma within the myometrium. The histopathology is often diffuse within the uterus, but localized areas of growth are called adenomyomas. Symptoms include painful, heavy periods most commonly seen in the fourth and fifth decade of life. ED management is aimed at symptomatic treatment, analgesics, and evaluation for anemia. Leuprolide acetate (Lupron), a gonadotropin-releasing hormone analog plus add-back therapy, or a levonorgestrel intrauterine device (Mirena) for 6 months may be initiated as an oupatient.[3] MRI is the imaging modality of choice, but US is a good alternative. Patients with severe bleeding unresponsive to medical management often require surgical management.

LEIOMYOMAS

Uterine fibroids (also called leiomyoma or myoma) are the most common benign tumors of the pelvis in women; an estimated 25% of white women and 50% of black women have fibroids in their reproductive years. This number increases with age. The cause is unclear, but fibroid growth is dependent on genetic factors and hormones: gonadotropin-releasing hormone, estrogen, and progestin. Leiomyomas decrease in size during menopause. In some cases, fibroids will enlarge early in pregnancy and with oral contraceptive pill use. Most fibroids are asymptomatic, but up to 30% of patients with leiomyomas experience pelvic pain and abnormal bleeding. Acute pain is rare, but severe pain may be experienced with torsion or degeneration. Degeneration results from rapid growth and loss of blood supply, often seen during early pregnancy. A rare case of spontaneous fibroid rupture causing massive intra-abdominal hemorrhage has been reported in the literature.[4]

Signs and symptoms of fibroids vary depending on fibroid size and location. Large fibroids may be palpated on abdominal or rectal exam. Symptoms of acute degeneration include tenderness, rebound guarding, fever, and elevated WBC count. Pedunculated subserosal leiomyomas may undergo torsion or cause uterine cramping. Rapid growth at any age or growth after menopause is highly suspicious for malignant transformation. The best diagnostic test is ultrasonography and is as sensitive as MRI.

The management of uterine fibroids depends on the severity and duration of symptoms. In the ED, management is focused on treating complications associated with fibroids. Iron deficiency anemia is often long-standing and may require a blood transfusion. Other complications are rarer, but constipation, urinary retention, vaginal or intraperitoneal hemorrhage, deep vein thrombosis, and mesenteric thrombosis have been reported.[5] Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstays for analgesia in the ED. Medical management with hormonal agents may be initiated in the ED with gynecologic consultation. Intrauterine fibroids are treated surgically with hysteroscopy. Surgical removal is associated with a 25% to 30% rate of recurrence and significant bleeding complications. Uterine artery embolization is an effective treatment for symptomatic fibroids, resulting in decreased fibroid volume and alleviation of symptoms.[6-8]

MALIGNANCY

Any malignancy of the genital tract, in particular endometrial or cervical cancer, may produce bleeding. **Consider endometrial hyperplasia or endometrial cancer in women >45 years old or in younger women**

TABLE 96-3 Causes of Bleeding by Age Group*

Adolescent	Reproductive	Perimenopausal	Postmenopausal
Anovulation (hypothalamic-pituitary-ovarian immaturity)	Pregnancy	Anovulation	Atrophic vaginitis (30%)
Pregnancy	Anovulation (PCOS)	Uterine leiomyomas	Exogenous hormone use (30%)
Exogenous hormones or OCP	Exogenous hormone use or OCP	Cervical and endometrial polyps	Endometrial lesions, including cancer (30%)
Coagulopathy	Uterine leiomyomas	Thyroid dysfunction	Other tumor—vulvar, vaginal, cervical (10%)
Pelvic infections	Cervical and endometrial polyps		
	Thyroid dysfunction		

Abbreviations: OCP = oral contraceptive pill; PCOS = polycystic ovary syndrome.

*Prepubertal bleeding is discussed in chapter 133, "Pediatric Urologic and Gynecologic Disorders."

TABLE 96-4 Factors Frequently Used to Determine the Cause of Abnormal Bleeding in Perimenopausal Women

	Cause of Bleeding					
Distinguishing Features	Perimenopause	Neoplasia	Fibroid	Adenomyosis	Polyp	Pregnancy Related
History						
Associated hot flashes	Yes	No	No	No	No	No
Increased cramping	No	Sometimes	Sometimes	Yes	No	Sometimes
Bleeding pattern						
Skips and misses	Yes	Possible	No	No	No	—
Amenorrhea	Yes	No	No	No	No	Yes
Regular but shorter interval	Yes	No	No	No	No	No
Regular but heavy	No	No	Yes	Yes	Yes	No
Irregular	Yes	Possible	No	No	Yes	Yes
Physical examination						
Enlarged uterus	No	Sometimes	Yes	Yes	No	Yes
Enlarged and tender uterus	No	No	No	Yes	No	Possible
Ultrasonography						
Enlarged uterus	No	No	Yes	Yes	No	No
Enlarged uterus with intrauterine mass	No	Yes	Sometimes	No	Yes	Yes
Laboratory tests						
Follicle-stimulating hormone	Elevated	Normal	Normal	Normal	Normal	Normal
Complete blood count	Usually normal	Normal/low	Normal/low	Normal/low	Normal/low	Normal/low
Human chorionic gonadotropin	Negative	Negative	Negative	Negative	Negative	Positive

with other risk factors.[1,9,10] The amount of bleeding does not correlate with the severity of disease. Elderly patients may not be able to accurately describe the location of pain or bleeding in the proximity of the bladder, uterus, or rectosigmoid. Therefore, make sure to adequately visualize the vagina and cervix on pelvic examination.

All patients with postmenopausal bleeding warrant prompt referral for evaluation. Outpatient US and endometrial biopsy should be arranged for stable patients.

Vaginal bleeding, especially when seen in conjunction with atrophic vaginitis, may be associated with the use of pessaries and douche solutions, which can irritate the mucosa. Cervical polyps can also cause vaginal bleeding. However, an endometrial biopsy is ultimately required to rule out other serious causes of bleeding (**Table 96-4**).

NONSTRUCTURAL CAUSES OF VAGINAL BLEEDING

Consider these causes in the differential diagnosis by methodical history and physical examination. Pursue as needed with further investigations and consultations.

COAGULOPATHIES

Primary coagulation disorders account for 5% to 20% of acute uterine bleeding in adolescents.[11,12] von Willebrand's disease is the most common cause, but myeloproliferative disorders and immune thrombocytopenia also may be diagnosed. In adults, bleeding may result from anticoagulation agents or acquired bleeding disorders. Cirrhosis may lead to bleeding secondary to reduced capacity of the liver to metabolize estrogens.

OVULATORY DYSFUNCTION

Acute uterine bleeding secondary to anovulation is seen in 10% to 15% of gynecologic patients. Signs include irregular and/or heavy menstruation. Ovulatory dysfunction is common in perimenarchal and perimenopausal women, as well as in patients with endocrine disorders, polycystic ovary syndrome, exogenous hormone use, and liver or renal disease.

Anovulatory uterine bleeding in adolescence is due to the immature hypothalamic-pituitary-ovarian axis. In this situation, the amount of bleeding is usually minimal and painless. Dilatation and curettage (D&C) is rarely required. Severe anemia from heavy menstrual bleeding in early adolescence should prompt evaluation for bleeding disorders (e.g., von Willebrand's disease, factor VIII deficiency). **Table 96-5** outlines the medical management of acute uterine bleeding from ovulatory dysfunction in the ED.

Anovulatory bleeding in the reproductive-age female may be regular in timing but more often is irregular because of fluctuating estrogen levels below the critical level required to maintain endometrial growth. The level of estrogen depends on the age, number, and activity of ovarian follicles. As some follicles degenerate, others resume the production of estrogen, and the endometrium continues to proliferate for weeks to

TABLE 96-5 Treatment of Acute Uterine Bleeding from Ovulatory Dysfunction

Drug	Suggested dose	Dose Schedule	Potential Contraindications
Conjugated equine estrogen (Premarin)	25 milligrams IV	Every 4–6 h for 24 h	Breast cancer, liver disease, VTE*
Combined oral contraceptives (e.g., Sprintec®, 0.25 milligram of norgestimate and 0.035 milligram of ethinyl estradiol)	Monophasic† combined OCP that contains at least 35 micrograms of ethinyl estradiol	Three times per day for 7 d	Smokers >35 y, HTN, VTE, CVA, breast cancer, liver disease, thromboembolic disorders, diabetes with vascular disease, heart disease, major surgery with immobilization
Medroxyprogesterone acetate (Provera)	20 milligrams orally	Three times per day for 7 d	VTE, liver disease, breast cancer

Abbreviations: CVA = cerebrovascular accident; HTN = hypertension; OCP = oral contraceptive pill; VTE = venous thromboembolism (including deep venous thrombosis and pulmonary embolism).

*Caution in patients with cardiovascular or thromboembolic risk factors.

†Monophasic delivers the same amount of estrogen and progestin every day.

months, which may cause glandular hyperplasia ("Swiss cheese" hyperplasia). The estrogen steady-state is insufficient to meet the growing needs of the endometrium and produces a relative estrogen insufficiency, and uterine bleeding ensues. Alternatively, when follicle degeneration and stimulation are not balanced, absolute estrogen levels fall, and withdrawal bleeding occurs. Characteristically, anovulatory cycles present as prolonged amenorrhea with periodic menorrhagia. Because of the lack of progesterone-mediated myometrial contractions and arteriolar vasospasm, anovulatory cycles are rarely associated with cramping. This pattern of bleeding increases the risk of endometrial hyperplasia and adenocarcinoma.

Hypothyroidism may be associated with heavy uterine bleeding or intermenstrual bleeding from ovulatory dysfunction, with an estimated incidence of 0.3% to 2.5%.[13] Eating disorders, excessive weight loss, stress, and exercise can also cause abnormal uterine bleeding. Obtain levels of thyroid-stimulating hormone in women with uterine bleeding of undetermined origin or in those with thyroid nodule or goiter.

ENDOMETRIAL CAUSES

Acute uterine bleeding that occurs in the context of normal ovulation and with a structurally normal endometrial cavity is attributed to endometrial causes. Normal ovulation is based on a history of predictable, cyclical menstrual periods. Bleeding may be preceded by breast tenderness, abdominal bloating, and pelvic pain. The diagnosis is made when patients have heavy menstrual bleeding with no other identifiable abnormalities.

Ovulatory bleeding is generally treated with oral contraceptives, NSAIDs, or progestins. Endometrial ablation may be useful for those who do not respond to medical therapy; hysterectomy is reserved for those who fail medical management and have excessive blood loss.

IATROGENIC CAUSES

Oral contraceptive pill (OCP) use remains the most common cause of intermenstrual bleeding. Additionally, medications (e.g., antiseizure medications) that increase the P450 system of the liver may increase the metabolism of endogenous hormonal glucocorticoids and may cause withdrawal bleeding.

Hormone replacement therapy, which can relieve symptoms associated with menopause, may also be associated with vaginal bleeding. Hormone replacement therapy for this purpose has been called into question, as there is no clear benefit for primary and secondary prevention of cardiovascular disease, and excessive risk of endometrial, breast, and colorectal cancer and thromboembolism has been noted.[14-16]

Forty percent of women receiving continuous OCP therapy will experience abnormal bleeding in the initial 4 to 6 months. Bleeding after 6 months of continuous combined hormone replacement therapy, unexpected bleeding with cyclic hormone replacement therapy, or bleeding that recurs after amenorrhea is established should prompt referral for evaluation. There are no acceptable criteria for "abnormal bleeding" on these therapies. The most common etiologies for bleeding while on hormone replacement therapy are poor compliance, poor GI absorption, drug interactions, failure to synchronize therapy with endogenous ovarian activity, and coagulation disorders.

OTHER CAUSES OF VAGINAL BLEEDING

Pelvic inflammatory disease or infections that cause endometritis can cause abnormal vaginal bleeding. Cervical erosions, polyps, and cervicitis may cause bleeding from the cervix. Vaginal infections, trauma, and foreign bodies may also present with abnormal bleeding. Emergency therapy should be directed at investigating and treating obvious causes of bleeding. For further details, see chapters 103, "Pelvic Inflammatory Disease" and 102, "Vulvovaginitis."

LABORATORY EVALUATION AND IMAGING

Obtain a pregnancy test in women of childbearing age (except those with hysterectomy) to rule out pregnancy as a cause of bleeding. A CBC identifies anemia. Obtain coagulation studies only when indicated by history or physical examination. In individuals with suspected endocrine disorders, determination of thyroid-stimulating hormone and prolactin levels may be helpful, but the levels may not be available for ED evaluation.

Ultrasonography is the first-line imaging modality for gynecologic conditions such as vaginal bleeding, adnexal or uterine masses, or pelvic pain. US can determine uterine size and endometrial characteristics and can identify the presence of leiomyoma, ovarian cysts, hydrosalpinx, pelvic adhesions, tubo-ovarian abscesses, endometriosis, and tumors. Transvaginal ultrasonography further delineates ovarian cysts and fluid in the cul-de-sac. Depending on the degree of pain and findings on physical examination, US can be done on an emergency basis or deferred for outpatient evaluation.

CT is used primarily in the ED for the evaluation of acute abdominal or pelvic pain (see chapter 97, "Abdominal and Pelvic Pain in the Nonpregnant Female"). MRI is used primarily for cancer staging and is rarely indicated during ED evaluation. The National Guideline Clearinghouse has published guidelines for radiology for abnormal vaginal bleeding.[17]

TREATMENT

ACUTE UTERINE BLEEDING

Patients who are hemodynamically unstable need immediate resuscitation and emergent gynecologic consultation (**Figure 96-2**). Do not attempt vaginal packing, because it increases the risk of infection and may hide ongoing blood loss. In addition to fluid resuscitation, blood transfusion, and correction of underlying coagulopathies, assess for other potential causes of bleeding including trauma, bleeding dyscrasia, infection, and retained foreign bodies. The options for management of acute hemorrhage include hormonal, surgical, and hemostatic interventions.

Perimenopausal women with abnormal uterine bleeding should have an endometrial biopsy *before* the initiation of hormone replacement therapy. Otherwise, hormonal agents are first-line medical management for acute uterine bleeding in patients without an underlying bleeding disorder.[18,19] Short-term hormonal treatment allows the endometrium to stabilize and slows acute bleeding. Acute treatment options include intravenous estrogen and oral progestins (**Table 96-5**). For severe hemorrhage, give conjugated estrogen (Premarin) at a dose of 25 milligrams IV every 4 to 6 hours until bleeding stops, with ED observation, followed by an oral contraceptive. In women with a history of blood clot or cardiovascular disease, high-dose estrogen therapy is contraindicated. Progestin is used when there is concern for underlying endometrial pathology or hyperplasia. US finding may reveal a thickened endometrial strip, fibroids, or polyps.

Tranexamic acid, a lysine derivative that prevents fibrin degradation, is used primarily for intraoperative gynecologic bleeding.[20,21] Use depends on geography and institution, so obtain gynecologic consultation if administration is considered, especially to discuss risks and benefits. Clinical studies on the effectiveness of tranexamic acid have excluded patients with potential for thrombosis.

HEAVY MENSTRUAL BLEEDING

Heavy menstrual bleeding is treated with NSAIDs and combined or progestin-only oral contraceptives. Progesterone works by decreases the number of available estrogen receptors and stabilizing the endometrium. Common side effects of this regimen include nausea and vomiting. One recent report recommended IM depot-medroxyprogesterone combined with a short 3-day oral course of an oral contraceptive; the mean time for bleeding cessation was 2.6 days, and all patients stopped bleeding within 5 days.[22] Simplified ED regimens for combined OCPs and progestin-only pills are outlined in Table 96-5. The median time to stop bleeding for either regimen (combined OCP or progestin-only regimen) is 3 days. However, multiple different hormonal doses and schedules are also effective. In general, for young healthy women where bleeding is often related to anovulation and there is no concern for endometrial pathology, then OCPs are favored. For older patients, or obese/perimenopausal patients where there could be concern for endometrial pathology, then progestin-only is preferred.

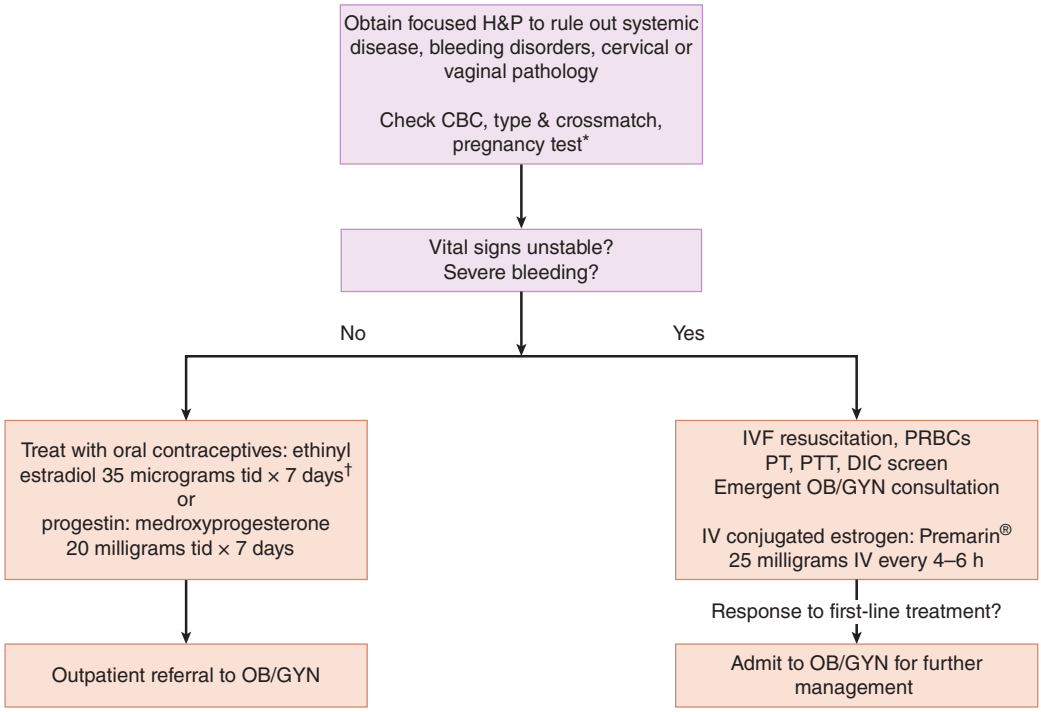

FIGURE 96-2. Algorithm for ED evaluation and treatment of acute vaginal bleeding (**Also see Table 96-5 for more detail.**). *Consider other laboratory tests if positive screen for suspected bleeding disorders based on history and physical (H&P). †Contraindications to hormonal agents need to be considered before administration. Other oral contraceptive and progestin formulations and dose schedules may be equally effective. DIC = disseminated intravascular coagulation; IVF = IV fluid; OB/GYN = obstetrician/gynecologist; PRBCs = packed red blood cells; PT = prothrombin time; PTT = partial thromboplastin time.

DISPOSITION AND FOLLOW-UP

Stable patients can be discharged home with arrangements for prompt follow-up within 1 week.

The need for surgical management is based on clinical stability. If medical management fails or if there is a contraindication (e.g., thromboembolic disease), then surgical management is the next step. Surgical options are directed by suspected etiology and include dilatation and curettage, hysteroscopy, endometrial balloon tamponade, and uterine artery embolization. Hysterectomy is used as a last resort in patients with acute life-threatening bleeding unresponsive to other treatment measures.

Provide referral for endometrial biopsy for patients at risk for endometrial cancer and all women >45 years old. Perimenopausal bleeding is associated with malignancy in 10% of women. Risk factors include obesity, nulliparity, history of anovulation, tamoxifen use, infertility, and a family history of endometrial or colon cancer. Other diagnostic procedures performed at follow-up may include sonohysterography, hysterosalpingography, and hysteroscopy with directed biopsy and dilatation and curettage.[23]

LONG-TERM MANAGEMENT

It is essential to establish a definitive diagnosis before initiating long-term management. Expectant management is appropriate if episodes of heavy or irregular bleeding are infrequent. Several choices for long-term medical management of heavy menstrual bleeding exist. Overall, there is insufficient evidence to define an optimal medical management strategy.[24,25]

OCPs have long been an excellent choice for adolescents and women requiring contraception. Heavy menstrual bleeding is decreased by 50%, with a similar reduction in the degree of pain associated with bleeding. However, a recent systemic review found levonorgestrel intrauterine device (71% to 95% reduction) superior to combined OCPs (35% to 69% reduction) and NSAIDs (10% to 52% reduction).[26]

NSAIDs are effective in reducing pain and blood loss in 20% to 50% of women with abnormal uterine bleeding secondary to ovulatory dysfunction.[27] NSAIDs should be started on the first day of the period and continued until bleeding stops and pain resolves.

All NSAIDs inhibit cyclooxygenase in the arachidonic acid cascade. Prostaglandin inhibitors alter the ratio of prostaglandin $F_2\alpha$, which causes vasoconstriction, to prostaglandin E_2, which causes vasodilation. NSAIDs also increase levels of thromboxane A_2, which causes vasoconstriction and increases platelet aggregation. NSAIDs have a mild side effect profile and are inexpensive. Treatment choices include mefenamic acid, 500 milligrams three times a day PO, naproxen, 500 milligrams twice per day PO, and ibuprofen, 400 milligrams every 6 hours. Any of these may be administered to reduce bleeding and pain associated with use of an intrauterine device.[28] NSAIDs are less useful in patients with uterine leiomyomas.

Additional long-term treatment options that may be prescribed at follow-up include clomiphene citrate, medroxyprogesterone acetate, gonadotropin-releasing hormone agonists, and tranexamic acid. Clomiphene citrate may be used to decrease bleeding as well as to induce ovulation if pregnancy is desired. If there is no contraindication to progestin usage, medroxyprogesterone acetate, 10 milligrams daily PO for 10 days, can be used to produce scheduled bleeding. Intrauterine progesterone release is a highly effective treatment option. Patients may still ovulate when using this medication. Gonadotropin-releasing hormone agonists may be used to induce amenorrhea, but women on this therapy become menopausal. Other drawbacks include medication expense and bone loss when used for >6 months. Tranexamic acid, a fibrinolytic, reduces vaginal bleeding with minimal side effects. An improved quality of life in patients using tranexamic acid when compared with hormone therapy and NSAIDS has been reported.[29]

Nonmedical invasive management strategies may be required if medical treatment fails. These include hysteroscopy, endometrial ablation, or myomectomy. Hysteroscopy can be used to sample the endometrium and resect polyps and myoma. Endometrial ablation may be performed in patients who do not desire fertility, have no pathologic diagnosis, and for whom medical therapy has failed.[30] Myomectomy may be useful in patients with symptomatic fibroids. Hysterectomy is reserved for selected patient populations. Uterine artery embolization is an effective nonsurgical option for the management of bleeding caused by fibroids.[31]

SPECIAL POPULATIONS

GENITAL TRAUMA

Vaginal injuries after intercourse are not uncommon. The majority of coital injuries result from vigorous voluntary sexual activity, although violent involuntary sexual activity should be considered. The most common site of injury is the posterior vaginal fornix. Misdiagnosis of coital injuries occurs frequently because either the physician fails to take an adequate history or the patient does not admit to antecedent sexual activity. Most coital injuries are minor, but severe injuries may lead to hemorrhagic shock.

BLOOD DYSCRASIAS

Bleeding disorders may become apparent with an initial presentation of abnormal menstrual bleeding. Uterine hemostasis is not well understood, and any disorder of blood vessels, platelet abnormalities, and coagulation disorders, including von Willebrand's disease, may result in excessive menstrual bleeding. Of historical interest, the first described case of von Willebrand's disease was in a 13-year-old who died as a result of uncontrollable uterine bleeding.[32] Abnormal uterine bleeding is present in the majority of women with von Willebrand's disease or factor XI deficiency and in carriers of hemophilia.

A multidisciplinary approach is recommended. Initial treatment options are similar to those without bleeding disorder: antifibrinolytics, OCPs, and levonorgestrel intrauterine device. Hormonal agents raise factor VIII and von Willebrand factor levels and are an effective and popular form of therapy. Antifibrinolytics, such as tranexamic acid, reduce both plasminogen activator activity and plasmin activity. Desmopressin acetate (DDAVP) stimulates endogenous release of factor VIII and von Willebrand factor and may be used prophylactically for minor procedures or treatment of bleeding episodes and heavy menstrual bleeding. Desmopressin acetate is administered intranasally, parenterally, or by SC injection. The blood of patients with von Willebrand's disease must be typed and screened for antibodies before instituting desmopressin acetate because it may induce thrombocytopenia in certain subgroups. NSAIDs are ineffective in decreasing uterine bleeding and may increase blood loss in this population.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome, one of the most common endocrine disorders, is the association of hyperandrogenism and anovulation without underlying disease of the adrenal or pituitary glands.[33] A triad of obesity, hirsutism, and oligomenorrhea is classically described, although obesity is not universally seen. When menses occurs, it is heavy and prolonged. The syndrome is further characterized by acne, androgen-dependent alopecia, elevated serum concentrations of androgens, hyperinsulinemia, and hypersecretion of luteinizing hormone with a normal or low follicle-stimulating hormone level. Typical ovarian morphology, which may be seen by US, is not necessary for the diagnosis and may, in fact, represent a response of the ovary to chronic anovulation. The differential diagnosis includes hyperprolactinemia, acromegaly, congenital adrenal hyperplasia, and androgen-secreting tumors of the ovary or adrenal gland. Management of menorrhagia in women who do not desire fertility includes low-dose oral contraceptives or cyclic progestin administration.

HUMAN IMMUNODEFICIENCY VIRUS

In general, there is no need to change the approach to vaginal bleeding in human immunodeficiency virus–positive women. Look for associated infections and complications of chronic illness. The rate of vaginal and pelvic infections and cervical dysplasia is high in this cohort of patients. In a cross-sectional survey of 386 women <50 years old, with and without human immunodeficiency virus, neither infection nor immunosuppression affected menstruation or the rate of abnormal vaginal bleeding.[34] This was also seen in a study of 85 seropositive women, although the power of the study was low.[35]

STRESS, ILLNESS, AND RAPID WEIGHT CHANGE

Periods of physical or psychological stress, illness, malnutrition, rapid weight gain or loss, and intense physical regimens affect the hypothalamus and disrupt the normal pattern of gonadotropin release. This usually causes amenorrhea but may result in irregular, heavy bleeding. In obese women, menorrhagia may be a result of increased circulating levels of estrogen from peripheral conversion of androstenedione to estrone in fatty tissue. Patients with liver and renal disease may also develop irregular bleeding.

CHAPTER 97

Abdominal and Pelvic Pain in the Nonpregnant Female

Melanie Heniff
Heather R.B. Fleming

INTRODUCTION AND EPIDEMIOLOGY

This chapter reviews diagnosis and treatment of abdominal and pelvic pain in nonpregnant women. Even after the possibility of pregnancy is eliminated, abdominal pain in women remains a challenging diagnosis because of physical proximity and overlapping spinal segment innervation and similar symptoms of GI, urologic, and gynecologic organ systems. Discussion of the pregnant woman with abdominal/pelvic pain is found in chapters 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period," 103, "Pelvic Inflammatory Disease," and 71, "Acute Abdominal Pain."

CLINICAL FEATURES

HISTORY

Define characteristics of the pain including onset, duration, location, quality, radiation, and exacerbating and alleviating factors. History should include questions about GI symptoms (nausea, vomiting, diarrhea, and constipation), urologic symptoms (dysuria, hematuria, frequency, and urgency), and gynecologic symptoms (vaginal bleeding, discharge, dyspareunia, and menstrual history). **History of sexual activity and menstrual history should never be relied upon to exclude pregnancy.** Obtain past medical, surgical, and family history, as well as details of prior pregnancies and outcomes. Active lactation and medication use, including specific methods of birth control, should be part of the history. Ask about infertility treatments because ovulation-inducing treatments increase risk of ovarian torsion, cysts, and ovarian hyperstimulation syndrome. When obtaining a sexual history and social history, it is wise to interview the patient alone, which may help patients feel more comfortable discussing potentially sensitive or embarrassing topics. Ask about pelvic inflammatory disease risk factors including unprotected intercourse, prior sexually transmitted infections, and multiple sexual partners. While the patient is alone, ask her about safety at home, and assess for any potential abusive situations. Patients with history of physical and sexual abuse may develop a variety of somatic complaints including abdominal and pelvic pain, and this pain is often chronic in nature. Social history should include living situation, occupation, and personal habits (use of tobacco, alcohol, and drugs).

PHYSICAL EXAMINATION

A standard head-to-toe systematic approach beginning with vital signs is essential. The patient should be adequately undressed for a careful examination. In focusing on the examination of the abdomen, it is helpful to determine in what quadrant(s) of the abdomen the pain is located; this may help to narrow the differential diagnosis (**Figure 97-1**).

In addition to palpating for tenderness or masses, evaluate for surgical scars, rashes, bruising, or ascites. Peritoneal signs may be less obvious in

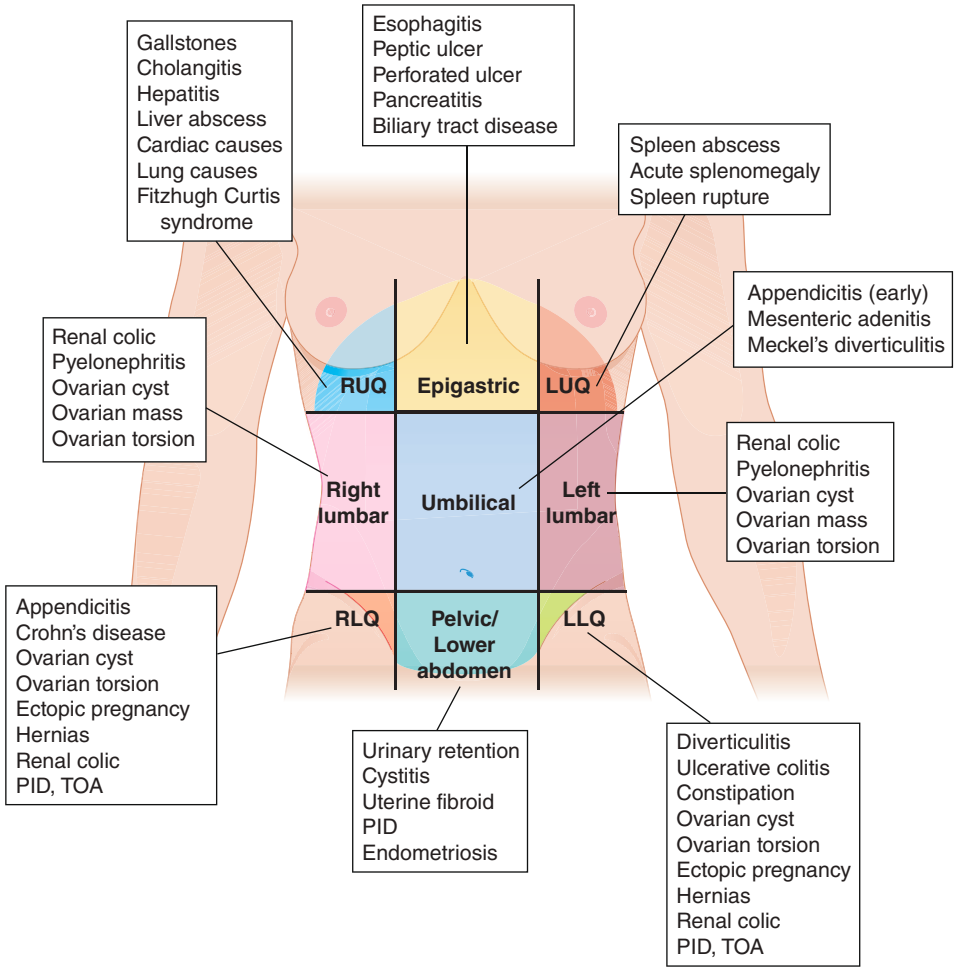

FIGURE 97-1. Differential diagnosis of abdominal pain based on location.

patients who are elderly, are obese, or have altered neurologic status. A digital rectal exam is helpful, if indicated, to evaluate complaints of rectal pain or bleeding.

A pelvic examination is usually a routine component of the exam of women with lower abdominal pain, but studies report a lack of accuracy and reproducibility of pelvic examination findings.[1,2] Pelvic examination is useful for obtaining lab specimens for sexually transmitted infections, palpation for tenderness or mass, and to check for vaginal bleeding, discharge, or foreign body.

DIAGNOSIS

In a nonpregnant female with abdominal pain, ED testing beyond a thorough history and exam is not always mandatory. For example, in a patient with multiple prior similar presentations and recent normal imaging studies, it is unnecessary, rarely helpful, and potentially harmful to repeat imaging.[3] In cases where further ED testing is determined to be unnecessary, the physician must still pay careful attention to symptom control, careful reassessment, and disposition. At the time of discharge, providers should review with the patient arrangements for close follow-up, often in 12 to 24 hours, as well as indications for return to the ED. **When benign causes are not clear from the initial evaluation and concerns for serious pathology remain, lab and/or imaging tests are necessary.**

LABORATORY EVALUATION

Obtain a pregnancy test in all women of childbearing age who still have a uterus and ovaries. See chapter 98, "Ectopic Pregnancy and Emergencies in the First 20 Weeks of Pregnancy" for a detailed discussion of pregnancy testing. A CBC is often obtained, but the WBC count is not reliable to rule in or exclude serious disease.[5] Obtain a urinalysis, and add a urine culture in pediatric patients, pregnant women, and patients at risk for complicated urinary tract infections. See chapter 91, "Urinary Tract Infections and Hematuria" for detailed discussion of urinalysis. **Be cautious in making a definitive diagnosis of urinary tract infection as the sole cause of a patient's symptoms.** For further discussion, see chapter 71.

IMAGING

US is the imaging modality of choice for genital tract pathology (ovarian cyst, ectopic pregnancy, uterine or ovarian mass, or tubo-ovarian abcess). CT is preferred when GI or GU pathology (appendicitis, diverticulitis, bowel obstruction, or renal stones) is highest in the differential diagnosis.

Bedside US can facilitate rapid diagnosis and treatment. For example, a positive focused assessment with sonography for trauma exam could help diagnose a ruptured ectopic pregnancy or significant hemorrhage from an ovarian cyst.[5] ED US can quickly identify a normal intrauterine pregnancy. Pelvic US is the primary imaging modality for evaluation of lower abdominal pain in the female patient in whom a gynecologic diagnosis is considered most likely. US is useful in diagnosis of pelvic inflammatory disease, tubo-ovarian abcess, leiomyoma, and ovarian cysts. In evaluation of possible ovarian torsion, pelvic US should include Doppler flow. Transabdominal and intravaginal probes are used for imaging of pelvic organs. In transabdominal imaging alone, a full bladder aids visualization of pelvic organs. In transvaginal imaging, an empty bladder aids visualization. US studies should never be delayed waiting for a full bladder, particularly when there is concern for a serious diagnosis such as ovarian torsion. US may be useful to evaluate for appendicitis, but it is less sensitive than CT and is operator dependent.

CT of the abdomen and pelvis is sensitive for evaluation of most abdominal and pelvic conditions. Usually IV contrast alone is sufficiently sensitive for evaluation of possible appendicitis.[6] If there is concern for pelvic abscess, or the patient weighs less than 70 kg, oral contrast may enhance accuracy of evaluation. MRI is accurate in diagnosis of many abdominal and pelvic conditions, but cost and limited availability limit its use in most EDs.

TREATMENT

Specific treatment depends on diagnosis (see below), but because the diagnostic process can be time consuming, control of pain and nausea and fluid resuscitation take priority. There is no evidence that judicious use of opiates obscures abdominal exam findings or negatively impacts outcomes. Opiates can be titrated to control pain, without causing excessive somnolence or respiratory depression. Antiemetics including ondansetron, metoclopramide, promethazine, and prochlorperazine are safe and effective. Antibiotics should be given in the ED for suspected severe intra-abdominal infection or sepsis. Choice of antibiotics depends on severity of infection and factors relevant to patients' individual risk, such as comorbid conditions and possibility of hospital-acquired infections.[7,8] See chapters 71 and 103 for further discussion of antibiotic selection.

DISPOSITION AND FOLLOW-UP

When a serious or potentially surgical diagnosis is considered likely, early consultation with the appropriate specialist (general surgery, urology, or obstetrics/gynecology) is indicated. If there is persistent concern for serious pathology, admission or observation is appropriate. This applies even if the diagnosis is unclear. Patients with abnormal vitals, poorly controlled pain, and/or vomiting are best served by inpatient treatment. In many cases, diagnosis is clear after a period of observation and serial exams. Many patients seen in the ED have significant symptoms, but a specific condition may not be diagnosable in the relatively brief period of time a patient spends in the ED. Significant comorbid conditions (immunocompromised, unstable medical problems, inability to care for oneself at home) should prompt strong consideration for observation or admission.

In most patients with abdominal/pelvic pain in the ED, hospitalization is not necessary. **It is common and appropriate to discharge patients with a diagnosis of undifferentiated abdominal pain. In patients who are discharged, instructions for follow-up and indications for return to the ED should be very specific. Instructions should specify a time course during which patients should be seen for repeat exam.** Re-evaluation in 12 to 24 hours is appropriate for patients with acute abdominal pain and diagnostic uncertainty. In more chronic abdominal/pelvic pain, follow-up with a primary care provider is still important, but timing of follow-up should be specified according to individual patient needs.

OVARIAN CYSTS

Ovarian cysts, when symptomatic, usually present with sudden-onset unilateral pain that is more common on the right than left. Cervical motion tenderness and mild vaginal bleeding are sometimes present. Pain often starts during physical activity such as exercise or sexual intercourse. Functional (benign) cysts are fluid-filled sacs that develop during a normal menstrual cycle. **Follicular cysts** contain a maturing ovum and rupture at ovulation. **Corpus luteum cysts** are present after the ovum is released. If no conception occurs, the corpus luteum involutes. If fertilization takes place, the corpus luteum cyst enlarges and secretes estrogen and progesterone. **Hemorrhagic cysts** occur if a blood vessel in the cyst wall ruptures (**Figure 97-2**).

Mittelschmerz (German for middle pain) is midcycle pain at the time of ovulation caused by normal follicular enlargement prior to ovulation or follicular bleeding at ovulation. Pain is usually mild and lasts a few hours up to a few days.

FIGURE 97-2. A 4-cm hemorrhagic ovarian cyst demonstrated by endovaginal US. [Reproduced with permission from Ma OJ, Mateer JR, Blaivas M: *Emergency Ultrasound*, 2nd ed. © 2008, McGraw-Hill, New York. Fig. 14-10, p. 362.]

Complicated cyst rupture is characterized by abnormal vital signs and an acute abdomen. Hospitalization or observation is needed for serial examinations and hematocrits. Surgery may be necessary to control hemorrhage.

A **dermoid cyst** is an ovarian germ cell neoplasm that presents as a multicystic mass that contains various types of tissue including fat, skin, hair, and teeth. These cysts usually occur between age 10 and 30 years. Most are benign, but risk factors for malignant teratomas include age over 45, diameter greater than 8 cm, and rapid growth. Most uncomplicated cyst ruptures are from follicular and corpus luteum cysts. Vital signs are stable, and symptoms only last a few days.

Ovarian cysts that are <8 cm, unilocular, and unilateral are generally observed and typically resolve within two menstrual cycles. **Cysts that are large (>8 cm), solid, and multiloculated are worrisome for neoplasm, dermoid cysts, or endometriomas**. Patients with ovarian cysts, regardless of size, should be referred to the gynecologist or primary care physician for follow-up.

ENDOMETRIOMAS

Endometriomas are called "chocolate cysts" because they usually contain thick brown fluid. They present as a pelvic mass caused by growth of ectopic endometrial tissue within an ovary. Endometriomas may rupture, and patients can present with peritoneal signs/symptoms. Endometriomas may also present similar to endometriosis (pelvic pain, dysmenorrhea, and dyspareunia).

OVARIAN NEOPLASM

An ovarian mass in a postmenopausal woman is malignant until proven otherwise. The mean age at diagnosis is 50 to 60 years. Patients present with nonspecific signs/symptoms, including anorexia, dyspepsia, early satiety, constipation, bloating, and ascites. Cancers of the endometrium, breast, and GI tract may metastasize to ovaries and fallopian tubes.

OVARIAN HYPERSTIMULATION SYNDROME

Ovarian hyperstimulation syndrome is a complication of ovulation induction treatments, with a clinical spectrum of severity. The syndrome can occur early, 5 to 7 days after ovulation, or later, due to rising human chorionic gonadotropin levels.

The severe syndrome is characterized by massive transudation of albumin and fluid from the vascular compartment to the peritoneal,

pleural, and sometimes, pericardial cavities.[9] Venous and arterial thrombosis are the most dreaded complications. Reports include thrombosis of the jugular, subclavian, retinal, and extremity veins and cerebral venous thrombosis. Stroke, ST-segment elevation myocardial infarction, and pulmonary embolism are also reported.[9]

ENDOMETRIOSIS AND ADENOMYOSIS

Endometriosis occurs when endometrium-like tissue outside the uterus induces a chronic inflammatory reaction. This is a common cause of pelvic pain and infertility. When endometrial tissue is in the uterine wall, it is termed adenomyosis. Both conditions cause chronic, recurrent, and cyclic pain. Dysmenorrhea and dyspareunia are often reported. US may show cystic or solid masses. Laparoscopy is the definitive method of diagnosis. Primary diagnosis is usually not made in the ED. If suspected, pain control and outpatient referral are appropriate.

FOREIGN BODY/TRAUMA

Vaginal foreign bodies (such as a retained tampon) may cause pelvic pain and vaginal discharge or bleeding. Trauma or foreign body should be considered in the differential diagnosis. Patients are not always immediately forthcoming with history due to fear or embarrassment. Complications such as abscess or perforation are rare.

OVARIAN TORSION

Ovarian torsion is a surgical emergency that requires prompt diagnosis to preserve ovarian function. Adnexal torsion is an ischemic condition almost always associated with ovarian enlargement, generally due to ovarian cysts or masses. The enlargement causes the ovary to twist, creating a fulcrum around which the oviduct revolves. Initial blockage of venous return causes congestion, leading to decreased distal arterial blood flow, which produces ischemia and necrosis of the ovary. Although the process may involve the ovary alone, torsion of both the ovary and the oviduct (adnexal torsion) is more common. Nearly 70% of torsions occur on the right side, due to the increased length of the utero-ovarian ligament on the right and the sigmoid on the left, limiting space for movement.[10]

Risk factors for torsion are pregnancy due to enlarged corpus luteum, presence of large ovarian cysts or tumors, chemical induction of ovulation (ovarian hyperstimulation syndrome), and tubal ligation. Classically, patients present with sudden-onset, severe, unilateral, lower abdominal pain that may develop after episodes of exertion. Unfortunately, atypical presentations are common, with half of patients reporting gradual onset of pain that is intermittent in nature. Nausea and vomiting is present in 70% of cases.[11]

Clinical findings classically consist of unilateral lower abdominal tenderness with guarding, unilateral adnexal tenderness on bimanual examination, and presence of a latero-uterine mass. Conversely, nearly 30% of patients have bilateral adnexal tenderness on bimanual examination, and a minority of patients may have no tenderness at all. Fifty percent of patients are initially misdiagnosed.[12]

Transvaginal US with Doppler is the primary diagnostic modality for suspected torsion. An ovary greater than 4 cm in size due to cyst, tumor, or edema is the most common ultrasonographic finding associated with torsion.[13] Conversely, given the dynamic nature of the torsion process, up to 26% of US studies reveal normal adnexa. Up to 60% of cases of torsion can be missed on arterial Doppler alone, given that arterial disruption of flow is a late clinical finding.[14] However, a positive Doppler study has a 100% positive predictive value for adnexal torsion. Recent improvements in US technology have led to assessment of venous Doppler flow, which may be the only abnormality identified in early ovarian torsion.[15] Given the dynamic nature of the torsion process, there is no one finding that conveys certainty of the absence of torsion. Thus, clinical suspicion based on history and physical exam remains important in involving gynecologic consultation if US is negative, but clinical concern remains high.[16]

CHAPTER 98

Ectopic Pregnancy and Emergencies in the First 20 Weeks of Pregnancy

Heather A. Heaton

GENERAL APPROACH TO WOMEN OF CHILDBEARING AGE

The differential diagnosis for women of childbearing potential who present with abdominal or pelvic symptoms or abnormal vaginal bleeding is broad (**Table 98-1**). The major clinical goals are, first, diagnosis of pregnancy, and then if pregnant, differentiating ectopic pregnancy from threatened abortion. Consider ectopic pregnancy in women of childbearing age who report abdominal or pelvic pain or discomfort, vaginal spotting or a cycle of amenorrhea, or unexplained signs or symptoms of hypovolemia. There are rare case reports of ectopic pregnancy in patients with ovaries but without a uterus. No combination of signs or symptoms is sufficient to exclude ectopic pregnancy. **If pregnancy is detected, ectopic pregnancy remains in the differential diagnosis until it can be either confirmed or excluded with conviction.**

PREGNANCY TESTING

The diagnosis of pregnancy is central to the diagnosis of ectopic pregnancy. Pregnancy tests currently in use rely on the detection of the β subunit of human chorionic gonadotropin (β-hCG) in the urine or serum. hCG is a hormone produced by the trophoblast. Intact hCG consists of the α and β subunits. Tests based on detection of the intact molecule or the α subunit can cross-react on immunologic assays with hormones found in the nonpregnant individual and are thus less specific than tests for the β-hCG subunit.

hCG preparations are currently standardized in relation to the Third International Reference Preparation. Other standard preparations are not equivalent. A preparation often referred to in earlier literature is the Second International Standard. The Third International Reference Preparation is

TABLE 98-1 Differential Diagnosis of Ectopic Pregnancy

All Patients	Pregnant Patients
Appendicitis	Normal (intrauterine pregnancy)
Inflammatory bowel disease	Threatened abortion
Ovarian pathology	Inevitable abortion
Cyst	Molar pregnancy
Torsion	Heterotopic pregnancy*
Pelvic inflammatory disease	Implantation bleeding
Endometriosis	Corpus luteum cyst
Sexual assault/trauma	
Urinary tract infection	
Ureteral colic	

*Heterotopic pregnancy = combined intrauterine pregnancy and ectopic pregnancy.

TABLE 98-2 Estimated β-Human Chorionic Gonadotropin (β-hCG) Levels After Conception[4]

Postconception Week	β-hCG Levels (mIU/mL)
<1 week	5–50
1–2 weeks	50–500
2–3 weeks	100–5000
3–4 weeks	500–10,000
4–5 weeks	1000–50,000
5–6 weeks	10,000–100,000
6–8 weeks	15,000–200,000
8–12 weeks	10,000–100,000

roughly equal to 1.7 times the Second International Standard. To avoid confusion when interpreting the literature, pay attention to the standard used. In this chapter, hCG and β-hCG concentrations refer to the Third International Reference Preparation unless otherwise noted.

Very early in either an intrauterine pregnancy (IUP) or an ectopic pregnancy, detectable amounts of β-hCG are released into the serum and filtered into the urine. The concentration of β-hCG is fairly closely correlated in the urine and serum, with urinary concentration also depending on urine specific gravity. Qualitative urine and serum tests for pregnancy usually use the enzyme-linked immunosorbent assay methodology. In the laboratory setting, enzyme-linked immunosorbent assay tests can detect β-hCG at concentrations <1 mIU/mL.

Qualitative tests in clinical use are typically reported as "positive" when the β-hCG concentration is ≥20 mIU/mL in urine and ≥10 mIU/mL in serum. A positive qualitative test therefore implies that β-hCG is present in at least this concentration. At this level of detection, the false-negative rate for detection of pregnancy will not be >1% for urine and 0.5% for serum. In clinical use, the performance of urine qualitative testing is 95% to 100% sensitive and specific compared with serum tests.

Urine tests can be performed rapidly at the bedside, and kits from some manufacturers may be used for either urine or serum. **Dilute urine may cause a false-negative urine pregnancy test**, particularly early in pregnancy when β-hCG levels are low (<50 mIU/mL). Additionally, when hCG levels are present in large amounts (generally with concentrations of 1,000,000 mIU/mL), a **"hook effect phenomenon"** can occur, giving false-negative results. This is thought to be related to excess hCG saturating both the fixed, solid-phase antibody and the labeled, soluble antibody of the assay, causing an absence of signal. The resultant false-negative test can be mitigated by diluting the sample.[1] Point-of-care hCG whole-blood assay shows promising results, with 95.8% sensitivity (negative predictive value, 97.9%) when compared with standard urine testing.[2]

When a bedside urine test is negative and ectopic pregnancy is still being considered, perform a quantitative serum test. **The sensitivity of quantitative serum testing for the diagnosis of pregnancy is virtually 100% when an assay capable of detecting ≥5 mIU/mL of β-hCG is used.**[3] Estimated β-hCG levels after conception are listed in **Table 98-2**.

ECTOPIC PREGNANCY

INTRODUCTION AND EPIDEMIOLOGY

Ectopic pregnancy occurs when a conceptus implants outside of the uterine cavity and is a leading cause of maternal death in the first trimester of pregnancy.[5]

The current incidence of ectopic pregnancy is difficult to determine but is probably increasing. Reasons include the increased incidence of sexually transmitted tubal infections, unsuccessful tubal sterilizations, assisted reproductive techniques, previous pelvic surgery, and more sensitive and earlier diagnostic techniques. Major risk factors are shown in **Table 98-3**, but a significant number of ectopic pregnancies occur in women in whom no risk factors are identified.[6,7]

TABLE 98-3 Major Risk Factors for Ectopic Pregnancy

Pelvic inflammatory disease, history of sexually transmitted infections
History of tubal surgery or tubal sterilization
Conception with intrauterine device in place
Maternal age 35–44 (age-related change in tubal function)
Assisted reproduction techniques (cause unknown, as tube is bypassed in implantation)
Previous ectopic pregnancy
Cigarette smoking (may alter embryo tubal transport)
Prior pharmacologically induced abortion

PATHOPHYSIOLOGY

Fertilization of the oocyte usually occurs in the ampullary segment of the fallopian tube. In normal pregnancy, after fertilization, the zygote passes along the fallopian tube and implants into the endometrium of the uterus. An ectopic pregnancy occurs when the zygote implants in any location other than the uterus—the fallopian tube or extratubal sites (the abdominal cavity, cervix, or ovary). Death results from maternal exsanguination after tubal rupture.

The vast majority of ectopic pregnancies implant in the ampullary portion of the **fallopian tube**. The underlying cause is most often damage to the tubal mucosa from previous infection, preventing transport of the ovum to the uterus. Other causes include tubal surgery, defects in the ovum resulting in premature implantation, and elevated estradiol or progesterone levels, which inhibit tubal migration.

Tubal implantation results in the penetration of the ovum into the muscular wall of the tube, and maternal blood seeps into tubal tissue. Intermittent distention of the fallopian tube with blood can occur, with leakage of blood from the fimbriated end of the fallopian tube into the peritoneal cavity. The aborting ectopic pregnancy and associated hematoma can be completely or partially extruded out of the end of the fallopian tube or through a rupture site in the tubal wall.

Abdominal ectopic pregnancies (~1% of ectopic pregnancies) most commonly derive from early rupture or abortion of a tubal pregnancy, with subsequent reimplantation in the peritoneal cavity.

Cervical ectopic pregnancies occur in <1% of ectopic pregnancies, with predisposing factors similar to those associated with ectopic pregnancies (previous dilatation and curettage, previous cesarean delivery, in vitro fertilization, adhesions or fibrosis of the endometrium, prior instrumentation, infertility, previous ectopic pregnancy). Patients develop profuse vaginal bleeding. Bimanual exam reveals a soft, large cervix when compared to the uterus or an hourglass-shaped uterus, and diagnosis is confirmed with US.[8,9]

Cesarean scar pregnancy is rare but can cause massive maternal hemorrhage. Diagnosis is difficult and is based on US demonstrating an empty uterine sac and cervical canal and a gestational sac in the uterine isthmus.

HISTORY

Determine the timing and characteristics of the last few periods. The menstrual history is often, but not always, abnormal. The classic sign of amenorrhea from 4 to 12 weeks after the last normal period is reported in 70% of ectopic pregnancy cases. **No missed menses are reported in 15% of ectopic pregnancy cases.** Although vaginal bleeding is often scant, heavy bleeding does not exclude an ectopic pregnancy.

Ask about previous pregnancies, pregnancy problems, and miscarriages. Typical early pregnancy symptoms may occur and may not differ from symptoms of previous normal IUPs. Discuss previous medical and surgical history, and ask about substance abuse and smoking. Ask about sexual activity and contraception. Identify risk factors for ectopic pregnancy or spontaneous abortion. Determine current medications, including over-the-counter drugs.

Pregnancy in a patient with prior tubal surgery for sterilization is assumed to be an ectopic pregnancy until proven otherwise. Patients are at particularly high risk if they have undergone laparoscopic partial

salpingectomy or electrodestruction tubal ligation at a young age (age <28 years), especially 5 to 15 years after the procedure.[10]

In a woman of childbearing age, hysterectomy with oophorectomy excludes ectopic pregnancy. In the situation of hysterectomy without oophorectomy, ectopic pregnancy is exceedingly rare. A literature review identified only 27 such case reports since 1918, after both vaginal and abdominal hysterectomies. The theory is that a fistulous tract after hysterectomy enables embryo implantation in the tube or adnexae.[11]

Abdominal pain or discomfort is the most common symptom of ectopic pregnancy and is reported in 90% of ectopic pregnancies.[12] Pain is due to tubal distention or rupture. The classic pain of rupture is lateralized, sudden, sharp, and severe. Shoulder pain due to diaphragmatic irritation from a ruptured ectopic pregnancy can also occur. Any lateral or bilateral abdominal discomfort or tenderness in a woman of childbearing age requires consideration of ectopic pregnancy. **Lack of pain in a woman with vaginal spotting or bleeding does not exclude ectopic pregnancy.**

PHYSICAL EXAMINATION

Obtain vital signs and focus on the abdominal and pelvic examination. The physical examination in ectopic pregnancy is highly variable, and ectopic pregnancy is difficult to diagnose or exclude based on physical examination. In cases of ruptured ectopic pregnancy, patients may present in shock, with no findings on pelvic examination, or with peritoneal signs and an adnexal mass and tenderness. Cervical motion tenderness can be elicited on pelvic exam in some cases. Relative bradycardia may occur as a consequence of vagal stimulation. There is poor correlation between the volume of hemoperitoneum and vital signs in ruptured ectopic pregnancy.[13] In cases of rupture without hemodynamically significant bleeding, a more benign abdominal exam may be present without significant alteration of vital signs. Fever is rare. In the more common situation of an unruptured ectopic pregnancy, the vital signs are likely to be normal.

If an adnexal mass or fullness with tenderness is detected, it may be due to ectopic pregnancy or to a **corpus luteum cyst,** a 3- to 11-cm, thin-walled, unilocular cyst seen after ovulation that can cause pain and tenderness on exam as well as menstrual irregularities, mimicking an ectopic pregnancy. Cervical motion tenderness may be seen, and blood is often present in the vaginal vault; however, the pelvic exam may be completely normal. The cervix may have a blue coloration, as in a normal pregnancy. Uterine size for estimated gestational age is most often normal. Vaginal examinations in stable women presenting with first-trimester bleeding may add little to the clinical diagnosis; some providers are moving away from routine use of vaginal examinations in initial patient assessment as long as a transvaginal US is obtained.[14]

DIAGNOSIS

The definitive diagnosis of ectopic pregnancy is made by US, by direct visualization by laparoscopy, or at surgery. No single or combination of laboratory tests has a sufficient negative or positive predictive value to completely exclude ectopic pregnancy or to definitively establish the diagnosis.

Serum β-hCG Differences in the dynamics of β-hCG production in normal and pathologic pregnancy are useful in the diagnosis of ectopic pregnancy. Early in normal pregnancy, β-hCG levels rise rapidly until 9 to 10 weeks of pregnancy and then plateau. Expected postconception ranges of β-hCG are listed in Table 98-2. β-hCG levels decline in nonviable pregnancies and in successfully treated ectopic pregnancy. Absolute levels of β-hCG tend to be lower in pathologic pregnancies than in IUPs, but there is much overlap. Due to the variability in absolute levels and the overlap between normal and pathologic pregnancies, **no single β-hCG level can reliably distinguish between a normal and a pathologic pregnancy**. *Doubling time* refers to the time needed for β-hCG concentration in the serum to double. Absolute levels of β-hCG are lower and doubling times longer in ectopic pregnancy and other abnormal pregnancies. This and many other observations have led to the widely used rule of thumb stating that the serum concentration of β-hCG approximately doubles every 2 days early in a normal pregnancy and that longer doubling times indicate pathologic pregnancy. Varying degrees of sensitivity (36% to 75%) and specificity (63% to 93%) are obtained using different criteria for evaluating the rate of increase of β-hCG levels for the diagnosis of ectopic pregnancy. The minimum hCG rise in normal pregnancy may be as low as 53% in 48 hours,[15] and the median rise in β-hCG level was 53% in 1 day and 124% in 2 days. Conversely, in spontaneous abortion, hCG is expected to fall by 21% to 35% in 2 days.[16] Thus, hCG levels that fail to increase by 53% or more in 2 days are suggestive but not diagnostic of ectopic pregnancy or an abnormal IUP. However, **an increase of >53% does not rule out ectopic pregnancy**.

In stable patients, serial measurements of β-hCG are used to either heighten or lower the suspicion for ectopic pregnancy, but are not diagnostic. Repeat serum β-hCG measurement made at least 2 days after the initial presentation is useful in characterizing the risk of ectopic pregnancy and the probability of a viable IUP.[17] Although rates of decline vary depending on the initial hCG value, a decrease of less than 21% at 2 days or 60% at 7 days suggests retained trophoblasts or an ectopic pregnancy; additional testing should be performed.[15] **Table 98-4** describes the American College of Emergency Physicians' clinical policy regarding women with early pregnancies.[17]

Progesterone Progesterone is a steroid hormone secreted by the ovaries, adrenal glands, and placenta during pregnancy. During the first 8 to 10 weeks of pregnancy, ovarian production of progesterone predominates, and serum levels remain relatively constant. After the tenth week of pregnancy, placental production increases and serum levels rise. Absolute levels of progesterone are lower in pathologic pregnancies and fall when a pregnancy fails. This observation has led multiple authors to propose various progesterone levels as a diagnostic aid in differentiating an early normal from a pathologic pregnancy. Most pathologic pregnancies have progesterone levels of ≤10 nanograms/mL. With progesterone ≤5 nanograms/mL, nearly 100% of pregnancies will be pathologic; there are no normal pregnancies reported with progesterone ≤2.5 nanograms/mL. Progesterone levels >25 nanograms/mL have 97% sensitivity for viable IUP. An empty uterus or nonspecific fluid collection on US associated

TABLE 98-4 ED Management of Early Pregnancy[17]

Clinical Issue	Recommendation	Level of Recommendation*
Use of transvaginal US to detect IUP, ectopic pregnancies when serum β-hCG <1000 mIU/mL	Perform or obtain a transvaginal US for symptomatic pregnant patients with β-hCG below the discriminatory threshold.	Level C
Use of β-hCG for predicting ectopic pregnancy in women with indeterminate transvaginal US	β-hCG values do not exclude the diagnosis of an ectopic pregnancy in patients with indeterminate transvaginal US.	Level B
Implications for ED management of women receiving methotrexate for confirmed or suspected ectopic pregnancy	Consider ruptured ectopic pregnancy for persistent abdominal pain or vaginal bleeding.	Level B
Anti-Rh_0 (D) immunoglobulin for ectopic pregnancy	50 micrograms of RhoGAM for all Rh-negative women with threatened loss or loss of established first-trimester pregnancy (full dose of 300 micrograms is not needed when the patient is at <12 weeks of gestation due to the small volume of red cells in the feto-placental circulation).	Level B

Abbreviations: β-hCG = β-human chorionic gonadotropin; IUP = intrauterine pregnancy.

*Level A: reflects high degree of clinical certainty; Level B: reflects moderate clinical certainty; Level C: reflects preliminary or conflicting evidence or based on consensus.

with progesterone ≤5.0 nanograms/mL is highly predictive of abnormal IUP or ectopic pregnancy.[18]

There is considerable overlap between progesterone levels in normal and pathologic pregnancy. Thus, very low values for serum progesterone should increase the clinical suspicion for ectopic pregnancy or abnormal IUP, but as with β-hCG levels, no value is diagnostic or can completely exclude or definitively diagnose ectopic pregnancy. Progesterone levels may not be routinely available on an urgent basis, and as noted, many patients have intermediate values, thus limiting the usefulness of the test. Consequently, the role of serum progesterone assays is currently unclear.

Numerous other serum markers for the diagnosis of ectopic pregnancy have been investigated. These include secretory endometrial protein, estradiol, the pregnancy-associated proteins A to D, and others, as well as routine laboratory tests such as amylase, creatine kinase, erythrocyte sedimentation rate, and others. None has been accepted as equal or superior to β-hCG measurements at this time.

US and Ectopic Pregnancy **The primary goal of US in early pregnancy is determination of a viable IUP and exclusion of ectopic pregnancy (Figure 98-1).**

US findings may also be useful in planning therapy when an ectopic pregnancy is discovered. Additionally, US provides information regarding fetal age and viability when an IUP is present.

It has previously been assumed that if an IUP exists, the diagnosis of ectopic pregnancy has been excluded. This assumption is based on the historical incidence of heterotopic pregnancy (combined IUP and ectopic pregnancy), reported to occur in 1 in 30,000 pregnancies. This is no longer a completely safe assumption, with heterotopic pregnancy now occurring in up to 1 in 3000 pregnancies in the general population. **In vitro fertilization and other efforts to enhance fertility with the use of ovulation-inducing drugs have resulted in a higher incidence of heterotopic pregnancy.** A study of 725 in vitro fertilization pregnancies found 4% to be ectopic pregnancies with 2 of 29 heterotopic gestations.[18] Heterotopic pregnancy should be considered even when US demonstrates an IUP in the assisted reproduction population. For other patients, demonstrating an IUP still provides a high degree of confidence in ruling out ectopic pregnancy. This confidence should be somewhat tempered when a patient has risk factors for ectopic pregnancy.

Advances in sonographic imaging and the use of transvaginal US scanning allow earlier detection of an IUP or an ectopic pregnancy. These advances have contributed to increasing use of real-time, bedside US in the ED performed by emergency physicians. ED US has the further advantage of allowing a potentially unstable patient to remain under continuous observation in the ED. When performed by trained individuals, bedside ED US in the first trimester of pregnancy is accurate and contributes to earlier diagnosis and treatment of ectopic pregnancy. However, US is operator-dependent, and there is limited validation in the community setting of the positive results obtained in academic teaching hospitals. Therefore, keep in mind the limitations of the procedure, equipment, and operator experience.[19]

The sequencing of transabdominal versus transvaginal US is situation- and operator-dependent. Usually, transabdominal scanning is performed first. Among other differences, transabdominal scanning is less invasive and offers a wider field of view and easier orientation to the pelvic organs. A full bladder is required for an appropriate acoustic window.

When transabdominal US is not diagnostic, transvaginal scanning should be performed. A full bladder is not required. The shallower depth of field and higher frequencies made possible by the lack of interposed abdominal fat allow better visualization of early pregnancies. There are reports of negative transvaginal but positive transabdominal US in cases of ectopic pregnancy, so both studies should be performed if the study performed first is not diagnostic. However, in one study of >5000 women with early pregnancy, pregnancy location was accurately diagnosed in >90% with a single transvaginal scan.[20]

When US reveals an unequivocal IUP and no other abnormalities, ectopic pregnancy is effectively excluded unless the patient is at high risk for heterotopic pregnancy. An embryo with cardiac activity seen within the uterine cavity is referred to as a *viable IUP*. When an embryo without cardiac activity is visualized within the uterus, the diagnosis of fetal demise can be entertained, provided that the crown–rump length is at least 5 mm. Briefly, transvaginal scanning can usually visualize the early sonographic signs of pregnancy, the gestational sac, yolk sac, and fetal pole, at 4.5, 5.5, and 6.0 weeks, respectively. Visualization by transabdominal scanning can be done approximately 1 week later.

No further diagnostic testing is needed when sonographic findings confirm or are highly suggestive of ectopic pregnancy. An empty uterus with embryonic cardiac activity visualized outside the uterus is diagnostic of ectopic pregnancy. This is seen in <10% of ectopic pregnancies using transabdominal scanning, but in up to 25% of cases when the transvaginal approach is used. When a pelvic mass or free pelvic fluid is seen in conjunction with an empty uterus, ectopic pregnancy is considered highly likely (**Figure 98-2**). The combination of an echogenic adnexal mass with free fluid in the setting of an empty uterus confers a risk of ectopic pregnancy near 100%, whereas a large amount of free

fluid alone has a 86% risk (**Table 98-5**). In addition to a living extrauterine pregnancy, an extrauterine gestational sac is highly predictive of ectopic pregnancy (**Figure 98-3**). Any adnexal mass (other than a simple cyst) seen with US also has high positive predictive value for the diagnosis of ectopic pregnancy.[21,22] It has also been suggested that increased thickness of the endometrial stripe is predictive of ectopic pregnancy when no other diagnostic findings are noted on US. However, the wide overlap between endometrial stripe thickness in normal and ectopic pregnancy limits the usefulness of this observation.[23]

The Discriminatory Zone If US fails to reveal a definite IUP or fails to show findings strongly suggestive or diagnostic of an ectopic pregnancy, the test should be considered indeterminate and interpreted in light of quantitative serum β-hCG levels. The concept of the "discriminatory zone" was developed to relate β-hCG levels and US findings in a clinically useful way.[22] The discriminatory zone is the level of β-hCG at which findings of an IUP are expected on US. A β-hCG level higher than the discriminatory zone and an empty uterus on US suggest an ectopic pregnancy. An empty uterus with a β-hCG level below the discriminatory zone is indeterminate, neither confirming nor negating the diagnosis of ectopic pregnancy. The actual level of β-hCG representing the discriminatory zone is operator- and technique-dependent. With transvaginal scanning, the discriminatory zone is often considered to be 1500 mIU/mL. For transabdominal scanning, an IUP should be detectable when the β-hCG level reaches about 6000 mIU/mL. Clinicians should understand this concept and collaborate closely with imaging specialists in equivocal cases to avoid confusion. **When ectopic pregnancy is suspected, US should be performed even in patients with low β-hCG levels**, because ectopic pregnancy can occur even at very low (<500 mIU/mL) β-hCG levels.[24] Further, decision to intervene on a pregnancy should not be made solely on a single hCG level; if the patient is hemodynamically stable with a β-hCG greater than the discriminatory zone and no visible intrauterine or extrauterine pregnancy, watchful waiting is an appropriate management strategy with close follow-up and strict return precautions.[25]

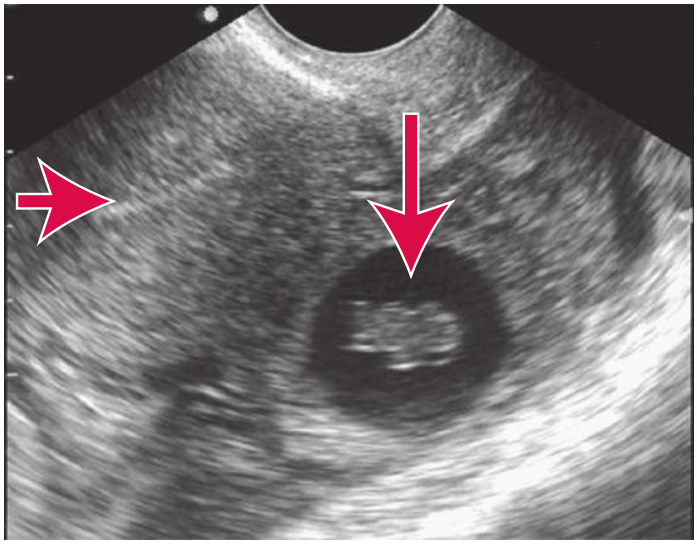

FIGURE 98-3. US of ectopic pregnancy. A living embryo in the adnexa and empty uterus is seen in this ectopic pregnancy (endometrial echo is visible in the left upper portion of the image). Embryonic cardiac activity was present on real-time imaging. Transvaginal image. *Horizontal arrow* points to empty uterus (uterine stripe), and *vertical arrow* points to ectopic pregnancy in the adnexa. Other Diagnostic Modalities **MRI** has high sensitivity and specificity for the diagnosis of ectopic pregnancy, but cost, availability, and the time to perform the study make the use of MRI of only theoretical interest at the present time.

Culdocentesis has been supplanted by tests for β-hCG in combination with US, but it may have use when US is unavailable. A positive test facilitates an appropriate, rapid surgical intervention. Possible results include a dry aspiration, which has no diagnostic value. If clear, nonbloody peritoneal fluid is aspirated, the tap is considered negative. Aspiration of nonclotting blood constitutes a positive tap and is considered indicative of an ectopic pregnancy. However, there is no consensus regarding the criteria for a positive test. Various authors have proposed volumes between 0.3 and 10 mL, with hematocrit from 3% to 15%. The pathophysiologic basis for culdocentesis is that a ruptured ectopic pregnancy will bleed into the pelvic peritoneal cavity. Some 85% to 90% of patients with a ruptured ectopic pregnancy will have a positive culdocentesis. Surprisingly, up to 70% of patients with an unruptured ectopic pregnancy will also have a positive result. A basic limitation of the technique is that it is less sensitive in the diagnosis of unruptured than ruptured ectopic pregnancy. Another cause of false-negative results is that, in cases of rapid bleeding, intraperitoneal blood may clot due to the lack of sufficient dwell time to produce defibrination. False-positive results occur because of technical errors (entering a vein or other vascular structure with the needle) or a ruptured corpus luteum cyst. Aspiration of purulent material may indicate another diagnosis, such as pelvic inflammatory disease.

Laparoscopy may be both diagnostic and therapeutic. Laparoscopy is primarily useful in patients with suspected ectopic pregnancy and a nondiagnostic US. It may provide an earlier diagnosis and a possible route for definitive treatment when compared with serial β-hCG measurements and US. As with other invasive techniques, results vary with the skill of the operator and the quality of the available equipment.

Dilatation and curettage may provide a definitive diagnosis of IUP, thus excluding ectopic pregnancy except in cases of heterotopic pregnancy. Dilatation and curettage diagnoses an IUP when chorionic villi are obtained from the uterine cavity. The procedure terminates an IUP and is applicable only when termination of pregnancy is desired or when a nonviable pregnancy has been documented.

TREATMENT

The treatment of ectopic pregnancy can be divided into surgical and medical approaches. If laparoscopy is needed for diagnosis, a surgical approach is most appropriate. For unruptured ectopic pregnancy, the most frequently used surgical approach is laparoscopic salpingostomy; the most frequently used medical approach is systemic methotrexate treatment. There is no difference in success rates between methotrexate, salpingotomy, and salpingectomy in appropriately selected women with unruptured ectopic pregnancies.[26,27] Laparotomy is the treatment of choice in hemodynamically unstable patients. Laparoscopy is preferred in a hemodynamically stable patient.

Methotrexate **Methotrexate** is the only drug currently recommended as a medical alternative to surgical treatment of ectopic pregnancy and is ideally used in patients with hemodynamic stability, minimal abdominal pain, the ability to follow up reliably, and normal baseline liver and renal function tests. Contraindications to methotrexate use are listed in

TABLE 98-6 Contraindications to Methotrexate Administration[28]

Absolute Contraindications	Relative Contraindications
Intrauterine pregnancy	Embryonic cardiac activity detected by transvaginal US
Evidence of immunodeficiency	Human chorionic gonadotropin concentrations >5000 mIU/mL
Moderate to severe anemia, leukopenia, or thrombocytopenia	Ectopic pregnancy >4 cm in size as imaged by transvaginal US
Sensitivity to methotrexate	Refusal to accept blood transfusion
Active pulmonary disease	Inability to reliably return for follow-up
Active peptic ulcer disease	
Clinically important hepatic or renal dysfunction	
Breastfeeding	
Hemodynamic instability	

Table 98-6.[28] Methotrexate is a folic acid antagonist that inhibits dihydrofolate reductase, causing depletion of cofactors needed for DNA and RNA synthesis. Different methotrexate regimens have been used, including both systemic IM injections and direct injection into the ectopic gestational sac. IM methotrexate is the most commonly used approach, eliminating the need for laparoscopy or US guidance. The failure rate is 14.3% or higher with single-dose methotrexate when pretreatment β-hCG levels are >5000 mIU/mL, compared with 3.7% for levels <5000 mIU/mL.[29] If β-hCG levels are higher than 5000 mIU/mL, multiple doses may be appropriate.[30] The success rate of the multiple-dose regimen was statistically significantly higher than that seen with a single dose of methotrexate (92.7% vs 88.1%).[31]

The most common side effects associated with methotrexate include abdominal pain after treatment (up to 75% of patients) followed by flatulence and then stomatitis. Lower abdominal pain lasting up to 12 hours is common 3 to 7 days after methotrexate treatment and is thought to be secondary to methotrexate-induced tubal abortion or tubal distention due to hematoma formation ("separation pain").[32] The pain is usually self-limited and may respond to nonsteroidal anti-inflammatory drugs.

Abdominal pain after methotrexate treatment represents a clinical dilemma. It is difficult to differentiate expected pain from therapeutic tubal abortion and hematoma formation with fallopian tube distension (separation pain) from pain associated with rupturing persistent ectopic pregnancy.[32] Suggested evaluation of patients presenting with abdominal pain in this time frame after methotrexate administration includes a CBC and abdominopelvic US to rule out tubal rupture and hemoperitoneum and consideration of other causes of abdominal pain.[3] Such patients may need admission to the hospital for observation. Hemodynamic instability and/or falling hematocrit require consideration for surgical intervention. Many centers will proceed to surgical intervention in patients with moderate to severe pain, free fluid in the cul-de-sac, or rebound tenderness, although conservative treatment has proven successful in stable patients after methotrexate therapy.[32] Prognostic factors associated with a higher failure rate for methotrexate treatment include larger tubal diameter, higher initial β-hCG levels, severe abdominal pain, and fetal cardiac activity.[33]

Methotrexate administration in properly selected patients with ectopic pregnancy may be initiated in the ED, clinic, or obstetrician/gynecologist's office. Treatment initiated in the ED should be in close conjunction with an obstetrician/gynecologist or other physician capable of providing follow-up care. Keep pelvic examinations after methotrexate treatment to a minimum to decrease the risk of tubal rupture. Patient instruction on discharge should include the following points:[34]

- Treatment failure occurs in up to 36% of cases.
- Elective or emergency surgical treatment may be necessary if medical therapy fails or tubal rupture occurs (~5% of cases).
- Vaginal bleeding, abdominal pain, weakness, dizziness, or syncope after treatment should be evaluated immediately as possible signs of tubal rupture.[16]
- Patients should refrain from sexual intercourse for 14 to 21 days after treatment (until β-hCG levels are undetectable), because it may increase the risk of tubal rupture.

Rh Seroconversion and Indications for Anti-D Immunoglobulin

Rh_0 (D) antigen can be detected as early as 5.5 weeks and certainly by 6 weeks of gestation. Alloimmunization can occur with as little as 0.1 mL of fetal blood admixing with the mother's. Alloimmunization can occur from ectopic pregnancy. Circulating blood volume of the fetus is <5 mL in the first trimester. **Both the American College of Emergency Physicians and the American College of Obstetricians and Gynecologists recommend treatment with 50 micrograms of RhoGAM for Rh-negative women with ectopic pregnancy when diagnosed prior to 12 weeks of gestation due to the small volume of red cells in the fetoplacental circulation, although administration of a full dose of 300 micrograms is acceptable as well.**

DISPOSITION AND FOLLOW-UP

When a patient with signs or symptoms suggestive of ectopic pregnancy is found to be pregnant, determine if the pregnancy is intrauterine (**Figure 98-4**). The nature and timing of additional diagnostic measures depend on the clinical condition of the patient. Unstable patients with suspected ectopic pregnancy should receive resuscitation, urgent consultation, and operative intervention. Surgery may be both diagnostic and therapeutic if an ectopic pregnancy is found or may reveal another cause for the patient's condition. When bedside ED US is available, it may be valuable even in unstable patients, as it should not interfere with resuscitation, consultation, and rapid transfer to the operating room.

Ideally, all pregnant patients with suspected ectopic pregnancy should receive immediate US. However, issues of availability during off hours may make this impractical. Stable patients who are judged to be at low risk for ectopic pregnancy can be considered for discharge and outpatient follow-up. Such patients should have a quantitative β-hCG level obtained to facilitate subsequent management. Culdocentesis remains an option where US is unavailable, but currently is used rarely due to its limitations and the unfamiliarity of many emergency physicians with the technique.

Stable patients with β-hCG levels above the discriminatory zone and an empty uterus on US, with or without other US findings of an ectopic pregnancy, are presumed to have an ectopic pregnancy. These patients should receive consultation in the ED.

Management options for stable patients with a β-hCG level below the discriminatory zone and indeterminate US include consultation in the ED or discharge for follow-up in 2 days for reexamination and repeat β-hCG levels. Culdocentesis, dilatation and curettage, and laparoscopy are also options in this circumstance; however, the decision is normally left to the obstetrician's discretion. Figure 98-4 illustrates a suggested diagnostic approach.

OTHER CAUSES OF BLEEDING IN THE FIRST 20 WEEKS OF PREGNANCY

Common causes of bleeding during early pregnancy are listed in **Table 98-7**.

SPONTANEOUS ABORTION

The World Health Organization defines spontaneous abortion as loss of pregnancy before 20 weeks or loss of a fetus weighing <500 grams. Estimates of pregnancies that abort spontaneously range from 20% to 40%. Approximately 75% of spontaneous abortions occur before 8 weeks of gestation (**Table 98-8**).

The most common cause of fetal loss is chromosomal abnormalities. Other associations include advanced maternal age, prior poor obstetric history, concurrent medical disorders, previous abortion, infection (including syphilis and human immunodeficiency virus), and some anatomic abnormalities of the upper genital tract. Exposure to some agents, such as certain anesthetic agents, certain heavy metals, and tobacco, may also contribute to the incidence of abortion.

Bleeding with or without abdominal pain is the most common presenting complaint.

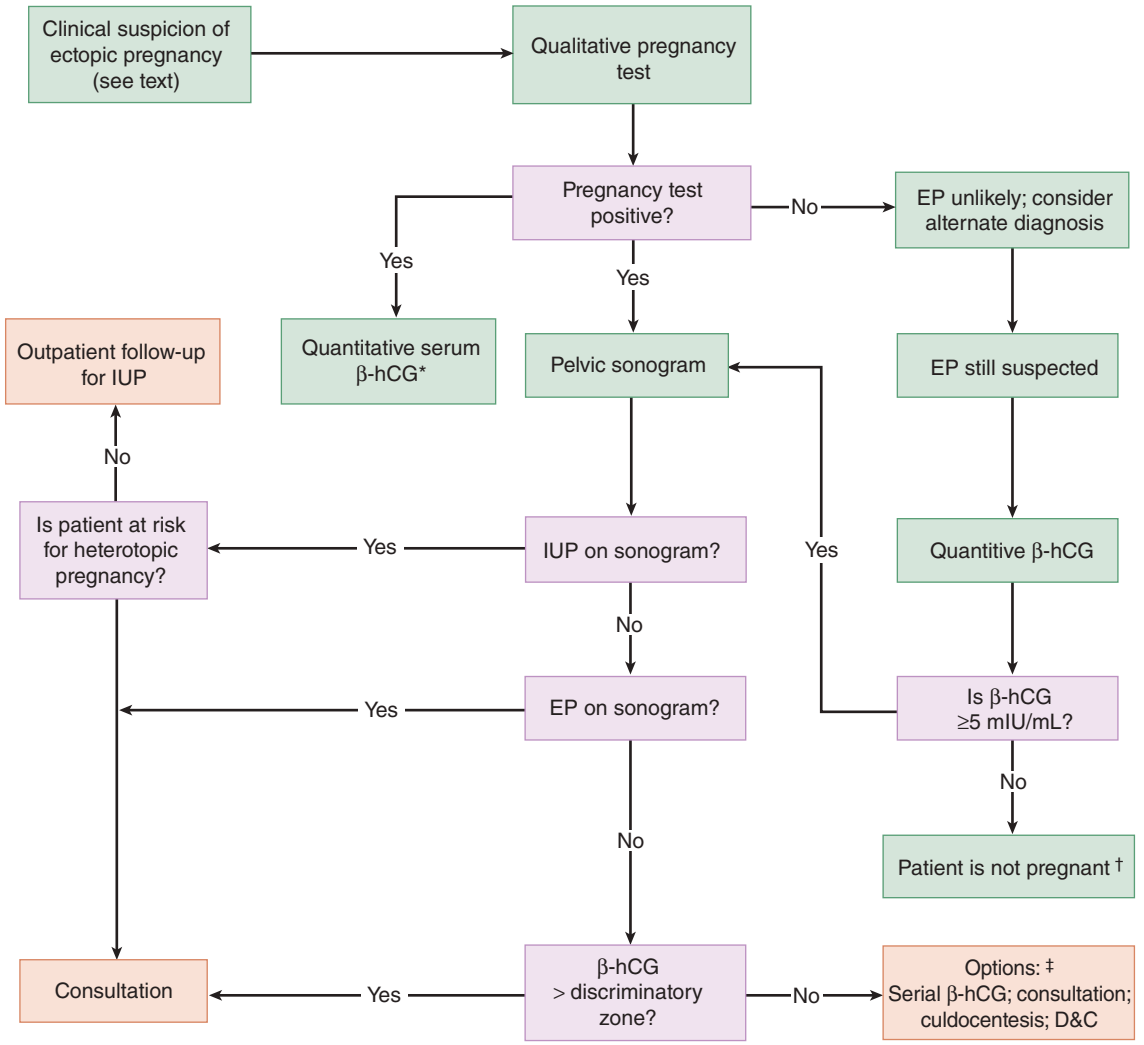

FIGURE 98-4. Diagnostic algorithm for suspected ectopic pregnancy. *Quantitative measurement of β subunit of human chorionic gonadotropin (β-hCG) before US may facilitate rapid patient disposition by saving time. †There have been extremely rare reports of pregnancy with β-hCG <5 mIU/mL. ‡Serial outpatient β-hCG measurements are recommended only for stable patients judged to be at low risk for ruptured ectopic pregnancy. D&C = dilatation and curettage; EP = ectopic pregnancy; IUP = intrauterine pregnancy.

TABLE 98-7 Common Causes of Vaginal Bleeding During the First Trimester of Pregnancy

Abortion
Ectopic pregnancy
Gestational trophoblastic disease
Implantation bleeding (physiologic)

TABLE 98-8 Spontaneous Abortion Terminology

Terminology	Definition
Threatened abortion	Pregnancy-related bloody vaginal discharge or frank bleeding during the first half of pregnancy without cervical dilatation
Inevitable abortion	Vaginal bleeding and dilatation of the cervix
Incomplete abortion	Passage of only parts of the products of conception
	More likely to occur between 6 and 14 weeks of pregnancy
Complete abortion	Passage of all fetal tissue, including trophoblast and all products of conception, before 20 weeks of conception
Missed abortion	Fetal death at <20 weeks without passage of any fetal tissue for 4 weeks after fetal death
Septic abortion	Evidence of infection during any stage of abortion

DIAGNOSIS

In addition to the standard medical history, determine the amount of bleeding as pads used per hour to anticipate blood loss, last menstrual period, and past obstetric history. A pelvic examination is needed to define the type of abortion and to determine the amount and site of bleeding, whether the cervix has dilated, and whether any tissue has been passed.

The diagnosis of pregnancy is central to the diagnosis of abortion. Obtain a quantitative serum β-hCG level, CBC to evaluate for blood loss, blood type, Rh factor and antibody screen, and urinalysis (urinary tract infection has been associated with increased fetal wastage). US can help rule out ectopic pregnancy, aid as a prognostic tool for fetal viability, and diagnose retained products of conception. US studies combined with determinations of β-hCG levels can be both diagnostic and prognostic. Although a β-hCG of 1500 IU/mL is a somewhat arbitrary value when evaluating pregnancy, it is still useful when comparing with US findings. Although institution-dependent, an IUP should be visible on transvaginal US at this concentration. **Table 98-9** describes expected US findings at certain gestational ages and β-hCG values.[35]

TREATMENT

Patients with threatened abortion can be discharged safely if follow-up is ensured. Although a low level of activity and even bed rest are

TABLE 98-9 Comparison of Gestational Age, β-hCG, and US Findings

Gestational Age	β-hCG (mIU/mL)	Transvaginal US Findings	Transabdominal US Findings
4–5 weeks	<1000	Intradecidual sac	N/A
5 weeks	>2000	Yolk sac (± embryo)	Gestational sac
6 weeks	10,000–20,000	Embryo with cardiac activity	Yolk sac (± embryo)
7 weeks	>20,000	Embryonic torso/head	Embryo with cardiac activity

sometimes advised, there is no proven effectiveness of this practice. Generally speaking, a miscarriage cannot be avoided. Patients should avoid intercourse and tampons to minimize risk of infection.

Patients with a diagnosis of incomplete abortion should have the uterus evacuated. The decision to proceed with medical treatment, such as PO misoprostol, 600 micrograms, or surgical treatment, such as dilatation and curettage, should be made in consultation with the patient and an obstetrician.[36]

Patients with a complete abortion, as shown by US and complete passage of products of conception, can be discharged safely, with follow-up ensured. If there is any doubt, obtain obstetrics consultation for possible dilatation and curettage.

Patients with a nonviable fetus can be either admitted or discharged to be followed up within 1 week, depending on the comfort level of the patient and physician with this decision. Patients should return immediately if there is heavy bleeding (more than one pad per hour for 6 hours), pain, or fever.

Pregnant women with vaginal bleeding who are Rh-negative should be treated with Rh_0 (D) immunoglobulin (RhoGAM). RhoGAM should be administered before discharge, if possible, but it also can be administered within 72 hours by the primary care physician or obstetrician when the woman presents several days or weeks after vaginal bleeding has begun.

SEPTIC ABORTION

A septic abortion is a spontaneous or other abortion complicated by a pelvic infection. Presenting complaints include fever, abdominal pain, vaginal discharge, vaginal bleeding, and history of recent pregnancy. The most common causes are retained products of conception due to incomplete spontaneous or therapeutic abortion and introduction of either normal or pathologic vaginal bacteria by instrumentation.

Perform a history and physical examination, including a pelvic examination. Obtain a quantitative serum β-hCG level, CBC to evaluate for anemia due to blood loss, blood type, Rh factor and antibody screen, urinalysis, and blood cultures. An US will help identify retained products of conception in the uterus, adnexal masses, and free fluid in the cul-de-sac. Treatment consists of fluid resuscitation, broad-spectrum IV antibiotics, and early obstetric consultation for evacuation of the uterus. Antibiotics, such as ampicillin/sulbactam, 3 grams IV, or clindamycin, 600 milligrams, plus gentamicin, 1 to 2 milligrams/kg IV, should cover both normal vaginal flora and those causing sexually transmitted disease.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease consists of a broad spectrum of conditions ranging from an uncomplicated partial hydatidiform molar pregnancy to stage IV choriocarcinoma with cerebral metastases.[37] It is a neoplasm that arises in the trophoblastic cells of the placenta. It complicates 1 in 1700 pregnancies in North America and is more common in Asian women. The noninvasive form of the disease is the hydatidiform mole, which is either complete or partial. Complete moles are more common, and in this form, there is no actual fetus, whereas in the partial mole, a deformed, nonviable fetus is present. Both moles and invasive forms are composed of trophoblasts that produce β-hCG. Patients with a history of hydatidiform molar pregnancy are at increased risk of future molar pregnancies, with a risk of 1% in subsequent gestations after one molar pregnancy and a risk as high as 23% after two molar gestations.

Symptoms include vaginal bleeding in the first or second trimester (75% to 95% of cases) and hyperemesis (26%). Gestational trophoblastic disease, or molar pregnancies that persist into the second trimester, are associated with pre-eclampsia. **When pregnancy-induced hypertension is seen before 24 weeks of gestation, consider the possibility of a molar pregnancy.** The uterus is excessive in size for gestational age and shows a placenta with many lucent areas interspersed with brighter areas on US study. Because not all molar pregnancies are found on US, all tissue extracted from the uterus on suction curettage or during pelvic examination should be sent for histologic examination. If trophoblastic disease is suspected because of abnormally high β-hCG levels, a uterine size either larger or smaller than expected, and US findings suggestive of the diagnosis, obtain obstetric consultation. Treatment is by suction curettage in the hospital setting because of risk of hemorrhage. β-hCG levels that fail to decrease after evaluation are evidence of persistent or invasive disease necessitating chemotherapy. Metastasis to lung, liver, and brain may occur, but the prognosis for most patients is very good. Trophoblastic embolization, although extremely rare, may occur, with resulting rapid onset of respiratory distress resembling amniotic fluid embolus.

IMPLANTATION BLEEDING

Implantation bleeding can occur as the embryo implants into the vascular uterine decidual tissue. Bleeding can be scant or like menstrual bleeding and usually occurs at 5 or 6 weeks after the last period. Pelvic examination is normal. Implantation bleeding is diagnosed only after excluding ectopic pregnancy.

NAUSEA AND VOMITING OF PREGNANCY AND HYPEREMESIS GRAVIDARUM

EPIDEMIOLOGY

Nausea and vomiting of pregnancy generally are seen in the first 12 weeks. The etiology is unknown. Severe nausea and vomiting of pregnancy is known as hyperemesis gravidarum and is defined as intractable vomiting with weight loss, volume depletion, and laboratory values showing hypokalemia or ketonemia. It occurs in up to 2% of all pregnancies. Patients with gestational trophoblastic disease also may present with intractable vomiting for unknown reasons.

CLINICAL FEATURES

Findings on physical examination in nausea and vomiting of pregnancy are usually normal except for signs of volume depletion. Laboratory tests to consider include CBC, serum electrolytes, BUN, creatinine, and urinalysis. The finding of ketonuria is important because it is an early sign of starvation. However, there is no evidence that ketosis per se is harmful to the fetus. Serial measurements of urinary ketones can be used to determine success of therapy.

The presence of abdominal pain in nausea and vomiting of pregnancy or hyperemesis gravidarum is highly unusual and should suggest another diagnosis. Ruptured ectopic pregnancies occasionally present with nausea and vomiting, as well as diarrhea and abdominal pain. Gallbladder dilatation and biliary sludge increase in pregnancy, predisposing to stone formation. Cholelithiasis and cholecystitis are more common in pregnant women than in women of comparable age and health status who are not pregnant. Differential diagnosis of vomiting or vomiting with abdominal pain should include cholecystitis, cholelithiasis, gastroenteritis, pancreatitis, appendicitis, hepatitis,

TABLE 98-10 Antiemetics

Antiemetic	Brand Name	U.S. Food and Drug Administration Category	PO	PR	IV
Promethazine	Phenergan	C	12.5–25 milligrams every 4 h	12.5–25 milligrams every 4 h	IV administration is generally recommended against; 12.5–25 milligrams IM every 4 h
Prochlorperazine	Compazine	—	10 milligrams every 6–8 h	25 milligrams every 12 h	10 milligrams over 2 min Maximum of 40 milligrams every 24 h
Chlorpromazine	Thorazine	C	10–25 milligrams every 4–6 h	100 milligrams every 6–8 h	25 milligrams in 500 mL NS at 250 mL/h
Ondansetron	Zofran	B	4–8 milligrams every 8 h	—	8 milligrams IV over 5 min
Metoclopramide	Reglan	B	10 milligrams orally every 6–8 h	—	10 milligrams over 1–2 min every 6–8 h
Maintenance Therapy for Nausea and Vomiting					
Doxylamine with pyridoxine	Diclegis/ Diclectin	A	2 tablets every evening	—	—
Vitamin B_6	—	—	25 milligrams every 8 h	—	—
Ginger	—	—	500–1000 milligrams daily	—	—
Diphenhydramine	Benadryl	B	25–50 milligrams every 6 h	—	—

peptic ulcer, pyelonephritis, ectopic pregnancy, fatty liver of pregnancy, and the syndrome of *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets (HELLP syndrome).

TREATMENT

Treatment consists of IV fluids containing 5% glucose in either lactated Ringer's solution or normal saline to replete volume and reverse ketonuria. A number of antiemetic drugs can be used (**Table 98-10**) for patients who remain nauseated or continue to vomit. Initially, the patient should be given nothing by mouth. Oral fluids should be started after the nausea and vomiting are controlled but before discharge.

DISPOSITION AND FOLLOW-UP

The patient may be discharged after reversal of ketonuria, correction of electrolyte imbalance, and a successful trial of oral fluids. Discharge with antiemetic medication is usually necessary. There is no clear drug of choice.

Phenothiazines can cause drowsiness or dystonic reactions in some patients. Ondansetron (Zofran®), 8 milligrams IV or 4 milligrams PO three times daily, can cause headache, constipation, diarrhea, or lightheadedness. It does not cause dystonia. Its chief disadvantage is cost. It is apparently no more effective than promethazine.[15] Doxylamine and pyridoxine (Bendectin®), a mainstay of therapy in the past, was discontinued due to fears of teratogenicity, but with new information, it does not represent an increase in fetal risk and has been reintroduced on the North America market as Diclegis/Diclectin (also put in trademark sign after Diclegis/Diclectin).[16,38]

Admission guidelines include uncertain diagnosis, intractable vomiting, persistent ketone or electrolyte abnormalities after volume repletion, and weight loss of >10% of prepregnancy weight.

CHAPTER 99

Comorbid Disorders in Pregnancy

Lori J. Whelan

INTRODUCTION

This chapter reviews the most common comorbid conditions encountered in pregnant women in the ED environment: diabetes and hypoglycemia; thyroid disorders; hypertensive disorders; cardiac arrhythmias; thromboembolism; asthma; renal disease; urinary tract infections; sickle cell disease; headache; seizures; substance abuse; and intimate partner violence. Drug risk during pregnancy, lactation, and fetal effects of radiation are summarized based on currently available data. Resuscitation is covered in chapter 25, "Resuscitation in Pregnancy."

DIABETES IN PREGNANCY

Maternal diabetes affects >8% of the 4 million live births annually in the United States.[1] Three fourths of pregnant patients with diabetes have either gestational diabetes or type 2 diabetes diagnosed through prenatal screening. Of the remaining 25%, 1% have preexisting type 1 diabetes, and the remaining are type 2 diabetics. Pregnant diabetic women are at increased risk for spontaneous abortion, particularly patients with poor glycemic control early in pregnancy, preexisting vascular disease, and pre-eclampsia. Pregnant diabetics are also at increased risk for several pregnancy complications, including pregnancy-induced hypertension, preterm labor, spontaneous abortion, pyelonephritis, and diabetic ketoacidosis (DKA). The goal of treatment during pregnancy is to prevent spontaneous abortions, hyperglycemia-induced congenital abnormalities and ketoacidosis, and hypoglycemia.

Oral hypoglycemic agents, such as metformin and glyburide, are occasionally used in select patients with gestational diabetes.[2] A significant portion of gestational diabetics can be managed with diet alone if they can maintain glycemic goals with frequent glucose monitoring.

The American College of Obstetricians and Gynecologists recommends the following goals for maintaining euglycemia in pregnant diabetic patients: a fasting blood glucose concentration of ≤95 milligrams/dL and a 2-hour postprandial glucose concentration

≤120 milligrams/dL.[3] Patients with gestational diabetes who are managed by diet alone rarely develop acute hyperglycemic complications because glucose values rarely reach levels consistent with DKA. Among patients with preexisting type 1 and type 2 diabetes, the need for insulin increases throughout the course of pregnancy. Historically, all type 2 diabetics were switched to insulin as soon as possible (even prior to conception) to ensure appropriate glycemic control and due to concerns over the safety of oral hypoglycemic agents in pregnancy. Recent studies in gestational diabetes have not shown metformin or glyburide to have any harmful fetal effects, but long-term studies are needed. Although metformin may be continued in select patients, there is no consensus on the use of these oral agents alone in the pregnant patient with type 2 diabetes.[2-5]

In general, during the first trimester, the initial insulin requirement is 0.7 units/kg/day. By late pregnancy, patients generally require 1 unit/kg/day.[6]

Neutral protamine Hagedorn (NPH)/regular insulin combinations are still first-line insulin therapy, but the long-acting analog insulin detemir (Levemir) is approved by the U.S. Food and Drug Administration for use in pregnancy and is category B. Compared to NPH, insulin detemir improves fasting plasma glucose and decreases hypoglycemic events. There is a strong evidence base to recommend insulin detemir in pregnancy, but the lack of definitive fetal benefit means that there is no pressing need to switch a woman whose diabetes is well controlled by NPH insulin to insulin detemir.

Insulin glargine (Lantus) is still category C. It is generally not initiated during pregnancy. However, it seems reasonable to continue insulin glargine when it was successful maintaining excellent glycemic control in a woman who is now pregnant.[7]

HYPOGLYCEMIA

Women with type 1 diabetes have three to five times more hypoglycemic episodes than the period prior to pregnancy.[8] Risk factors for severe hypoglycemia during pregnancy include a history of severe hypoglycemia in the year preceding pregnancy, impaired hypoglycemia awareness, long duration of diabetes, low HbA_{1c} in early pregnancy, fluctuating plasma glucose levels, and excessive use of insulin injections between meals.[8] Hypoglycemia generally presents as sweating, tremors, blurred or double vision, weakness, hunger, confusion, paraesthesias, anxiety, palpitations, nausea, headache, or stupor. Moderate and infrequent hypoglycemic episodes are generally well tolerated by the fetus.[4] Pregnant diabetic women should be educated about the symptoms and treatment of hypoglycemia. Treat mild hypoglycemia (i.e., a glucose level of <70 milligrams/dL in patients who are able to follow commands) by giving juice, glucose, or food by mouth. Provide standard treatment for more severe hypoglycemia, with IV glucose or PO glucose or glucagon 1 to 2 milligrams SC or IV (see chapters 223, "Type 1 Diabetes Mellitus" and 224, "Type 2 Diabetes Mellitus").

DIABETIC KETOACIDOSIS IN PREGNANCY

A pregnant diabetic who is ill appearing, has persistent nausea and vomiting, and/or has a blood glucose level ≥180 milligrams/dL should be screened for DKA with serum or urine ketones and a serum chemistry panel. Management guidelines for pregnant women with DKA are the same as for nonpregnant patients[9] (see chapter 225, "Diabetic Ketoacidosis"). In addition to the usual care, obtain fetal heart tones, administer oxygen, and for third-trimester patients, place in the left lateral decubitus position to displace the uterus and improve uterine blood flow. Most fetal heart rate abnormalities subside after correction of maternal hypovolemia and acidosis. Consult with the patient's physician, and admit the patient to the hospital.

The incidence of DKA in pregnancy decreases with early diagnosis of insulin-dependent diabetes, improved prenatal counseling, and care with an identifiable primary care provider.[10,11] DKA most commonly affects women in the second or third trimester or pregnant women with new-onset type 1 diabetes.[10,12]

Women who use continuous SC insulin infusions (the insulin pump) can develop DKA whether they are pregnant or not. DKA can develop very quickly and unexpectedly, especially in patients who have recently started using the pump.[13,14] Use of continuous insulin pumps during pregnancy is equivalent, but not superior, to scheduled injections. Management of DKA in a pregnant woman with an insulin pump is the same as the nonpregnant patient.

DKA is not an indication for delivery. Although fetal heart rate monitoring in maternal DKA may initially demonstrate a nonreassuring pattern, patterns usually improve as maternal ketoacidosis is corrected, and mother will tolerate delivery or cesarean section better once acidosis resolves.[10,15]

THYROID DISORDERS

TRANSIENT HYPERTHYROIDISM OF HYPEREMESIS GRAVIDARUM

Women in the first trimester with weight loss, tachycardia, and vomiting consistent with hyperemesis gravidarum may also demonstrate laboratory evidence of hyperthyroidism, or biochemical or transient hyperthyroidism. The most likely cause is thyrotropin receptor stimulation from high human chorionic gonadotropin serum concentrations. Women with transient hyperthyroidism have no previous history of thyroid disease, no palpable goiter, and except for tachycardia, no other symptoms or signs of hyperthyroidism. Test results for thyroid antibodies are negative. With transient hyperthyroidism of hyperemesis gravidarum, thyroid-stimulating hormone (TSH) may be suppressed and free thyroxine (T_4) elevated, but triiodothyronine (T_3) is **lower** than in true hyperthyroidism. With true hyperthyroidism, both free T_4 and T_3 are usually **elevated**. Only symptomatic treatment is suggested for transient hyperthyroidism, and antithyroid medication is not recommended.[16]

HYPERTHYROIDISM

True hyperthyroidism in pregnancy increases the risk of pre-eclampsia, low birth weight, and possibly congenital malformations. Symptoms of hyperthyroidism can mimic symptoms of normal pregnancy and may consist of nervousness, palpitations, heat intolerance, and inability to gain weight despite a good appetite. Methimazole and propylthiouracil (PTU) are equally efficacious in the treatment of pregnant women. However, methimazole has a possible association with congenital abnormalities during first-trimester organogenesis, and PTU can cause hepatotoxicity. Therefore, during the first trimester, hyperthyroidism in pregnancy is treated with PTU followed by methimazole during the second and third trimesters.[17-19] Agranulocytosis and aplastic anemia are rare but serious complications in patients treated with antithyroid drugs. If this occurs, immediately discontinue the medication and obtain obstetrical consultation.

THYROID STORM

Patients with thyroid storm develop fever, volume depletion, or high-output heart failure. Labor, cesarean section, and infection all may precipitate thyroid storm in a woman with a history of hyperthyroidism. Thyroid storm has been associated with a mortality rate of up to 25%. The principles of treatment are summarized in **Table 99-1** and are similar to those for nonpregnant patients (see chapter 229, "Hyperthyroidism").

HYPERTENSION

Hypertensive disorders are the most common medical complication of pregnancy. Hypertension in pregnancy can be divided into five categories: chronic hypertension in pregnancy, gestational hypertension, preeclampsia, HELLP syndrome, and eclampsia. Chronic hypertension is discussed below, and the other disorders are discussed in detail in chapter 100, "Emergencies after 20 Weeks of Pregnancy and the Postpartum Period."

TABLE 99-1 Principles of Treatment of Thyroid Storm during Pregnancy

Principle	Comment
Inhibit thyroid hormone release with thionamides (PTU is preferred over methimazole; also blocks conversion of T_4 to T_3)	**Propylthiouracil** (PTU) 600–1000 milligrams PO loading dose followed by 200–250 milligrams PO every 4 h (first trimester) or **Methimazole** 40 milligrams PO loading dose followed by 25 milligrams PO every 4 h (second and third trimesters)
Inhibit new thyroid hormone production (give at least 1 h after above step)	**Lugol solution** 8–10 drops every 6–8 h or **Potassium iodine** 5 drops PO every 6 h or **Iopanoic acid** 1 gram IV every 8 h **Do not use radioactive iodine because the fetus will concentrate iodine-131 after the 10th to 12th week of gestation, resulting in congenital hypothyroidism**
Block peripheral thyroid hormone effects	**Propranolol** 1–2 milligrams IV every 10–15 min and start **Propranolol** 40 milligrams PO every 6 h or **Esmolol** 500 micrograms/kg IV bolus, then 50 micrograms/kg/min maintenance Hold if evidence of heart failure is present
Prevent conversion of T_4 to T_3	**Hydrocortisone** 100 milligrams IV every 8 h or **Dexamethasone** 2 milligrams IV every 6 h
Supportive care	Left lateral decubitus position Oxygen Cooling blankets IV fluids Acetaminophen 650 milligrams PO every 4 h[20]

CHRONIC HYPERTENSION IN PREGNANCY

Chronic hypertension is sustained elevation of blood pressure to >140/90 mm Hg, measured on two separate occasions before 20 weeks of gestation or persistent beyond 12 weeks postpartum.[21,22] Patients with mild hypertension (140/90 mm Hg) and no evidence of renal disease should be counseled on lifestyle modifications and observed. Because there is no consensus that antihypertensives can reduce the risk of fetal death, growth restriction, abruption, or eclampsia, treatment with antihypertensive medication is **not** usually necessary unless renal disease develops.[23] Despite the lack of evidence supporting the benefit of antihypertensive therapy in women with blood pressure <180/110 mm Hg, there is a general consensus that pregnant women with hypertension in the blood pressure range of 150 to 160/100 to 110 mm Hg should be treated with antihypertensive therapy.[22-24] There is insufficient evidence to support or refute the theory that bed rest, either in the hospital or at home, improves outcomes.[25]

Maternal mortality in patients with chronic hypertension results from **severe** hypertension and associated congestive heart failure or stroke. Fetal perinatal outcome is associated most closely with pre-eclampsia or placental abruption.

Commonly used agents for the treatment of chronic hypertension in pregnancy are listed in **Table 99-2** and include labetalol, α-methyldopa (Aldomet), clonidine, and nifedipine. Based on the overall low rate of adverse effects and good efficacy, labetalol is a good option for first-line treatment of chronic hypertension in pregnancy.[22] Thiazide diuretics can be continued during pregnancy.[22] **Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are the only class of antihypertensive medications contraindicated in pregnancy.**[22]

CARDIAC ARRHYTHMIAS

Pregnancy can precipitate cardiac arrhythmias not previously present in seemingly well individuals. The risk of arrhythmias rises during labor and delivery. Factors that promote arrhythmias in pregnancy include the direct cardiac electrophysiologic effects of hormones, changes in hemodynamics or autonomic tone, hypokalemia, and underlying heart disease. Reduction of uterine blood flow during prolonged tachyarrhythmic episodes may adversely affect the fetus. The incidence of arrhythmias in pregnancy is rising due to increasing maternal age and pregnancies in women successfully treated for congenital heart disease.[26] **Just as in a nonpregnant patient, treat any hemodynamically unstable arrhythmia in pregnancy with direct-current cardioversion (50–200 J).**[27,28] Treat hemodynamically stable arrhythmias medically. The chronic use of β-blockers in pregnancy can influence fetal and newborn size, but only atenolol is singled out as being a Food and Drug Administration class D drug in this regard (some evidence for harm to the fetus). Other β-blockers are Food and Drug Administration class B (sotalol) or C. Digoxin, verapamil, diltiazem, and adenosine have their usual efficacy without adverse fetal affects.[26]

CARDIAC ARRHYTHMIA TREATMENT

Paroxysmal supraventricular tachycardia is the most common nonsinus tachycardia in women of childbearing age. The treatment of supraventricular tachycardia in pregnant women is the same as for nonpregnant women.[26] If vagal maneuvers are ineffective, give adenosine. Case reports show both efficacy and a lack of any direct adverse or teratogenic side effects to the fetus.[29] Additionally, acute treatment with β-blockers, verapamil, and diltiazem is safe in pregnancy when used in standard dosage.

The goal of management of **atrial fibrillation** in pregnancy is rate control or conversion to sinus rhythm. Use diltiazem, β-blockers, and/or digoxin, all of which are safe in pregnancy and with unchanged dosages.[29] Anticoagulation with unfractionated or low-molecular-weight heparin is safe in pregnancy and should be used if the patient meets criteria for anticoagulation described for nonpregnant patients.

Ventricular arrhythmias may occur during pregnancy, particularly in patients with congenital heart disease, cardiomyopathy, or valvular disease. **Amiodarone is categorized as class D** because its main metabolite (desethylamiodarone) and iodine cross the placenta. Chronic fetal exposure to amiodarone and its subsequent iodine overload are associated with neurotoxicity, fetal/neonatal hypothyroidism, and less frequently, goiter. Therefore, the use of amiodarone in pregnancy is limited to maternal/fetal tachyarrhythmias that are resistant to other drugs or are life threatening, because short-term use has not been linked to any harmful effects.[29]

The presence of an artificial pacemaker or implantable cardiac defibrillator does not affect the course of pregnancy.[30]

THROMBOEMBOLISM

A detailed discussion of clinical features, diagnosis, and treatment of thromboembolism in pregnancy is found in chapter 100.

The pregnancy-related changes that increase the risk of thromboembolism include physiologic alterations in coagulation and reduced venous return from the legs, with venous pooling and endothelial injury. The clinical assessment is difficult because many of the typical clinical signs and symptoms are seen in normal pregnancy, including leg edema, shortness of breath, and tachycardia. The Wells Score for deep venous thrombosis (see Table 56-4), the most validated clinical decision rule in the diagnosis of deep vein thrombosis, has not been validated in pregnant women.[31,32]

Obtain Doppler compression ultrasonography for diagnosis.[33] D-Dimer levels normally increase throughout pregnancy, and thromboembolism has been reported with normal D-dimer levels.[34,35] Imaging modalities for diagnosis are provided in Table 100-1.

Treatment is low-molecular-weight heparin (Table 100-2).[36] Do not use warfarin in pregnancy because it crosses the placenta and is

TABLE 99-2 Treatment of Hypertension in Pregnancy

Agent	For Existing Hypertension	Adjunct to Existing Treatment	Urgent Control of Acute Hypertension	Potential Adverse Effects (Maternal)
Hydralazine	N/A	50–300 milligrams daily in 2–4 divided doses; use with methyldopa or labetalol to prevent reflex tachycardia*	Loading dose of 5 milligrams IV or IM, maintenance dose thereafter of 5–10 milligrams every 20–40 min up to 300 milligrams; *or* constant infusion of 0.5–10 milligrams/h	Delayed hypotension
Hydrochlorothiazide	N/A	12.5–50 milligrams daily	N/A	Volume depletion and electrolyte disorders
Labetalol	200–2400 milligrams daily in 2–3 divided doses	N/A	Loading dose of 20 milligrams IV; maintenance dose of 20–80 milligrams up to 300 milligrams; *or* constant infusion of 1–2 milligrams/min	Headache
Nifedipine	30–120 milligrams daily as slow-release preparation	N/A	10–30 milligrams orally, repeated after 45 min if needed	Headache, interference with labor
Methyldopa	0.5–3.0 grams daily in 2–3 divided doses	N/A	N/A	Sedation, elevated liver function tests, depression

Abbreviation: N/A = not applicable.

*Risk of fetal bradycardia and neonatal thrombocytopenia.

associated with embryopathy in the first trimester; in the second and third trimesters, it may lead to CNS and ophthalmologic abnormalities. Protamine sulfate may be used safely in pregnancy for patients who require rapid reversal of heparin anticoagulation. Thrombolytics are not contraindicated and have been used successfully in multiple cases. Reported rates of maternal bleeding complications are between 1% and 6% with no maternal deaths, and rates of fetal loss are between 2% and 5%.[37-40]

ACUTE ASTHMA

Asthma is the most common medical disease in pregnancy and complicates between 3.7% and 8.4% of all pregnancies.[41] The clinical course may improve, remain unchanged, or worsen during pregnancy. Women with asthma have higher odds of pre-eclampsia, gestational diabetes, placental abruption, placenta previa, preterm delivery, low birth weight, maternal hemorrhage, pulmonary embolism, and intensive care unit admission.[42]

Symptoms of cough, wheezing, and dyspnea are the same as in nonpregnant patients. Initial assessment should include history of asthma exacerbations and intubation, peak expiratory flow rate measurements or forced expiratory volume in 1 second, physical examination, assessment of oxygen saturation, and a fetal assessment (if >20 weeks' gestation). Peak expiratory flow rate is not altered in pregnancy, with normal rates ranging between 380 and 550 L/min. Use peak expiratory flow rate as a guide to therapy. If the pregnancy has reached viability, apply continuous electronic fetal monitoring.

Treat rapidly and aggressively to reduce re-admission rates and improve fetal outcomes.[43] The principles of management are the same as in nonpregnant patients. Maintain oxygen saturation >95%, administer repetitive or continuous inhaled β_2-agonist (albuterol/salbutamol); give inhaled ipratropium and systemic corticosteroids; monitor maternal response to therapy; and monitor the fetus for signs of distress.[44] Terbutaline sulfate, 0.25 milligrams every 20 minutes, administered SC, may be used if needed. Avoid epinephrine because concerns exist about epinephrine vasoconstriction of the uteroplacental circulation.

Admission and discharge criteria are the same as in the nonasthmatic patient. For discharged women, prescribe oral prednisone, 40 to 60 milligrams per day (or equivalent), for 5 to 10 days, and a short-acting rescue β-agonist. Inhaled corticosteroids reduce recurrence during pregnancy and decrease re-admission rates following a hospitalization for asthma.[45] Anticipate maternal hyperglycemia when systemic corticosteroids are given.

CHRONIC RENAL DISEASE

Maternal risks associated with renal disease are linked to the patient's degree of renal compromise. Patients with mild renal insufficiency and no hypertension tend to have good outcomes and preserved renal function. Patients with moderate or severe renal insufficiency are more prone to further decline in renal function and pre-eclampsia and preterm delivery. Patients with lupus nephropathy are at greatly increased risk for disease exacerbation and superimposed pre-eclampsia.

Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers, which are frequently used in patients with chronic renal failure, are teratogenic and should be stopped at the first indication of pregnancy.

ASYMPTOMATIC BACTERIURIA, CYSTITIS, AND PYELONEPHRITIS

Hormonal and mechanical changes of pregnancy increase the risk of urinary stasis and subsequent urinary tract infection. After mid-pregnancy, mild right-sided hydronephrosis is found in 75% of women, and mild left-sided hydronephrosis is found in 33%.

Asymptomatic bacteriuria is diagnosed by urine culture, demonstrating the presence of bacteria in the urine in the absence of maternal symptoms of urinary tract infection. Reagent strips have limited sensitivity, and use in screening depends on resources available, but in general, a positive leukocyte esterase or urinary nitrite should be treated and a negative specimen should be cultured.[46,47] Treatment reduces the incidence of pyelonephritis and low birth weight.[48]

Causative organisms of symptomatic cystitis and pyelonephritis are similar to those in the general population and include *Escherichia coli* (75%), *Klebsiella pneumoniae*, *Proteus*, and gram-positive organisms such as group B *Streptococcus*. Obtain a urinalysis and culture with drug sensitivities in pregnant women with urinary tract symptoms and also in those with hyperemesis. Urinary tract infections need prompt treatment because acute pyelonephritis can precipitate preterm labor, bacteremia, or septic shock.

Recurrent infections can occur as a result of bacteriuria, glycosuria, and mechanical compression of the ureter in the third trimester. Reflux nephropathy increases the risk of sudden escalating hypertension and worsening renal function.[49] Urolithiasis is associated with recurrent urinary tract infections.

Treat asymptomatic bacteriuria and simple cystitis with oral nitrofurantoin, 100 milligrams PO two times per day, or an oral cephalosporin. Recommendations on the length of treatment vary from 3 to 10 days. Trimethoprim-sulfamethoxazole is not a good choice in pregnancy.

Trimethoprim, a folate antagonist, can be used **after the first trimester**; sulfonamides can be taken during the first and second trimesters **but not during the third trimester** because sulfonamides can cause kernicterus in the infant. Do not use fluoroquinolones and tetracyclines during pregnancy because of possible toxic effects on the fetus.

Pregnant women with pyelonephritis are generally hospitalized, aggressively hydrated, and treated with parenteral antibiotics. The antibiotic of choice is a second- or third-generation cephalosporin. Continue IV antibiotics until the patient is afebrile for at least 48 hours and costovertebral angle tenderness has resolved. The most common reason for treatment failure is antibiotic resistance. Patients discharged after hospitalization need to complete a 10-day course of therapy. Many providers choose to continue women with an episode of pyelonephritis on antibiotic suppression for the remainder of pregnancy. Nitrofurantoin, 50 to 100 milligrams PO once per day, is a common treatment.

SICKLE CELL DISEASE

Women with sickle cell disease, including sickle cell trait, are at increased risk for miscarriage, preterm labor, and other complications due to impaired oxygen supply and sickling infarcts in the placental circulation. Maternal complications are more common in the third trimester and postpartum period and include cerebral vein thrombosis, pneumonia, sepsis, and pyelonephritis.

Presentation and treatment of painful crises in pregnancy are similar in pregnant women and nonpregnant patients (see chapter 237, "Acquired Hemolytic Anemia"). Cornerstones of management are oxygen, aggressive hydration, PO or IV narcotics, and evaluation and treatment of the precipitating cause. Place the woman in the left lateral decubitus position, if in the third trimester. Avoid nonsteroidal anti-inflammatory drugs, particularly after 32 weeks of gestation, because these drugs cross the placenta. In early pregnancy, nonsteroidal anti-inflammatory drugs are associated with miscarriage and neonatal defects. In later pregnancy, nonsteroidal anti-inflammatory drugs are associated with risk of oligohydramnios and premature closure of the fetal ductus arteriosus. Blood transfusions are reserved for sickle cell crises when conservative measures have not improved maternal or fetal status.[50] Indications for transfusion include severe anemia with a hemoglobin level <5 milligrams/dL, preeclampsia, hypoxemia, acute chest syndrome, new-onset neurologic event, or anticipation of surgical intervention or angiographic dye load.[51]

Institute fetal monitoring and consult with an obstetrician if the fetus is potentially viable. Fetal heart rate patterns should normalize as the crisis resolves. Consult with an obstetrician for emergency delivery in the face of ongoing fetal distress.

HEADACHE AND STROKE SYNDROMES IN PREGNANCY

In pregnant women, headaches can be a symptom of a variety of neurologic or systemic disorders. **Table 99-3** lists the differential diagnosis of headaches in pregnancy (see chapter 165, "Headache").

TABLE 99-3 Causes of Headaches in Pregnancy

Life threatening
Subarachnoid hemorrhage
Intraparenchymal hemorrhage
Central venous thrombosis
Ischemic stroke
CNS tumor or infection
Pre-eclampsia/eclampsia
Non–life threatening
Tension headache
Migraine
Sinus headache
Benign intracranial hypertension (pseudotumor cerebri)

TABLE 99-4 Warning Symptoms and Signs of Headaches

New-onset headaches in pregnancy
Postpartum headaches
Need to exclude cerebral vein thrombosis
Headaches with different characteristics from previous headaches
Worst headache of life
Focal neurologic deficit
Meningismus
Fever
Altered consciousness
Papilledema or other signs of increased intracranial pressure
Retinal hemorrhages
Increased blood pressure (may herald pre-eclampsia or eclampsia)

Warning symptoms and signs of a potentially life-threatening disease are important to elicit during the initial evaluation and are listed in **Table 99-4**.

Obtain imaging studies if concerning signs or symptoms are encountered. CT scan of the brain can be safely performed with appropriate shielding of the fetus. CT scan is best to evaluate acute intracranial or subarachnoid hemorrhage, whereas MRI is superior for evaluation of cerebral infarct, tumor, infection, or cerebral vein thrombosis.

INTRACEREBRAL HEMORRHAGE

In pregnancy, the incidence of intracerebral hemorrhage ranges from 0.01% to 0.05 % but is the cause for 5% to 12% of all maternal deaths.[52] The risk of cerebral hemorrhage extends from pregnancy through the **6-week postpartum period**.[52] Risk factors include older maternal age, African American race, and alcohol or cocaine use. The most common cause for spontaneous intracerebral hemorrhage is **hypertension**. If there is no history of hypertension, then consider other causes such as neoplasm, hemorrhagic disorder, and vascular malformation.

Presenting symptoms vary with the location and extent of hemorrhage, so consider cerebral hemorrhage in a woman with an abrupt neurologic change. For diagnosis, obtain CT/MRI and consult the neurosurgeon. Treatment is blood pressure control and correction of coagulopathy.

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage during pregnancy is the third most common cause of nonobstetric maternal death, and more than half of cases occur **postpartum.**[52] Causes include hypertension,[53] aneurysm, vascular malformation, tumors, and venous thrombosis.

Independent risk factors for subarachnoid hemorrhage from all etiologies include advancing age; African American race; Hispanic ethnicity; hypertensive disorders; coagulopathy; tobacco, drug, or alcohol abuse; intracranial venous thrombosis; sickle cell disease; and hypercoagulability.

Suspect subarachnoid hemorrhage in a woman with severe headache, nausea, vomiting, decreased level of consciousness, or seizure. Diagnosis is by CT/MRI and/or lumbar puncture. In general, pregnant women should be treated the same as nonpregnant patients with bed rest, analgesia, sedation, neurologic monitoring, and control of blood pressure.[52]

STROKE

Pregnancy is associated with an increased risk of ischemic and hemorrhagic stroke, and stroke contributes to more than 12% of all maternal deaths, with the majority occurring in the **third trimester or puerperium**.[54] Arterial occlusion is the most common cause of pregnancy-related stroke.[54] Risk factors include hypertension, heart disease, smoking, diabetes, lupus, sickle cell disease, African American heritage, substance abuse, and cesarean delivery. Consider stroke in women with neurologic deterioration or new focal neurologic deficits.

Once hemorrhage and eclampsia are excluded, consider thrombolytic therapy after consultation with neurology and obstetrics. To date, there are no randomized controlled trials of thrombolytics for stroke in pregnancy; however, recombinant tissue plasminogen activator (risk category C) does not cross the placenta, and there is no evidence of teratogenicity in animal studies.[55] There are more than 200 reports in the literature of pregnant women who have received thrombolytic therapy for various indications including myocardial infarction, pulmonary embolism, superior vena cava syndrome, and ischemic stroke.[54] Use of thrombolytics in pregnancy is not without its risks, although the overall maternal mortality and fetal loss is relatively low at 1% and 6%, respectively.[54]

CENTRAL VENOUS THROMBOSIS

Central venous thrombosis usually presents in the second and third trimesters and may occur up to 4 weeks postpartum. Symptoms include severe headache, focal neurologic deficit, vomiting, or seizure, depending on which veins are occluded. Venous thrombosis increases venous pressure and cerebral blood volume, elevating dural sinus pressure and leading to rupture of small cortical veins.[56] Treatment is low-molecular-weight heparin, unless there is associated intracranial hemorrhage. Once the patient has been stabilized and hemorrhage from an aneurysm is excluded, the mainstay of treatment for the underlying thrombosis is still anticoagulation for the duration of the pregnancy.[56]

MIGRAINE HEADACHE

Although the ergot alkaloids are contraindicated in pregnancy, acute migraine headaches can be successfully treated in pregnancy with the same first-line antiemetics that are used in nonpregnant patients. Metoclopramide (Reglan) is class B, and prochlorperazine (Compazine), promethazine (Phenergan), and droperidol (Inapsine) are all class C. Avoid nonsteroidal anti-inflammatory drugs. Sumatriptans (class C) do not appear to increase fetal malformations, and if already prescribed by the obstetrician or primary physician during pregnancy, sumatriptans can be continued as an outpatient.[57]

GI DISORDERS IN PREGNANCY

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is extremely common in pregnancy and is characterized by epigastric pain or burning radiating into the chest and neck, pain with recumbency, and pain exacerbated by acidic foods. Symptoms increase in the second trimester and peak in the third trimester due to loosening of the lower esophageal sphincter and delayed gastric emptying from pregnancy-related hormones. Treat mild symptoms with H_2 antagonists such as cimetidine or ranitidine. Moderate to severe symptoms can be treated with sucralfate and proton pump inhibitors. Both H_2 antagonists and proton pump inhibitors have been extensively studied for teratogenic effects, and no significant abnormal findings have been associated with their use in pregnancy.[58,59]

HEMORRHOIDS

Hemorrhoids are common during pregnancy and are caused by a combination of constipation due to slowed bowel transit from progesterone effects in the last trimester and elevated pressure in the veins below the level of the enlarged uterus. Most symptoms are mild and can be treated with prevention of constipation with increased fluids and high-fiber intake and topical medications including witch hazel compresses, suppositories, corticosteroids, or topically applied anesthetics.[60] Do not use agents containing epinephrine or phenylephrine. Proctofoam has specifically been studied and is safe.[61] Consider surgical or obstetric referral for prolapsed, bleeding, or incarcerated hemorrhoids or when conservative measures fail. There are no studies of the risks/benefits of ED excision of a thrombosed clot in pregnancy. Risks include hemorrhage and recurrence.

CHOLECYSTITIS

During pregnancy, approximately 1 in 1000 women will develop cholecystitis. Pregnancy-related hormones affect gallbladder contractility and increase residual gallbladder volume and sludge, which in turn can lead to gallstone formation. Many women ultimately require cholecystectomy during pregnancy for persistent symptoms. It is preferable to wait until the second trimester if the patient's condition allows, as surgery during the first trimester carries a risk of spontaneous miscarriage, and cholecystectomy in the third trimester is technically difficult and can result in preterm labor.[62]

APPENDICITIS

Appendicitis occurs about once in every 500 to 2000 pregnancies and is the most common extrauterine condition requiring abdominal operation in pregnancy. The diagnosis is often missed or delayed because mild abdominal discomfort, nausea, and vomiting occur frequently in normal pregnancies. Additionally, the appendix shifts in location from the right lower quadrant to the right upper quadrant during the second and third trimesters. The diagnosis is best made with US, which is 80% accurate with experienced technicians. However, if perforation has occurred, US accuracy decreases to 30%.[63,64] Adequate visualization of the appendix is more difficult later in pregnancy. If US is not available or is inadequate, obtain an MRI.[65] If CT is used to make the diagnosis, focal appendiceal CT provides less radiation to the fetus than full abdominopelvic CT. However, focal abdominal imaging may limit discovery of an alternate diagnosis. An abdomen/pelvis CT confers about 30 mGy of radiation, and 50 mGy of radiation is generally accepted to be safe in pregnancy.[66]

OVARIAN TORSION

Torsion of the ovary is a true gynecologic emergency, and up to one fifth of ovarian torsion occurs during pregnancy. Torsion can occur in any trimester, although it is most common in the first trimester.[67] Infertility treatment is a risk factor. Ovarian torsion can recur in the same pregnancy, in particular in enlarged multicystic ovaries.[68] The corpus luteal cyst and enlarged ovaries stemming from the pregnancy hormones are thought to increase the risk. Tissue necrosis can occur rapidly, so timely diagnosis is essential to preserve ovarian function and the pregnancy. The diagnosis is often missed due to the vague clinical presentation of moderate unilateral lower abdominal pain, which may also be intermittent or constant. US may show an enlarged or edematous ovary with absent or decreased blood flow. **However, the presence of ovarian blood flow does not exclude the diagnosis of torsion if symptoms are suggestive**.[69] Therefore, consult an obstetrician/gynecologist as soon as the diagnosis is clinically suspected.

SEIZURE DISORDERS

Seizure frequency can increase in pregnancy because of the increased volume of distribution and plasma clearance of antiepileptic drugs in pregnancy or because of poor medication compliance.

Most of the antiepileptic drugs can cause a range of birth defects.[70] **Valproic acid, carbamazepine, and phenytoin are all class D and are teratogenic.** Yet, discontinuing these drugs can increase morbidity and mortality for both the mother and fetus.[71] Therefore, the risks and benefits of chronic treatment should be discussed and managed by the primary physician. Medication doses may need to be increased in pregnancy. Therapeutic serum target levels remain unchanged. **Monotherapy with levetiracetam or lamotrigine (both class C) should be used whenever possible.**[72]

Acute treatment of seizures in the pregnant woman is similar to that in the nonpregnant patient (see chapter 171, "Seizures"). Even though lorazepam and diazepam are class D medications, they are so categorized based on long-term use. **Use of benzodiazepines for an acute seizure outweighs any potential risk to the fetus.**[73]

If the seizure if self-limited, administer oxygen and position the patient in the left lateral decubitus position and provide supportive care. Fetal bradycardia lasting for up to 20 minutes may follow a single brief maternal seizure. **Status epilepticus** poses a real threat to both mother and the fetus, with a significant maternal and fetal mortality. Provide aggressive management, including intubation and ventilation, early in the management of pregnant women with status epilepticus (see chapter 171).

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Pregnancy does not appear to alter the natural course of human immunodeficiency virus (HIV) disease, nor do uninfected babies born to HIV-positive women appear to be at increased risk for neonatal complications when compared with appropriate control patients.

Some women may choose to delay initiation of antiretroviral therapy until after the first trimester, when the fetus is less susceptible to the potential teratogenic effects of medications. However, all pregnant HIV-infected patients beyond 12 weeks' gestation should be on a highly active antiretroviral therapy three-drug regimen that includes zidovudine. Use of zidovudine has reduced the vertical transmission rate of HIV to <2% in the United States.[74] There are many combinations of three-drug regimens that can be used in pregnancy. However, several of the medications used in the highly active antiretroviral therapy regimen are potentially harmful when used during pregnancy. For example, the combination of didanosine and stavudine can cause a potentially fatal lactic acidosis in pregnant women. Nevirapine can cause severe hepatotoxicity.[75]

Recommended regimens as of this writing are as follows: **for a treatment-naïve HIV-infected pregnant female,** zidovudine *plus* lamivudine *plus* lopinavir/ritonavir *or* atazanavir/ritonavir; **for a treatment-naïve HIV-infected pregnant female with hepatitis B coinfection:** tenofovir *plus* lamivudine *or* emtricitabine *plus* lopinavir/ritonavir *or* atazanavir/ritonavir.[76]

Prophylaxis for opportunistic infections is similar to that for nonpregnant patients. Patients with CD4+ T-cell counts of <200/μL should be maintained on prophylaxis for *Pneumocystis jiroveci* pneumonia using trimethoprim-sulfamethoxazole. Weigh the risks and benefits of trimethoprim-sulfamethoxazole therapy during the first trimester. Folate supplementation may be added, but it is unclear whether folate supplementation lowers risk. Alternatively, aerosolized pentamidine may be used in the first trimester, as it is minimally systemically absorbed.[77]

Treatment of overt opportunistic infections in HIV-infected pregnant women is addressed in the same way as in nonpregnant women. Early intubation to reverse hypoxemia may be necessary to improve maternal-fetal outcome in women with respiratory infections.

SUBSTANCE ABUSE DURING PREGNANCY

Substance abuse in pregnancy results in approximately 225,000 infants yearly with prenatal exposure.[78] Refer pregnant women identified in the ED as substance abusers to a high-risk obstetrics clinic and offer them substance abuse counseling.

COCAINE

Cocaine use is associated with placental abruption, fetal death in utero, intrauterine growth restriction, preterm labor, premature rupture of membranes, spontaneous abortion, and cerebral infarcts in the fetus. Maternal complications of cocaine use include myocardial infarction, hypertension (which can result in aortic dissection), pulmonary edema, and cardiac dysrhythmias. Subarachnoid hemorrhage, ruptured aneurysms, and strokes are reported in cocaine users and are most likely related to transient hypertension. Treatment of the pregnant woman with acute cocaine intoxication is handled in the same manner as in the nonpregnant patient (see chapter 187, "Cocaine and Amphetamines").

OPIOIDS

Although acute opioid withdrawal poses minimal maternal risk, there is significant risk to the fetus, including meconium, hypoxia, preterm labor, and fetal demise.[79] Illicit opioid use can cause intermittent fetal withdrawal when there is maternal lack of access to the drug.

Therefore, it is standard to refer opioid-addicted pregnant patients for supervised methadone or buprenorphine therapy for the duration of the pregnancy. Even though methadone/buprenorphine will cause neonatal abstinence syndrome (opioid withdrawal) after birth, this is a treatable condition and carries less harm to the infant than acute opioid withdrawal in utero. Maternal detoxification from opioids should be done in a supervised inpatient setting, and only for select patients, as the relapse rate is very high.[79]

Maternal mild opioid withdrawal can be treated with clonidine 0.1 to 0.2 milligrams every hour until the signs of withdrawal resolve. Severe maternal opioid withdrawal may require administration of an opioid agonist and admission for fetal monitoring and induction of methadone therapy.[79,80]

ALCOHOL

Alcohol consumption during pregnancy is a risk factor for fetal alcohol syndrome, birth defects, and low birth weight. Binge drinking is particularly harmful to fetal neurodevelopment.

In the United States, the prevalence of fetal alcohol syndrome is estimated at 0.5 to 2.0 cases per 1000 births, but other fetal alcohol spectrum disorders are believed to occur approximately three times as often as fetal alcohol syndrome.[81]

Pregnant women who present in coma due to acute alcohol intoxication or in alcohol withdrawal are managed in the same way as nonpregnant patients. **Disulfiram (Antabuse) is a potential teratogen. Do not prescribe in pregnancy.**

INTIMATE PARTNER VIOLENCE

Between 4% and 20% of pregnant women are victims of intimate partner violence.[82] Factors associated with intimate partner violence during pregnancy are late entry into prenatal care, unintended pregnancy, drug and alcohol use, depression, and housing problems. Violence increases the risk for preterm labor, placental abruption, fetal fractures, uterine rupture, chorioamnionitis, delivering a low-birth-weight infant, and homicide. The American College of Obstetricians and Gynecologists recommends routine screening for intimate partner violence during pregnancy.[83]

Pregnant women with injuries should be treated according to usual trauma protocols. Institute fetal monitoring for direct or indirect blunt abdominal trauma and major multiple trauma. Administer Rh immunoglobulin to Rh-negative women with blunt abdominal trauma (see chapter 25, "Resuscitation in Pregnancy").

MEDICATIONS IN PREGNANCY AND LACTATION

The classic teratogenic period is 2 to 15 weeks of gestation. During this critical time, organs are forming, and teratogens may cause malformation. Administration of drugs early in the period of organogenesis affects the organs developing at that specific time, such as the heart or neural tube. Teratogens given closer to the end of the classic teratogenic period will affect the ear and palate. Before week 2, exposure to a teratogen produces an all-or-none effect (i.e., the conceptus either does not survive or survives without anomalies). If the organism remains viable after exposure before week 2, organ-specific anomalies do not develop because repair or replacement permits normal development. A similar insult at a later stage of development may produce organ-specific defects.

The U.S. Food and Drug Administration lists five categories of labeling for drug use in pregnancy (**Table 99-5**).

Some therapeutic agents that should not be used during pregnancy are listed in **Table 99-6**. The National Library of Medicine provides a detailed reference list in the Developmental and Reproductive Toxicology Database (see Useful Web Resources below).

Table 99-7 lists some general cautions for using drugs during lactation. When prescribing, check each drug individually. Because information can change, we recommend referring to the following sources for information about drug safety in lactation:

- Drugs and Lactation Database (LactMed), U.S. National Library of Medicine—http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT (accessed December 31, 2013)
- World Health Organization, Breastfeeding and Maternal Medication (last updated 2003)—http://whqlibdoc.who.int/hq/2002/55732.pdf (accessed December 31, 2013)
- Hale Thomas, Medications and Mothers' Milk, ISBN-13 (978-0984774630), Hale Publishing, May, 2012, 15th ed.

TABLE 99-5 U.S. Food and Drug Administration Categorization of Drug Risk in Pregnancy

Drug Category	Risk during Pregnancy
A	Controlled studies show no fetal risk in any trimester, and so the possibility of fetal harm is remote.
B	Animal studies show no fetal risk, but there are no controlled human studies. Or Animal studies have shown an adverse effect that was not confirmed in controlled human studies in women in the first trimester (and there is no evidence of risk in later trimesters).
C	Animal studies have shown adverse fetal effects (teratogenic or embryocidal), and there are no controlled studies in humans. Or No human or animal studies are available. Drugs should only be used if the potential benefit justifies the potential fetal risk.
D	Evidence of human fetal risk exists, but the benefits of use in pregnant women may be acceptable despite the risk.
X	Studies in animals or humans have shown fetal risk, or there is evidence of fetal risk based on human experience. The risk of use in pregnancy clearly outweighs any possible benefit. Drugs are contraindicated for use in women who are or may become pregnant.

FETAL RADIATION EFFECTS

For radiation imaging during pregnancy, weigh the risks of exposure and subsequent fetal adverse effects against the risk of incorrect maternal diagnosis. The major factor determining the degree of risk to the fetus is the quantity of ionizing radiation exposure during imaging. **Fetal exposure to low-dose radiation, defined as <5 rads (<50 mGy), does not increase the risk of fetal or infant death, mental defects, or growth retardation.** More than 5 rads (>50 mGy) is considered the threshold for human teratogenesis.[66] The fetus is most vulnerable to teratogenicity between 3 and 15 weeks of gestation at doses >10 rads (>100 mGy) (**Table 99-8**). The risk and incidence of carcinogenesis are not known.[66]

The estimated radiation doses involved in procedures commonly used for ED diagnosis are listed in **Table 99-9**.[66,84-86]

TABLE 99-6 Drugs Used in Emergency Settings with Known Adverse Effects in Human Pregnancy

Drug	Effect
Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers	Renal failure, oligohydramnios
Aminoglycosides	Ototoxicity (gentamicin class D, Black Box Warning)
Androgenic steroids	Masculinize female fetus
Anticonvulsants (carbamazepine, hydantoins, valproate)	Dysmorphic syndrome, anomalies, neural tube defects
Antithyroid agents	Fetal goiter
Aspirin (high doses)	Bleeding, antepartum and postpartum
Cytotoxic agents (e.g., methotrexate)	Multiple anomalies
Erythromycin estolate	Maternal hepatotoxicity
Fluoroquinolones	Fetal cartilage abnormality
Isotretinoin	Hydrocephalus, deafness, anomalies
Lithium	Congenital heart disease (Ebstein's anomaly)
Nonsteroidal anti-inflammatory drugs (prolonged use after 32 wk)	Oligohydramnios, constriction of fetal ductus arteriosus
Streptomycin	Fetal cranial nerve VIII damage
Sulfonamides	Fetal hemolysis, neonatal kernicterus (near term)
Tetracyclines	Fetal teeth and bone abnormalities
Trimethoprim, methotrexate	Folate antagonist (first trimester)
Thalidomide	Phocomelia
Warfarin	Embryopathy—nasal hypoplasia, optic atrophy

TABLE 99-7 World Health Organization General Cautions for Drugs and Breastfeeding

Guideline	Drugs
Breastfeeding contraindicated	Anticancer drugs, radioactive substances, nitrofurantoin (for <1 mo old, and for those with glucose-6-phosphate dehydrogenase deficiency)
Avoid unless absolutely necessary	Chloramphenicol, tetracyclines, metronidazole, fluoroquinolones
Monitor infant for drowsiness	Selected psychiatric and anticonvulsant agents
Monitor infant for jaundice	Sulfonamides, dapsone, sulfadoxine/pyrimethamine (Fansidar), mefloquine
May inhibit lactation; use alternative drug	Estrogens, thiazides

TABLE 99-8 Teratogenic Radiation Effects

Gestational Age	Effect of 5–10 rads (50–100 mGy)	Effect of >10 rads (>100 mGy)
0–2 wk	Probably none	Possible spontaneous abortion
3–8 wk	Unknown; probably none detectable	Possible malformations with increasing dose
9–15 wk	Unknown; probably none detectable	Possible mental development defects with increasing dose
≥16 wk	None	None detectable or none

TABLE 99-9 Radiation Exposure to the Uterus/Fetus

Procedure	Dosage in mGy
Threshold for human teratogenesis	100
Accepted as safe in pregnancy	**50**
Abdominal/pelvis CT	25–35
CT, kidney-ureter-bladder protocol (reduced radiation dose)	10
Lumbosacral spine series (three view)	1.6–3.5
Ventilation–perfusion scan (total)	2.1
Abdominal series (two view)	2
Lung **perfusion** scan with technetium	1.7
Normal background radiation over 9 months	**1**
Head CT	<0.5
Lung **ventilation** scan with xenon	0.4
Anteroposterior pelvis x-ray	0.4
Chest CT (10-mm slices, 10 slices), for standard or pulmonary embolism protocol	0.2
Cerebral angiography	0.1
Mammography—diagnostic for suspected breast cancers	0.07–0.2
Chest radiography (two view) with shielding of the maternal abdomen	<0.001
Cervical spine (two view)	<0.001

Note: 1 rad = 10 mGy = 10 mSv.

CHAPTER 100

Maternal Emergencies After 20 Weeks of Pregnancy and in the Postpartum Period

Janet Simmons Young

INTRODUCTION

This chapter examines the diagnosis and treatment of the most important maternal emergencies occurring after 20 weeks of pregnancy and during the postpartum period. The second half of pregnancy is often characterized as ≥20 weeks of gestation for simplicity, but until 24 weeks, the chances of fetal survival are less than 50%. The postpartum period is generally accepted as the 6 weeks after delivery. Vast physiologic shifts in maternal cardiovascular tone occur as pregnancy progresses, highlighting the need for maternal blood pressure recordings and fetal heart tones during any ED visit. Conditions discussed are thromboembolic disease; chest pain; disorders associated with elevated blood pressure (hypertension, preeclampsia and HELLP syndrome [hemolysis, elevated liver enzymes, and low platelet count], and eclampsia); vaginal bleeding in the second half of pregnancy; premature rupture of membranes; postpartum hemorrhage; amniotic fluid embolus; peripartum cardiomyopathy; and endometritis.

THROMBOEMBOLIC DISEASE OF PREGNANCY

Venous thromboembolism includes deep venous thrombosis (DVT) and pulmonary embolism (PE) and is the leading cause of maternal morbidity and mortality in industrialized nations. Compared with nonpregnant women, the risk of venous thromboembolism increases fivefold during pregnancy and is increased by 60-fold in the first 3 months after delivery.[1,2]

PATHOPHYSIOLOGY

Pregnancy-related hypercoagulability is due to increased levels of clotting factors, increased platelet and fibrin activation, and decreased fibrinolytic activity, all of which are adaptations to prevent maternal hemorrhage. Physiologic changes include venous stasis, decreased venous outflow, and uterine compression of the inferior vena cava and iliac veins (particularly the left common iliac and left leg veins). Clots tend to develop in the deep venous system of the legs and pelvis, which includes the internal iliac, femoral, greater saphenous, and popliteal veins. Up to 24% of DVTs are complicated by PE, so early DVT diagnosis is important.[1-6]

RISK FACTORS AND CLINICAL FEATURES

Physiologic signs and symptoms of thromboembolic disease, such as tachycardia, tachypnea, lower extremity edema, and dyspnea are nonspecific and also occur during normal pregnancy. Predictive scoring criteria, such as Wells criteria, have not been validated in pregnant women, but left leg symptoms, calf circumference difference ≥2 cm, and leg symptoms in the first trimester are associated with DVT. Iliac vein thrombosis often presents with unilateral swelling of the entire leg and groin or back pain.

A personal or family history of thrombosis is an important risk factor. Other major risk factors include thrombophilias (not identifiable at the first presentation), obesity, maternal age >35, smoking, sickle cell disease, diabetes, hypertension, immobility, in vitro fertilization (greater risk for twins than for singleton), and preeclampsia. Cesarean delivery and postpartum complications further increase the risk.[1,4,5]

DIAGNOSIS OF DEEP VENOUS THROMBOSIS

Compression or duplex US is the test of choice, with a reported sensitivity and specificity for detecting proximal DVT in nonpregnant patients of 89% to 96% and 94% to 99%, respectively.[7] Compression US is less accurate for isolated calf and iliac vein thrombosis. MRI, either with or without contrast venography, is highly sensitive and specific for the diagnosis of pelvic and iliac vein thrombosis. MRI without contrast is preferred with the addition of contrast only if absolutely needed.[8,9] Impedance plethysmography and CT scan of the pelvis are alternatives to diagnose iliac vein thrombosis if MRI is not available. Impedance plethysmography is not widely available and requires operator expertise. CT exposes the fetus to radiation, and iodinated contrast media may affect fetal thyroid tissue.[1] If imaging resources are limited, venography with pelvic shielding is another option.[10]

D-dimers are not useful to include or exclude DVT or PE because levels progressively increase throughout pregnancy, and venous thromboembolism has been reported with negative D-dimers.[11] See chapter 56, Venous Thromboembolism, for a detailed discussion of D-dimers.

DIAGNOSIS OF PULMONARY EMBOLISM

Pregnant women with symptoms suggestive of PE and compression US results positive for DVT should receive anticoagulation without waiting for further confirmatory diagnostic studies.

Women with normal findings on US with suspicion of PE require further diagnostic imaging. The major options for definitive imaging are chest CT–pulmonary angiography and pulmonary perfusion scanning. **As of this writing, the fetal and maternal radiation dose with either modality is felt to be within acceptable limits.**[1,12] Typically, in most institutions, a consensus is obtained between emergency physicians, obstetricians, and radiologists in deciding the imaging steps. **Table 100-1** lists advantages and disadvantages of different imaging modalities.

TABLE 100-1 Imaging Modalities for Diagnosis of Pulmonary Embolism in Pregnancy

	Radiation	Limitations	Disadvantages	Advantages	Lactation
Chest Radiograph	Minimal	Nonspecific and nonsensitive	Results determine next imaging study, requiring more time to diagnosis	May identify another cause of pulmonary symptoms	No change
CT-PA	High maternal breast radiation; lower fetal radiation than V/Q scan	Contrast allergy and renal insufficiency	Hyperdynamic state in pregnancy can affect interpretation	High sensitivity and specificity; needed if abnormal chest radiograph	No need to discard breast milk
V/Q scan	Low breast radiation but higher fetal radiation than CT-PA	Not useful if abnormal chest radiograph, asthma, COPD, underlying pulmonary disease	If negative or inconclusive and suspicion for PE remains, will need a CT-PA; limited availability and time for isotope preparation, which delays diagnosis	Negative perfusion study effectively rules out PE	Discard breast milk for 12 h
MRI/MRV	No radiation	Gadolinium safety for fetus is unknown; do not use in maternal renal insufficiency	Limited availability	Can detect pelvic and iliac thrombosis	No need to discard breast milk

Abbreviations: COPD = chronic obstructive pulmonary disease; CT-PA = chest CT–pulmonary angiography; V/Q scan = ventilation-perfusion scan; MRV = magnetic resonance venography.

Consensus documents based on expert opinions of pulmonologists and radiologists recommend a plain chest radiograph first.[13] If the chest radiograph is abnormal, or the patient has chronic pulmonary disease, asthma, or chronic obstructive pulmonary disease, chest CT–pulmonary angiography is preferred.[13] If the chest radiograph is normal, a negative perfusion scan can be relied upon to exclude the diagnosis of PE, but an inconclusive perfusion scan will then require a chest CT.[1,12-14]

Magnetic resonance angiography (MRA) can detect PE, but its use in pregnancy has not been well studied. Institutions in which MRA of the pulmonary vasculature is performed routinely have demonstrated a sensitivity of 78% and specificity of 99% when the study is qualified as technically adequate.[15]

TREATMENT OF DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Venous thromboembolism during pregnancy is treated with either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) (**Table 100-2**).[1,16,17] UFH and LMWH do not cross the placental barrier. UFH is preferred over LMWH in patients in a hemodynamically unstable condition with PE, patients who are likely to bleed, patients with renal insufficiency, patients in labor, those receiving regional anesthesia, and patients undergoing cesarean delivery. Monitor activated partial thromboplastin times when using UFH.[11] Dosing requirements of UFH and LMWH increase due to the physiologic changes of pregnancy. Adverse effects of UFH include uteroplacental hemorrhage, heparin-induced thrombocytopenia, and heparin-induced osteopenia. LMWH has fewer adverse effects and fewer bleeding episodes than UFH, and monitoring with anti–factor Xa levels is needed only in special circumstances. See chapter 239, Thrombotics and Antithrombotics, for further discussion of heparins.

Fondaparinux is used in the United States for the prevention and treatment of venous thromboembolism in heparin-allergic or heparin-intolerant pregnant patients.[1] However, fondaparinux is transported across the placenta in low concentrations, and minimal data exist on maternal-fetal safety.[1,17]

Do not prescribe warfarin (Coumadin®) in pregnancy because it crosses the placental barrier, causes CNS abnormalities, and causes warfarin embryopathy (bone and cartilage abnormalities and nasal and limb hypoplasia). Warfarin increases the risk of maternal and fetal hemorrhage, especially during delivery. Warfarin is only considered for women with mechanical heart valves who demonstrate a continued risk of venous thromboembolism despite treatment with UFH or LMWH.[1]

An inferior vena cava filter is indicated when anticoagulation is contraindicated, when an acute embolic event occurs despite anticoagulation, or when acute venous thromboembolism occurs with impending delivery of the fetus.[18]

Treatment of Life-Threatening Pulmonary Embolism Treatment options include systemic thrombolysis, catheter-guided thrombolysis, and surgical or catheter-guided embolectomy.[19-22] Data regarding maternal-fetal outcomes in conditions of maternal extremis are limited to case reports, and catheter-guided thrombolysis and embolectomy require precious time for preparation. **Recombinant tissue plasminogen activator** (10-milligram bolus, 90-milligram infusion over 2 hours) does not cross the placenta and has a lower rate of hemorrhagic complications and lower mortality rate than do streptokinase and urokinase in the nonpregnant population. **Streptokinase** (250,000-unit bolus, 100,000 units/h infusion for 24 hours) is also used but with a higher rate of subchorionic hemorrhage, allergic complications, and longer infusion duration than recombinant tissue plasminogen activator. Catheter-directed thrombolysis allows for earlier reperfusion and likely improves long-term pulmonary function compared with systemic therapy.[1,19] Fetal loss subsequent to surgical embolectomy is higher than with thrombolysis.[20,22]

CHEST PAIN

The differential diagnosis of chest pain in pregnant women is similar to that of nonpregnant women, but disorders such as aortic dissection and cardiomyopathy are associated with pregnancy. Advances in reproductive technology resulting in pregnancies in older women may result in an increase in **coronary artery disease** in this population. **Coronary artery dissection** and **coronary vasospasm** are more likely in women who smoke and those with migraine. Coronary artery disease is more likely in those >35 years old, diabetics, and hypertensives.[23] Treat **acute myocardial infarction** with low-dose aspirin, heparin, and percutaneous coronary intervention rather than with thrombolytics.[24,25] **Aortic dissection**, although rare, is usually encountered in the third trimester and the postpartum period. Risk factors are pregnancy, bicuspid aortic valve, connective tissue disorders (e.g., Marfan's syndrome), syncope, hypertension, and a family history of aneurysm.[26] Chest radiograph may not demonstrate a widened mediastinum, and diagnosis is made by MRI or CT scan.[23]

Peripartum cardiomyopathy is a dilated cardiomyopathy that can occur at any stage of gestation, but is classically defined as occurring in the last month of gestation or within the first 5 months after delivery, without an apparent cause or preexisting history of cardiac disease. The cause is unknown. Risk factors include cardiomyopathy during prior pregnancies, multiparity, maternal age >40 years old, chronic hypertension before pregnancy, gestational hypertension, preeclampsia, and HELLP syndrome. Symptoms and signs of peripartum cardiomyopathy are dyspnea, orthopnea, cough, palpitations, chest pain, edema, rales, and jugular venous distention. Diagnose and treat congestive heart failure and pulmonary edema with standard modalities (see chapter 53, Acute Heart Failure) **except that nitroprusside is relatively contraindicated in pregnancy because it can cause thiocyanate and cyanide accumulation in the fetus**. In the postpartum patient, angiotensin-converting enzyme inhibitors may be given. Anticoagulate with heparins because of increased risk of thromboembolism. **Do not use warfarin during pregnancy. Warfarin can be given in the postpartum period.**[27,28]

TABLE 100-2 Initial Treatment for Venous Thromboembolism during pregnancy[1,16,17]

Antithrombotic Agent	Initial Dose
Recommended: LOW MOLECULAR WEIGHT HEPARINS (LMWH)	
Enoxaparin (Lovenox®)	1 milligram/kg SC every 12 h
Dalteparin (Fragmin®)	100 units/kg SC every 12 h
Tinzaparin (Innohep®)	175 units/kg SC every 24 h
UNFRACTIONATED HEPARIN (LMWH)	10,000 units SC every 8-12 h to achieve aPTT 2-2.5 times base 6 hrs after dose
For heparin allergy or heparin-induced thrombocytopenia	
Fondaparinux (Arixtra®)	50-100 kg, 7.5 milligrams SC every 24 h; > 100 kg, 10 milligrams SC every 24 h
Danaparoid	removed from US market

DISORDERS ASSOCIATED WITH ELEVATED BLOOD PRESSURE: HYPERTENSION, PREECLAMPSIA AND HELLP SYNDROME, AND ECLAMPSIA

CHRONIC AND GESTATIONAL HYPERTENSION

The decrease in systemic vascular resistance results in a decrease in maternal blood pressure, and blood pressure reaches its nadir at 16 to 18 weeks of pregnancy. Blood pressure returns to prepregnancy values near the end of the second trimester.

Chronic hypertension in pregnancy is defined as a systolic blood pressure of ≥140 mm Hg or a diastolic blood pressure of ≥90 mm Hg that existed prior to pregnancy, is diagnosed before the 20th week of gestation, or persists longer than 12 weeks after delivery. Severe chronic hypertension is systolic blood pressure >160 mm Hg or diastolic pressure >110 mm Hg. Women with chronic hypertension are at increased risk for placental abruption, preeclampsia, low birth weight, cesarean delivery, premature birth, and fetal demise.[29]

Gestational hypertension is hypertension present only after the 20th week of pregnancy or in the immediate postpartum period but without proteinuria.

Safe treatment options for hypertensive women who are pregnant are labetalol and methyldopa.[30] **All antihypertensive drugs cross the placenta.** Labetalol is the first-line agent for chronic hypertension in pregnancy.[29] The starting dose is 100 milligrams PO twice a day, and the usual maintenance dose is 200 to 400 milligrams PO twice a day. Methyldopa, used safely in pregnancy for decades, is started at 250 milligrams every 6 hours PO and titrated to achieve the desired blood pressure. The usual daily dose is 500 milligrams to 3 grams divided in two to four doses per day, with a maximum of 3 grams per day.

Long-acting nifedipine may be added if blood pressure is not controlled with methyldopa or labetalol. Long-acting nifedipine is started at 30 milligrams PO once a day and can be increased up to 120 milligrams per day slowly if needed. For acute management of **hypertensive emergencies**, hydralazine 5 milligrams IV or IM, labetalol 20 milligrams IV, or nifedipine 10 to 30 milligrams PO (not a Food and Drug Administration–approved indication) may be used during pregnancy.[29-31] **Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are contraindicated because of their teratogenic effects on fetal scalp, lungs, and kidneys.**[29]

PREECLAMPSIA

Preeclampsia, or gestational hypertension with proteinuria, is characterized by hypertension before 20 weeks of gestation with either new-onset proteinuria, sudden increase in proteinuria, or development of **HELLP syndrome**.

The cause of preeclampsia is unknown. The histologic hallmark lesion of preeclampsia is acute atherosis of decidual arteries. Atherosis and thrombosis are thought to lead to placental ischemia and infarctions. Poor placental perfusion is presumed to lead to the formation of free radicals, to oxidative stress, and to inflammatory responses that may influence the mechanistic development of preeclampsia.[30]

Preeclampsia is associated with intrauterine growth retardation, premature labor, low birth weight, abruptio placentae, and future risk of maternal cardiovascular disease.[30,32]

Preeclampsia during an initial pregnancy increases the chances of recurrence in future pregnancies. Other important risk factors for preeclampsia include maternal age >40 years old, hypertension, diabetes, renal disease, collagen vascular disease, and multiple gestation. Low-dose aspirin therapy can prevent preeclampsia and its complications.[33,34]

Diagnosis of Preeclampsia Diagnostic criteria for preeclampsia are listed in **Table 100-3**, and laboratory evaluation is outlined in **Table 100-4**.[35]

HELLP Syndrome The **HELLP syndrome (Table 100-5)** is an important clinical variant of preeclampsia. HELLP is more common in the multigravid patient than in the primigravida. Hypertension may not be present initially or at all. This fact, combined with the usual complaint of epigastric or right upper quadrant pain, makes it easy to misdiagnose HELLP syndrome for other causes of abdominal pain, such as gastroenteritis, cholecystitis, hepatitis, pancreatitis, or pyelonephritis. **A pregnant woman at >20 weeks gestation or up to 7 days postpartum with abdominal pain should be evaluated for HELLP syndrome.**

Complications of severe preeclampsia, HELLP syndrome, and eclampsia include disseminated intravascular coagulopathy, spontaneous hepatic and splenic hemorrhage, end-organ failure, abruptio placentae, intracranial bleeding, maternal death, and fetal death.[35]

Treatment of Preeclampsia For **mild eclampsia**, outpatient management is an option after consultation with the obstetrician, as long as arrangements are made for frequent clinical and laboratory evaluation and close fetal surveillance.[35] Headache, scintillating scotomata or other visual changes, abdominal pain, vaginal bleeding, and decreased fetal movement require immediate reevaluation. Treat **severe preeclampsia** (blood pressure >160 mm Hg) with antihypertensive agents **(Table 100-6)**

TABLE 100-3 Diagnostic Criteria for Preeclampsia

Criteria for *mild* preeclampsia
Systolic blood pressure ≥140 mm Hg OR diastolic blood pressure ≥90 mm Hg
AND
Proteinuria >0.3 grams in a 24-h collection
AND
>20-wk gestation
AND
No other systemic signs or symptoms
Criteria for *severe* preeclampsia
Blood pressure ≥160 mm Hg systolic or ≥110 mm Hg diastolic measured on two occasions at least 6 h apart with the patient at rest
AND
Visual disturbances or mental status disturbances
OR
Pulmonary edema or cyanosis
OR
Epigastric or right upper quadrant pain; abnormal liver function studies
OR
Thrombocytopenia
OR
Oliguria (<500 mL in 24 h)
OR
Proteinuria of ≥5 grams in a 24-h collection or ≥3+ on two random urine samples collected at least 4 h apart
Impaired fetal growth

TABLE 100-4 Laboratory Evaluation for Preeclampsia

Test	Comments
CBC with differential	May see hemoconcentration or falling hematocrit. Thrombocytopenia suggests severe disease.
Creatinine	Elevation suggests severe disease.
Alanine and aspartate aminotransferase concentrations	Elevation suggests severe disease.
Lactate dehydrogenase level	Elevation suggests microangiopathic hemolysis.
Protein in urine	3+ proteinuria; 24-h collection may be done by obstetric service. >5 grams/24 h suggests severe disease.
Protein/creatinine ratio	0.1–0.3 indicates need for 24-h collection[29]
Uric acid level	Level ≥5.5 milligrams/dL may suggest superimposed preeclampsia on chronic hypertension[29]

TABLE 100-5 Laboratory Abnormalities in HELLP Syndrome

Test	Findings
CBC and test of peripheral smear	Schistocytes
Platelet count	<100,000/μL <150,000/μL suspicious for syndrome
Liver function tests (alanine aminotransferase, aspartate aminotransferase levels)	Elevated but below levels usually seen in viral hepatitis (<500 U/L)
Renal function tests	Normal or elevated blood urea nitrogen and creatinine levels
Coagulation profile	Abnormal
Lactate dehydrogenase	>600 U/L suspicious for hemolytic anemia
Total bilirubin	>1.2 milligrams/dL

and IV magnesium sulfate.[35-37] Consult with the obstetrician for admission or transfer to a center that manages high-risk pregnancy especially in the presence of HELLP syndrome. **The only *definitive* resolution for preeclampsia is delivery.**

The initial management of **HELLP syndrome** is similar to that of **severe preeclampsia** or **eclampsia**: IV magnesium, blood pressure control, and hospital admission for stabilization. Correct coagulopathy. If HELLP syndrome is suspected and obstetric care is not available locally, stabilize the patient as best as possible and transfer to a tertiary care center with high-risk obstetrics facilities. The definitive treatment is delivery, especially if the patient is ≥34 weeks of gestation. Corticosteroid administration can help delay delivery and improve fetal outcome in pregnancies <34 weeks of gestation.

ECLAMPSIA

Eclampsia is the development of new-onset seizures, superimposed upon preeclampsia, in a woman between 20 weeks of gestation and 4 weeks postpartum.

Eclampsia should be suspected and treated in any pregnant woman who is at >20 weeks of gestation or <4 weeks postpartum who develops seizures, coma, or encephalopathy. Occasionally, eclampsia can present with seizure in the absence of blood pressure elevation and proteinuria.[30] **Management of eclampsia includes treatment of seizures, treatment of hypertension, and emergent obstetric consultation to facilitate urgent delivery of the fetus.** Treat seizures with **magnesium sulfate**, 4 to 6 grams IV in 100-mL aliquot given over 20 to 30 minutes followed by an infusion of 2 grams per hour for at least 24 hours.[35-37] Magnesium is renally excreted, and in women with renal insufficiency, reduce the dose to 2 grams IV bolus and obtain a serum magnesium level before increasing the dose. The main side effects of high levels of magnesium are flushing, diaphoresis, hypothermia, hypotension, flaccid paralysis, and respiratory depression. When levels approach toxicity, patellar reflexes diminish and respiratory rate slows. Administer antihypertensives as suggested in Table 100-6. Replace coagulation factors if there is coagulopathy. Obtain emergency obstetric consultation for prompt delivery. If obstetric services are not available, stabilize the patient as best as possible and transfer to a center with facilities for advanced obstetric care.

VAGINAL BLEEDING IN THE SECOND HALF OF PREGNANCY

The causes of serious vaginal bleeding in the second half of pregnancy include abruptio placentae, placenta previa, and vasa previa. All can cause severe hemorrhage. **Do not perform a digital or speculum pelvic examination to assess vaginal bleeding until a transvaginal US is performed to determine the location of the placenta. Mechanical disruption of the placenta by speculum or digital examination may precipitate catastrophic hemorrhage.** When transvaginal US is properly and carefully performed by those experienced in transvaginal US (vaginal probe is angled against the anterior lip of the cervix, probe is not advanced to contact the placenta, probe is not inserted into the cervix), the technique does not cause hemorrhage.[40] If there is no evidence of placenta previa or vasa previa, then a sterile speculum examination may be performed to determine if premature rupture of membranes or abruption is present.

ABRUPTIO PLACENTAE

Abruptio placentae is the premature separation of a normally implanted placenta from the uterine lining (**Figure 100-1**). The incidence of spontaneous abruption is highest between 24 and 28 weeks of gestation.[41] Abruption can cause uteroplacental insufficiency and fetal distress or demise. Maternal complications include coagulopathy, hemorrhagic shock, uterine rupture, and multiple organ failure. Abruption usually occurs spontaneously but is also associated with trauma, even minor trauma. See chapter 256, Trauma in Pregnancy. Risk factors for abruption include abdominal trauma, cocaine use, oligohydramnios, chorioamnionitis, advanced maternal age or parity, eclampsia, and chronic or acute hypertension.

Clinical features depend on the degree of placental abruption. Mild abruption is characterized by mild uterine tenderness, no or mild vaginal bleeding, normal maternal vital signs, no coagulopathy, and fetal distress. Signs and symptoms of severe abruption are no or heavy vaginal bleeding, fetal distress, coagulopathy, severe uterine pain or tenderness, continuous or repetitive uterine contractions, and maternal hypotension or shock. Nausea, vomiting, and back pain may also be present. **Consider placental abruption in pregnant women with acute, painful vaginal bleeding or with acute abdominal/uterine pain.**

Diagnosis is made by the clinical features. Electronic fetal monitoring (cardiotocodynamometry) is very sensitive for identifying fetal distress as a sign of placental abruption and has a 100% negative predictive value for adverse outcomes when monitoring is reassuring.[42] Transvaginal US is fairly specific for the diagnosis, but is not sensitive for the detection of

TABLE 100-6 Antihypertensive Drugs for Treatment of Acute, Severe Hypertension in Preeclampsia and Eclampsia[38,39]

Generic Name	Mechanism of Action	Onset of Action	Dosage	Comment
Labetalol	Selective α and nonselective β antagonist	5 min	20 milligrams IV, then 40–80 milligrams IV every 10 min as needed (maximum, 300 milligrams); IV infusion 1–2 milligrams/min titrated	Less hypotension and reflex tachycardia than hydralazine. Higher doses cause neonatal hypoglycemia. Longer use associated with fetal growth restriction.
Hydralazine	Arterial vasodilator	20 min	5 milligrams IV or 10 milligrams IM, repeat at 20-min intervals; consider other drug if no response at maximum of 20 milligrams IV or 30 milligrams IM	Maternal hypotension, fetal distress; must wait 20 min for response between IV doses.
Nifedipine	Calcium channel antagonist	10–20 min	10 milligrams PO, repeat in 30 min if necessary	Food and Drug Administration does not approve short-acting nifedipine for treatment of hypertension.

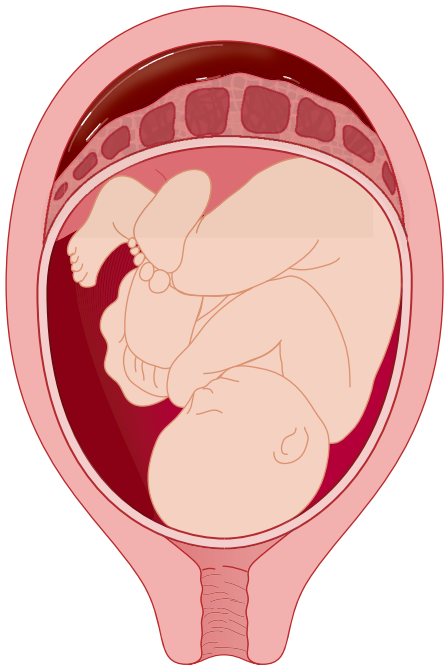

FIGURE 100-1. Abruptio placentae. The placenta has separated from the superior pole of the uterus.

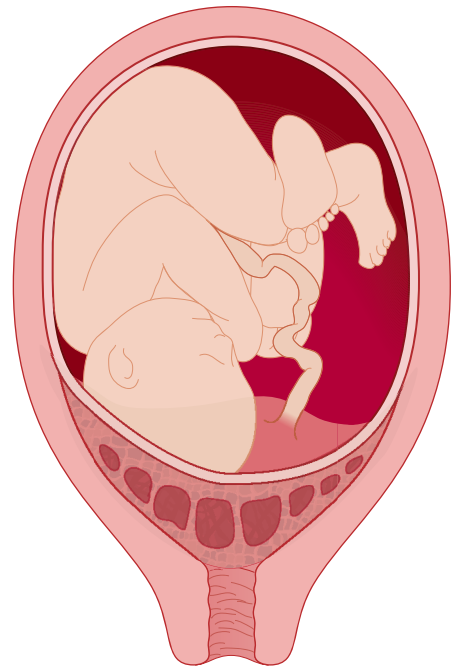

FIGURE 100-2. Complete placenta previa. Placenta overlies the internal os.

retroplacental clot because the appearance of clotted blood evolves in echotexture over time.[41] MRI is diagnostic but requires the transport of a potentially unstable patient out of the ED or intensive care unit for imaging.

Treatment consists of maternal stabilization, cardiotocographic monitoring to detect fetal distress, and emergency obstetric consultation. Place two large-bore IVs; obtain a CBC, metabolic panel, coagulation panel, fibrin degradation product, and fibrinogen levels; and type and cross-match maternal blood. Administer RhoGAM® if the mother is Rh negative. For disseminated intravascular coagulation, replace coagulation factors. Immediate delivery is indicated for severe abruption.

PLACENTA PREVIA

Placenta previa is a placenta that extends near, partially over, or beyond the internal cervical os. Normal placental implantation is in the corpus or fundal region, whereas in placenta previa, implantation is lower in the uterus. The cause is unknown. Although low-lying or partial placenta previa is not uncommon early in pregnancy, the placenta usually migrates to a normal position as the pregnancy nears term.

Risk factors for placenta previa include cesarean delivery, multiple uterine surgeries, advanced maternal age, minority group status, cigarette smoking, and cocaine use. Patients with symptomatic placenta previa present with painless bright-red vaginal bleeding, which should be differentiated from the normal passage of blood-stained mucus that occurs near the onset of labor. There are three subclasses of placenta previa: marginal placenta previa, which reaches the internal os but does not cover it; partial placenta previa, where the placenta partially covers the internal os; and complete placenta previa, which completely covers the internal os (**Figure 100-2**).

While proceeding with further patient assessment, place two large-bore IVs for fluid resuscitation; obtain CBC and coagulation parameters; and type and cross-match blood. **Do not perform a digital or speculum vaginal examination until normal placental position is confirmed by US, as disruption of the cervical-placental junction could precipitate catastrophic hemorrhage.** Carefully perform transvaginal US (see earlier). Once placenta previa is identified, consult obstetrics for management options. A double setup, in which two teams of staff are available in the operating room during a vaginal examination, may be indicated in cases where the placenta lies within 1 to 2 cm of the cervical os and labor is imminent. Otherwise, women in the second half of pregnancy with placenta previa are usually admitted to the hospital for observation and fetal monitoring

VASA PREVIA

Vasa previa is a rare cause of late-pregnancy bleeding. In vasa previa, umbilical vessels course in the amniotic membrane at the level of the cervical os, so that when the cervix begins to dilate in labor with membrane rupture, the blood vessels tear. Fetal distress or fetal demise may result from fetal exsanguination or vessel compression. Risk factors associated with vasa previa are placenta previa, in vitro fertilization, velamentous insertion of the umbilical cord, and bilobed placenta. Vasa previa can sometimes be diagnosed by Doppler color US performed early in pregnancy. Otherwise, it is seldom recognized prior to catastrophic vessel disruption during labor. Treatment is rapid operative delivery.

PREMATURE RUPTURE OF MEMBRANES, PRETERM LABOR, AND PRETERM BIRTH

Premature rupture of membranes is rupture of membranes prior to onset of contractions. **Membrane rupture before 37 weeks of gestation is known as preterm premature rupture of membranes.** The time from membrane rupture to delivery, known as the latent period, is usually inversely proportional to the gestational age when preterm premature rupture of membranes occurs. For pregnancies between 25 and 32 weeks, 33% had latent periods longer than 3 days. For pregnancies at 33 to 34 weeks and 35 to 36 weeks, 16% and 4.5% had latencies greater than 3 days, respectively.[43] The latent period allows for pharmacologic intervention to improve fetal lung maturity and increase fetal survival.

Preterm (premature) labor is labor prior to 37 weeks of gestation and is often preceded by premature rupture of membranes. Preterm labor is thought to be a syndrome initiated by multiple mechanisms, including infection, inflammation, uteroplacental ischemia or hemorrhage, uterine overdistention secondary to multiple gestation, stress, and other immunologically mediated processes.[44] Several non–genital tract infections, including pyelonephritis, asymptomatic bacteriuria, pneumonia, appendicitis, and periodontal disease, are also implicated in preterm labor.

Untreated *Chlamydia*, gonorrhea, *Trichomonas vaginalis*, and bacterial vaginosis infections increase the risk of preterm premature rupture

of membranes and preterm labor. With appropriate patient selection, vaginal progesterone gel or suppository or IM progesterone can reduce the likelihood of preterm delivery.[45]

Preterm birth is birth before 37 weeks of gestation, and may occur spontaneously or as a result of premature rupture of membranes or placental abruption or may be induced for medical reasons. Surviving preterm neonates are at risk for sepsis, neurologic defects, feeding problems, blindness, deafness, and respiratory distress. Infants weighing <1500 grams or born at <32 weeks of gestation are at greatest risk for these problems, but even infants born at between 34 0/6 and 36 6/7 weeks gestation (late preterm infants) may require intensive care admission for IV fluids, sepsis, hyperbilirubinemia, and mechanical ventilation.[41,43]

DIAGNOSIS OF PREMATURE RUPTURE OF MEMBRANES

Details of the history taking and physical examination that aid in the diagnosis of premature rupture of membranes are listed in **Table 100-7**. **Avoid digital cervical examination because it decreases the latent period and may increase the likelihood of infection. Perform speculum examination and visually examine the cervix to identify dilation and test vaginal fluid (Table 100-7).** The combination of history, nitrazine paper, and fern testing (**Figure 100-3**) are reported to diagnose 90% of cases of premature rupture of membranes.[46] US assessment of amniotic fluid volume correctly identifies premature rupture of membranes when a low amniotic fluid index (≤10 cm) is present.[47]

Premature labor or premature rupture of membranes requires obstetric consultation. If obstetric services are unavailable, transfer the patient to a center where such services are available. Obstetric treatment includes corticosteroids and antibiotics to treat group B *Streptococcus*.

Corticosteroids given at <34 weeks of gestation speed fetal lung maturity, decrease the incidence of intraventricular hemorrhage, reduce the duration of mechanical ventilation, and reduce the incidence of necrotizing enterocolitis without increasing maternal or fetal infection. Betamethasone (12 milligrams IM every 24 hours for 2 days) or dexamethasone (6 milligrams IM every 12 hours for 2 days) can be used for gestations between 24 and 34 weeks.[48]

Antibiotics can decrease neonatal infection, prolong latency, and reduce the incidence of postpartum endometritis, chorioamnionitis, neonatal infections, and intraventricular hemorrhage. Antibiotic choices are penicillin G (5 million units IV then 2.5 to 3 million units every 4 hours until delivery), ampicillin (2 grams IV then 1 gram every 4 hours until delivery), and cefazolin (2 grams IV). Clindamycin or vancomycin

FIGURE 100-3. Ferning of amniotic fluid. [Photo contributed by Robert Buckley, MD.]

TABLE 100-7 Keys to Diagnosis of Premature Rupture of Membranes

Information Obtained	Comments
History	
Gush of fluid and continued leakage of fluid	Ask patient to perform a Valsalva maneuver while speculum is in place to look for gush of fluid, or apply fundal pressure.
Details of contractions	Determine if active labor is in process.
Date of last menstrual period	Use to calculate estimated date of delivery and gestational age. Gestational age is number of weeks from first day of last menstrual period.
Vaginal bleeding	Raises concern for placenta previa.
Recent intercourse	
Fever	Infection raises fetal and maternal risk.
Physical Examination	
Measurement of fundal height	
Auscultation of fetal heart tones	
Sterile speculum examination	Check for: Cervical dilatation and effacement. Pooling in vagina of fluid leaking from cervix. If no fluid is noted, apply fundal pressure or ask patient to perform a Valsalva maneuver or cough.
Laboratory Evaluation	
Vaginal fluid	Test with nitrazine paper. **Blue color indicates pH >6.5, signaling presence of amniotic fluid.** Note: Blood, semen, bacterial vaginosis, trichomoniasis, soap, and antiseptics may cause false positive; false negative, about 7%.[46]
Swab of vaginal walls or posterior fornix; do not swab cervical mucus; cervical mucus produces thick, dark, wide arborization pattern, not delicate ferning	Examine glass slide preparation for ferning. **Ferning indicates presence of amniotic fluid.** Blood may obscure ferning. Mucus results in a false-positive fern test finding. Test for *Chlamydia*, *Neisseria gonorrhoeae*, group B streptococci, and bacterial vaginosis.

are alternatives for those allergic to penicillins. Macrolides are not recommended.[49] Do not give amoxicillin-clavulanate because it is associated with necrotizing enterocolitis. There is no need for prophylactic antibiotics if membranes are intact.[50]

Tocolytic therapy using magnesium sulfate, β-mimetics, indomethacin, or calcium channel blockers is controversial and is relatively contraindicated in the patient with preterm premature rupture of membranes. Tocolysis may allow time for antenatal administration of corticosteroids and antibiotics and transfer of the patient to an appropriate neonatal center. Because there are no widely accepted protocols for tocolytic management, consult the obstetrician, who can explain the pharmacologic risks, benefits, and alternatives to the patient. Magnesium sulfate may reduce the risk and severity of cerebral palsy in infants when birth is anticipated before 32 weeks of gestation.[51]

Management guidelines for expedited delivery in the near-term gestation vary. Expedited delivery was historically recommended in patients with preterm premature rupture of membranes at >34 weeks of gestation to avoid the complications of chorioamnionitis and neonatal sepsis, but recent trials suggest that induction of labor does not reduce the risk of neonatal sepsis.[52]

MATERNAL EMERGENCIES DURING LABOR AND DELIVERY

The most important maternal emergencies of labor and delivery are postpartum hemorrhage, uterine rupture, and amniotic fluid embolism. Difficult deliveries are discussed in chapter 101, Emergency Delivery.

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage usually occurs within the first 24 hours of delivery and is referred to as **primary postpartum hemorrhage**. The main causes of primary postpartum hemorrhage are **uterine atony**, **retained placental fragments**, **lower genital tract lacerations**, **uterine rupture**, **uterine inversion**, and **hereditary coagulopathy**. **Table 100-8** lists the most common risk factors. **Secondary postpartum hemorrhage** occurs after the first 24 hours and up to 6 weeks postpartum. The most common causes of secondary postpartum hemorrhage are failure of the uterine lining to subinvolute at the former placental site, retained placental tissue, genital tract wounds, and uterogenital infection.[53,54]

Excessive blood loss in the postpartum period is defined as a 10% drop in the hematocrit, a need for transfusion of packed red blood cells, or volume loss that causes symptoms of hypovolemia. Normally, plasma volume increases by 40% and red blood cell volume by 25% at the end of the third trimester. The hematologic changes of pregnancy can mask the typical symptoms of hemorrhage, and the first sign may be only a mild increase in pulse rate. Up to a 30% loss in total blood volume may be required before blood pressure drops.

Most cases of postpartum hemorrhage are due to uterine atony. Another 20% result from cervical, vaginal, or perineal lacerations. Retention of placental tissue may account for another 10%, and underlying coagulopathy is uncommon but potentially treatable.[55] **The initial steps are to begin aggressive fluid and blood resuscitation while simultaneously identifying and treating the underlying cause (Tables 100-9 and 100-10).** Nonpneumatic antishock garments can be applied in combination with fluid resuscitation and uterotonics, resulting in reduced blood loss and increased maternal survival in remote settings or with delayed transport.[56]

TABLE 100-8 Risk Factors for Postpartum Hemorrhage

Primiparity or grand multiparity
Previous postpartum hemorrhage
Preeclampsia
Prior cesarean section
Placenta previa or low-lying placenta
Marginal umbilical cord insertion
Transverse fetal lie
Labor induction or augmentation
Cervical or uterine trauma
Fetal age <32 weeks of gestation
Fetal birth weight >4500 grams
Prolonged third stage of labor

Uterine atony is the most common cause of postpartum hemorrhage. Risk factors include preeclampsia, prolonged use of uterotonics or tocolytics, prolonged labor, multifetal gestation or fetal macrosomia, multiparity, retained placenta, and uterine infection. Initiate bimanual uterine massage; place a fist in the anterior fornix and compress the uterine fundus against the hand in a suprapubic location (**Figure 100-4**).

Uterine inversion mostly results from previous cesarean section or overzealous attempts to remove the placenta to manage the third stage of labor.[53] Inversion can also occur in patients with connective tissue disorders and uterine structural anomalies. It can be a difficult diagnosis to make, especially if the fundus remains cephalad to the cervix. The diagnosis can be made with transvaginal or transabdominal ultrasound. Uterine inversion requires immediate manual replacement of the uterus. A Rüsch balloon catheter can be applied to correct uterine inversion.[57] Whatever technique is used, correction of uterine inversion is a very painful and difficult procedure that may require general anesthesia and tocolytic agents.

Retention of placental fragments or **abnormal placental implantation** (placenta accreta) may cause severe hemorrhage and may require emergency pelvic embolectomy, hemostatic brace sutures (B-Lynch sutures), or peripartum hysterectomy.

Uterine rupture is a rare complication but carries high maternal and fetal mortality. Previous cesarean section is the primary risk factor for uterine rupture, and single-layer surgical closure of the uterus, fetal size >3500 grams, and labor augmentation increase the rate of rupture during a trial of labor. Anatomic abnormalities such as a bicornuate uterus, grand multiparity, history of connective tissue disorders, and abnormal placentation are also associated with rupture. Clinical signs of uterine rupture are persistent abdominal pain, severe vaginal bleeding, loss of fetal station, and palpable uterine defect. Fetal monitors may show fetal distress and bradycardia. The diagnosis of uterine rupture must be made clinically and rapidly. Treatment is aggressive fluid and blood resuscitation and surgical delivery of the fetus.

AMNIOTIC FLUID EMBOLUS

Amniotic fluid embolus is a rare and often catastrophic complication of pregnancy that occurs when amniotic fluid and cells of fetal origin enter the maternal circulation during labor or delivery. Most cases occur before delivery. Fetal and maternal mortality rates are high. Amniotic fluid embolism is difficult to diagnose and is usually a diagnosis of exclusion. The onset of symptoms until cardiovascular collapse can range from seconds to over 4 hours. Presenting signs include respiratory distress, hypoxia, pulmonary edema, altered mental status, seizures, sudden maternal cardiovascular collapse, disseminated intravascular coagulation, and sudden onset of fetal distress.[58]

Postulated causes are antigenic stimuli or activation of the clotting cascade when amniotic fluid enters the maternal circulation. Physiologically, the hemodynamic changes shown on echocardiogram during confirmed cases of amniotic fluid embolism are due to the acute onset of severe pulmonary hypertension, right ventricular failure with leftward deviation of the septum, and the absence of pulmonary edema. Secondarily, left ventricular filling becomes impaired due to profound right heart failure, eventually resulting in myocardial ischemia.[58]

Death can occur rapidly. Treatment is supportive, and there are no specific interventions currently available; prevent and/or treat hypoxia, hypotension, and hypoperfusion. Place the woman in the left lateral decubitus position to minimize vena cava compression; give oxygen by nonrebreather mask or endotracheal tube; resuscitate with fluid and blood; and administer pressors to support maternofetal circulation until emergency delivery of the fetus is performed. Obtain emergency obstetric consultation. If the gravid patient cannot be resuscitated, perimortem cesarean delivery within 5 minutes of cardiac arrest increases the chances of neonatal survival.

TABLE 100-9 Drug Regimens for Postpartum Hemorrhage

Drug	Comments
Oxytocin (Pitocin®) 10 units IM *or* 20-40 units in 1 L NS; give 500 mL over 10 min, then 250 mL/h	First-line treatment. Uterotonic agent. Rapid administration may cause transient hypotension.
Carboprost (Hemabate®) 0.25 mg IM, repeat as needed every 15-90 minutes for a total dose of 2 milligrams	Prostaglandin. Side effects: nausea, vomiting, diarrhea, hypertension, bronchospasm. Avoid in patients with hypertension or asthma.
Misoprostol (Cytotec®, Apo-Misoprostol®) 1000 micrograms rectally	Prostaglandin. Side effects: nausea, vomiting, diarrhea. Not FDA approved for this indication; widely used internationally due to heat stability.
Methylergonovine (Methergine®) or Ergonovine® 0.2 milligrams IM, repeat as needed every 2-4 h to maximum of 5 doses	Ergot. Contraindicated in patients with hypertension or preeclampsia.

Abbreviations: FDA = Food and Drug Administration; NS = normal saline; SL = sublingual.

TABLE 100-10 Common Causes and Treatment of Postpartum Hemorrhage

Tone	Perform bimanual uterine massage. Give drugs to improve uterine tone as outlined in Table 100-9.
Trauma	Examine for cervical, vaginal, or perineal lacerations or hematomas. Repair lacerations. Incise, drain, and appropriately ligate bleeding vessels causing a hematoma. Correct uterine inversion with manual replacement. Uterine rupture requires surgery.
Tissue	Inspect the placenta for missing fragments; if a portion is absent, manually evacuate the uterine cavity. Invasive placentation may require hysterectomy. Perform transvaginal or transabdominal US to identify abnormal fluid-filled uterus. Consider a balloon tamponade with either uterine-specific balloon device (Bakri or Rüsch) or an adaptation of a Foley catheter or condom as a temporizing measure.
Thrombin	Consider DIC in the setting of severe preeclampsia, sepsis, placental abruption, shock, or intrauterine fetal demise, although undiagnosed coagulopathies may rarely present in nulliparas. Replace coagulation factors.

Abbreviation: DIC = disseminated intravascular coagulation.

POSTPARTUM ENDOMETRITIS

Most postpartum infections are identified after hospital discharge. **In a postpartum woman with fever, assume pelvic infection until proven otherwise. Also consider respiratory tract infection, pyelonephritis, mastitis, thrombophlebitis, and appendicitis.**[59] Risk factors for postpartum endometritis are listed in **Table 100-11**.

The most common pathogens are gram-positive and gram-negative aerobes, anaerobes, *Mycoplasma hominis*, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae*. *Gardnerella vaginalis* is isolated more often in younger women. Many infections are polymicrobial. Group A streptococcal infections are less common, but are increasing causes of postpartum endometritis.[60]

Symptoms of postpartum endometritis are fever, foul-smelling lochia, leukocytosis, tachycardia, pelvic pain, and uterine tenderness. Only scant vaginal discharge may be present, especially in patients infected with group B streptococci. In patients who are status post cesarean section, there may be surgical wound tenderness and purulent exudate.

Vaginal samples are of little value because of contamination with local flora. Blood cultures are rarely positive. Culture any purulent material from surgical incisions. Creatine phosphokinase levels may be elevated in group B streptococcal endometritis. Consult the obstetrician for disposition decisions. Admission is needed for patients who appear ill, have had cesarean section, or have underlying comorbidities. Treatment consists of antibiotics (**Table 100-12**), abscess drainage, and debridement of necrotic tissue.

After consultation with and recommendation by the obstetrician, patients with mild illness and those for whom follow-up in 24 hours is assured can be treated as outpatients with oral antibiotics, such as clindamycin, 300 milligrams three times per day PO for 10 days, or doxycycline, 100 milligrams twice per day for 10 days. **Do not give doxycycline to women who are breastfeeding**.

Complications of endometritis include parametrial phlegmons; surgical, incisional, and pelvic abscesses; infected hematomas; septic pelvic thrombophlebitis; necrotizing fasciitis; and peritonitis.

TABLE 100-11 Risk Factors for Postpartum Endometritis

Cesarean section*
Multiple gestation
Younger maternal age
Long duration of labor and membrane rupture
Internal fetal monitoring
Low socioeconomic level
Digital examination after 37 wk of gestation
Maternal human immunodeficiency virus infection

*Most significant risk factor.

TABLE 100-12 Inpatient Treatment of Postpartum Endometritis*

Cefoxitin (2 grams IV every 6 h) and vancomycin 1 gram IV every 12 h
OR
Cefotetan (2 grams IV every 12 h) and vancomycin 1 gram IV every 12 h
OR
Cefotaxime (2 grams IV every 6 h) and vancomycin 1 gram IV every 12 h
OR
Clindamycin (500 milligrams IV every 6 h) *plus* gentamicin (4.2 milligrams/kg IV daily) and vancomycin 1 gram IV every 12 h
OR
Ampicillin (2 grams IV every 4 h) *plus* gentamicin (4.2 milligrams/kg IV daily) and vancomycin 1 gram IV every 12 h
OR
Metronidazole (500 milligrams IV every 8 h) *plus* ampicillin (2 grams IV every 4 h) *plus* an aminoglycoside and vancomycin 1 gram IV every 12 h

*Consult the hospital pharmacist to determine if the antibiotic regimen selected is appropriate for breastfeeding.

TABLE 101-1 Equipment and Supplies for Emergency Delivery

Sterile gloves
Sterile towels and drapes
Povidone-iodine (Betadine) to cleanse the perineum
Sterile lubricant gel
Sterile scissors
Kelly clamps
Cord clamps
Rubber suction bulb
Towel or blanket for the infant
Gauze sponges (4×4)
Syringes (10 mL) and needles (22–24 gauge)
Placenta basin
Suture (3-0 chromic and 2-0 Vicryl) and needle driver

Note: List excludes standard adult and neonatal resuscitation equipment.

TRANSFER OF THE PREGNANT PATIENT AND THE EMERGENCY MEDICAL TREATMENT IN ACTIVE LABOR ACT

There are times when a pregnant woman must be transferred to another hospital. Emergency physicians who work in a hospital that does not provide obstetric services should be familiar with the protocols in place for transfer and inpatient care of such patients. The **Emergency Medical Treatment and Active Labor Act** specifically addresses the care of pregnant women before and during transfer (see chapter 303, Legal Issues in Emergency Medicine).

A woman having contractions is considered to have an emergency medical condition if there is insufficient time for transfer before delivery or if the transfer may pose a threat to the health or safety of the child. In such a situation, the patient should not be transferred prior to delivery unless the patient requests transfer. If contractions are not present, an emergency medical condition is not automatically present, and the regular rules of providing medical care and determining the need for transfer of patients apply.

CHAPTER 101

Emergency Delivery

Sarah Elisabeth Frasure

INTRODUCTION AND EPIDEMIOLOGY

The thought of a woman presenting to the ED in active labor is justifiably a cause for anxiety—the emergency physician must contend not only with the often rusty recollection of the stages of normal delivery, but also with the knowledge that there are serious and even fatal complications associated with labor. Maternal and fetal survival may depend on the ability to successfully manage pre-eclampsia, eclampsia, hemorrhage, shoulder dystocia, malpresentation, cord prolapse, breech delivery, or fetal distress. Every ED should be prepared to take care of a woman in active labor. Tools include a basic delivery kit, an infant warmer or isolate, and medical supplies and equipment for neonatal resuscitation (see chapter 108, "Resuscitation of Neonates" and **Tables 101-1** and **101-2**).

Out-of-hospital births occurred in 1.36% of births in 2012, and out-of-hospital births in the United States had a lower risk profile than in-hospital births, so that fewer teen, preterm, low-birth-weight, and multiple births occurred out of hospital.[1] Occasionally, planned home deliveries experience medical complications and require rapid transport to the ED to assist with labor and delivery. In a prospective study of home births in the United States and Canada, nearly 12% of 5400 women who had planned a home delivery ultimately required urgent transfer to a hospital during the course of labor. The majority of *intrapartum* transfers were performed for failure to progress, need for pain management, and maternal exhaustion. *Postpartum* transfers encompassed a variety of obstetric and/or neonatal complications such as maternal hemorrhage, retained placenta, or newborn respiratory distress.[2]

Out-of-hospital deliveries may also occur due to inadequate or nonexistent prenatal care, transportation difficulties, remote setting, or the onset of premature labor. Occasionally, a woman may also attempt to avoid the hospital/physician fees associated with pregnancy until the delivery of her child, presenting to a hospital for the first time when in active labor.

The development of obstetric centers for high-risk pregnancy has led to a significant decline in neonatal mortality in the United States, and transports to specialized units have increased. The most common reasons for transport include preterm labor (41%), premature rupture of membranes (21%), hypertensive disease (16%), and antepartum hemorrhage (13%).[3] Other indications for transport include eclampsia or pre-eclampsia, fetal distress, multiple gestation, fetal anomalies, and maternal health problems, including traumatic injuries. EMS units transporting an actively laboring patient should carry sterile delivery packs, relevant medical supplies (Table 101-1), and appropriate medications (Table 101-2). The transport team should be trained to assist in the precipitous delivery of an infant. Prehospital protocols regarding the complications of labor and delivery should be reviewed regularly to ensure that EMS personnel are adequately prepared for both normal delivery and potentially catastrophic pregnancy-related events.

For deliveries in an austere environment or in a disaster zone, the United Nations Population Fund provides a vaginal delivery kit for use during disaster relief, which includes a plastic sheet to lay on the ground, soap for washing hands and the perineum, string and a razor blade to tie and cut the umbilical cord, and a blanket to protect the newborn baby.[4]

TABLE 101-2 Medications for Emergency Delivery and Indications for Use

Classification	Medication	Dosage	Indication/Use	Contraindications
Uterotonic	Oxytocin	10–40 units/1000 mL normal saline or 10 units IM	Stimulation of uterine contraction or as uterotonic for PPH	Hypersensitivity
	Misoprostol	1000 micrograms PR once	Unlabeled use for PPH	Hypersensitivity
	Methylergonovine	0.2 milligram IM or IV or PO; may repeat at 2–4 h intervals	PPH	Hypersensitivity, hypertension
	Carboprost	250 micrograms IM every 15–90 min (total dose 2 milligrams)	PPH	Asthma
Antihypertensive	Hydralazine	5 milligrams IV, followed by 5- to 10-milligram boluses every 20 min	Pre-eclampsia/eclampsia, hypertensive emergency	Hypersensitivity
	Labetalol	20 milligrams IV, followed by doubled doses up to 80 milligrams (20–40–80–80) every 10 min; maximum total dose, 220 milligrams	Pre-eclampsia/eclampsia, hypertensive emergency	Hypersensitivity, sinus bradycardia
Anticonvulsant	Magnesium sulfate	Loading dose of 4–6 grams IV over 15 min, followed by 2 grams/h infusion; can also give 5 grams IM in each buttock	Seizure prophylaxis in pre-eclampsia/eclampsia	Myasthenia gravis
Electrolyte supplement toxicity	Calcium gluconate	1 gram IV over 5–10 min	Magnesium toxicity	Hypersensitivity, cardiac arrhythmia
Analgesic	Lidocaine 1%	1–10 mL injected locally	Local anesthetic	Hypersensitivity
	Fentanyl, 50 micrograms/mL	50 micrograms/mL	Short-acting opiate analgesic	Hypersensitivity
Opiate antagonist	Naloxone	0.4–2.0 milligrams IV every 2–3 min as need up to 10 milligrams cumulative dose	Narcotic overdose	Hypersensitivity
Antiemetic	Ondansetron	4 milligrams IV	Nausea, vomiting	Hypersensitivity

Abbreviation: PPH = postpartum hemorrhage.

PHYSIOLOGY

RUPTURE OF MEMBRANES

Determining rupture of membranes predicts not only the likelihood of imminent labor, but also the potential for complications, such as infection or cord prolapse. Spontaneous rupture of membranes occurs during the course of active labor in the majority of patients, although it also happens *prior* to onset of labor in approximately 8% of third-trimester patients.[5] Fifty percent of women who experience premature rupture of membranes deliver within 5 hours, and 95% give birth within 28 hours of this event.[6] The history of spontaneous rupture of membranes typically involves report of a gush of clear or blood-tinged fluid. Occasionally, patients recount continued leaking or dampening of their underwear on standing or with a Valsalva maneuver. Thick greenish brown fluid suggests the presence of meconium in amniotic fluid.

Rupture of membranes may be confirmed by using nitrazine paper to test residual fluid in the fornix or vaginal vault while performing a sterile speculum examination. **Amniotic fluid has a pH of 7.0 to 7.4 and will turn nitrazine paper a dark blue.** Vaginal fluid, on the other hand, typically has a pH of 4.5 to 5.5; the nitrazine strip, thus, remains yellow. False-positive results may occur, however, in the presence of blood, lubricant, *Trichomonas vaginalis*, semen, or even cervical mucus. **Another test that confirms rupture of membranes is ferning, which is the observation of sodium chloride crystals on a microscope slide as amniotic fluid dries (Figure 101-1).**

Premature Rupture of Membranes Rupture of the amnion and chorion *prior* to the onset of labor is called *premature* or *prelabor rupture of membranes.* If rupture of membranes occurs prior to 37 weeks of gestation, it is termed *preterm premature rupture of membranes.* Prolonged rupture of membranes transpires if delivery does not take place within 18 hours of rupture of membranes. It is important to understand the difference between and management of premature and preterm premature rupture of membrane as these patients may present to an ED for an initial evaluation.[7] Risk factors related to both premature rupture of membranes and preterm premature rupture of membranes include infection, history of trauma, multiple gestation, fetal anomalies, abruptio placentae, and placenta previa. Obtain emergency obstetrics consultation for preterm premature rupture of membranes.

CERVICAL DILATATION

Cervical dilatation describes the diameter of the internal cervical os and indicates the progression of labor. The index and middle fingers of the examining hand are used to estimate the diameter, which is expressed in centimeters (from closed to 10 cm). **Ten centimeters indicates full dilatation.** As labor progresses, the cervix also undergoes thinning, known as **effacement**, which is described in terms of a percentage (%) of normal cervical length. Unfortunately, this estimate is poorly reproducible among examiners. **Station** indicates the level that the fetus occupies in the pelvis. The maternal ischial spines serve as the reference point and are palpable on either side of the vaginal canal (located at 4 and 8 o'clock). If the presenting fetal part remains above the ischial spines, the station is described as negative. Once the presenting

fetal part has reached the level of the ischial spines, the station is 0, with further descent into the pelvis described as +1 or +2. Therefore, a +3 station corresponds to visible scalp at the introitus, indicating a fetal position consistent with impending delivery.

TRUE VERSUS FALSE LABOR

Distinguishing **true from false labor** is an important initial step in the management of the pregnant patient (**Table 101-3**). **False labor** is defined as uterine contractions that do not produce cervical changes and is characterized by irregular, brief contractions that are usually confined to the lower abdomen. Commonly known as **Braxton Hicks contractions**, they are irregular in both intensity and duration. False labor may persist for several days and is commonly treated with hydration and rest.

True labor, on the other hand, is characterized by painful, repetitive uterine contractions that increase steadily in both intensity and duration and result in cervical effacement and dilatation. Specifically, true labor pains typically commence in the fundal region and upper abdomen and radiate into the pelvis and lower back. True labor leads not only to cervical dilatation and effacement, but also to the progressive descent of the fetus into the pelvis, in preparation for delivery.

STAGES OF LABOR

There are three **stages of labor** (**Table 101-4**). The first stage commences with the onset of regular uterine contractions and ends with full cervical dilatation. The first stage can be subdivided into two phases: latent and active. The latent phase is characterized by moderately uncomfortable uterine contractions that are infrequent and irregular, resulting in gradual cervical changes. In this preparatory phase the uterus orients to contractions and the cervix undergoes both effacement and softening. The active phase is typically noted to arise once the cervix has dilated to 3 to 4 cm, and results in cervical dilatation at an average rate of 1.2 cm/h in nulliparous and 1.5 cm/h in multiparous women. The second stage of labor commences at full dilatation and ends with the delivery of the infant.[8] The mean length of the second stage of labor is 20 minutes for multiparous women and 54 minutes for nulliparous women.[9] The third stage of labor starts after the delivery of the infant and ends with the delivery of the placenta. The third stage usually lasts less than 10 minutes, and active intervention is usually not required until after 30 minutes, unless hemorrhage occurs.

TABLE 101-4 Stages of Labor

Stage	Definition	Comments
First stage	From onset of regular uterine contractions to full cervical dilatation	—
Latent phase	Irregular, infrequent contractions	Preparatory phase, cervix softens and effaces
Active phase	Begins once cervix has dilated to 3–4 cm	Nulliparas: cervix dilates at 1.2 cm/h Multiparas: cervix dilates at 1.5 cm/h
Second stage	From full dilatation to delivery	Nulliparas: mean duration 54 min Multiparas: mean duration 20 min
Third stage	From delivery of infant to delivery of placenta	10 min; intervention not needed until >30 min

FETAL DISTRESS

Fetal distress may occur during active labor. Thus, evaluate for signs of fetal status frequently. Indicators of fetal distress include fetal bradycardia or tachycardia, or late decelerations in fetal heart rate, which are defined as persistent drops in fetal heart rate both during and more than 30 seconds after a contraction. A physician or nurse trained in fetal monitoring can identify fetal distress (**Figure 101-2**). Doppler measurement of fetal heart tones is not reliable to detect decelerations. If decelerations are suspected, obtain emergency obstetrics consultation, and try to increase maternal blood flow by positioning the patient in the left lateral position, provide IV hydration, and administer oxygen. Further information is provided in the Advanced Life Support Course for Obstetrics (see later section "Useful Web Resources").

CLINICAL EVALUATION

When a patient >20 weeks' gestation presents to the ED with signs of labor, immediately obtain both maternal vital signs (blood pressure, heart rate, respiratory rate, oxygen saturation, temperature) and the fetal heart rate. Doppler US can be used to measure fetal heart rate; a **normal fetal heart rate is generally 120 to 160 beats/min, bradycardia is defined as less than 110 beats/min, and tachycardia is greater than 160 beats/min**.[10] A persistently slow fetal heart rate indicates fetal distress and requires emergency obstetric consultation. As part of the initial evaluation, obtain IV access, procure baseline laboratory studies including blood type, and send a urinalysis.

HISTORY

Ask about the onset and frequency of uterine contractions, fetal membrane status, presence or absence of vaginal bleeding, and presence or absence of fetal movement. The obstetric history should include parity, history of complications with prior deliveries, history of precipitous deliveries, prenatal care during this pregnancy, and estimated date of delivery. Obtain a medical and surgical history, a list of current medications, and allergies, and ask the patient about substance abuse. Inquire about symptoms of infection, such as fevers, chills, or foul-smelling vaginal discharge.

Gestational Age If the patient knows the first day of her last menstrual period, the estimated date of delivery can be calculated by adding 9 months and 7 days to that date (**Nägele's rule**). Fundal height also provides a rapid estimate of gestational age and is measured in centimeters (cm) from the pubic symphysis to the top of the fundus (cm = weeks of gestation ± 2 weeks). Fundal height may be falsely overestimated in the obese patient. Bedside US also provides a useful assessment of gestational age in the third trimester, but estimated age can vary by ± 3 weeks.

PHYSICAL EXAMINATION

Monitor vital signs for evidence of maternal fever, tachycardia, or elevated blood pressure. Assess fetal heart tones for bradycardia or tachycardia. Do not keep the pregnant woman flat on her back for a prolonged time period; compression of venous return by the gravid uterus can lead to hypotension in the mother, which in turn results in decreased blood supply to the fetus. So, place the **patient in the left lateral position following the physical examination**. On abdominal examination, determine fundal height, abdominal or uterine tenderness to palpation, and presence of uterine contractions. Examine the perineum for perineal lesions, such as those caused by herpes simplex virus, which might be a contraindication for a vaginal delivery.

PELVIC EXAMINATION

Patients with vaginal bleeding should be evaluated with bedside US prior to speculum or bimanual examination, in order to rule out

placenta previa. Patients without vaginal bleeding should be evaluated first with a sterile speculum examination to determine if membranes have been ruptured, to note cervical dilatation and effacement, and to determine fetal station and presentation.

If rupture of membranes is suspected, perform a sterile speculum examination (do not use lubricant because lubricant may produce a false-positive nitrazine test), but do not perform a digital examination because even one digital examination increases the risk of infection.[11] **Also avoid digital examinations in the preterm patient in whom the prolongation of gestation is desired.**

Using sterile vaginal examination, examine the cervix for dilatation, effacement, and station.

Bedside US is the simplest method to verify presentation. Vertex presentation and lie can also be confirmed through palpation of the cranial sutures on digital examination. Palpation of small parts, such as feet or hands, often indicates malpresentation. If meconium is present on the examining finger, be prepared for neonatal resuscitation (see chapter 108).

EMERGENCY DELIVERY

The first steps in the management of a woman in active labor are to measure vital signs and initiate supportive therapy. Obtain venous access, provide IV hydration, and initiate maternal and fetal monitoring (if available). Delivery is imminent if the pelvic examination reveals complete cervical effacement and the fetus is at the introitus. Labor can progress very rapidly, particularly in multiparous patients. Both the stage of labor and the parity of the patient should be taken into account when considering whether to transport a laboring patient to the labor and delivery suite or to another facility. **If the cervix is fully effaced and dilated or the fetal head is visible during contractions, the obstetrician**

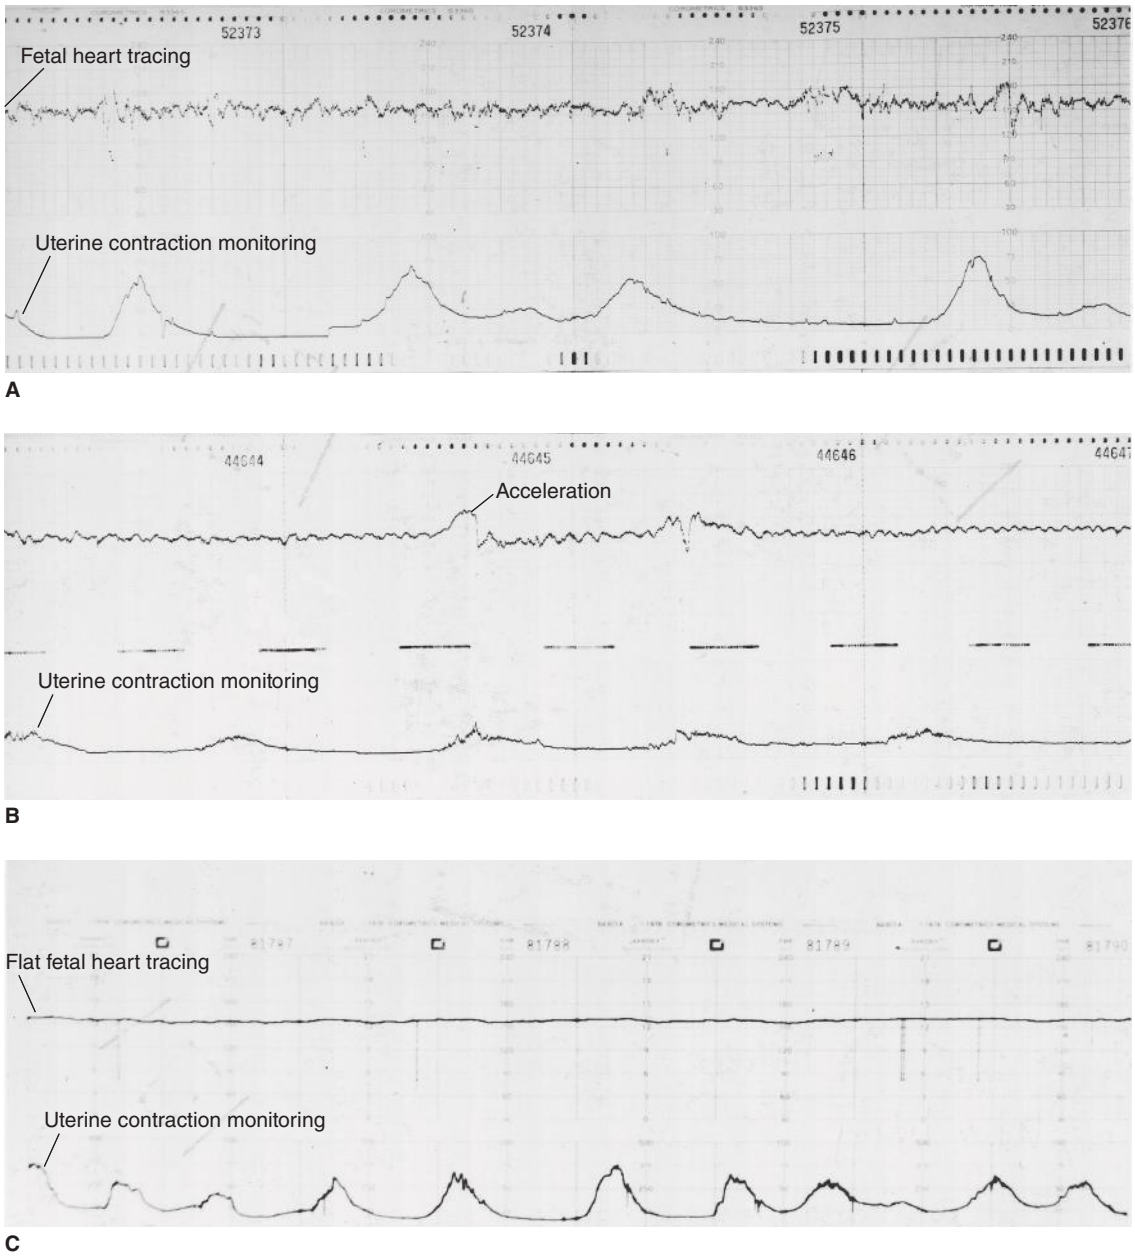

FIGURE 101-2. Fetal heart rate variability and uterine contraction patterns. **A.** Good variability. **B.** Good variability with brief accelerations. Fetal heart rises above baseline and quickly returns to normal. A reassuring pattern. **C.** Poor variability. May be due to fetal hypoxia. **D.** Variable decelerations. No relationship to uterine contractions. May represent cord compression. **E.** Late deceleration. Occurs at onset of contraction and slow return to baseline after contraction ends. Signifies uteroplacental insufficiency and fetal hypoxia. Figs. 10-9 and 10-10, pp. 131 and 132.]

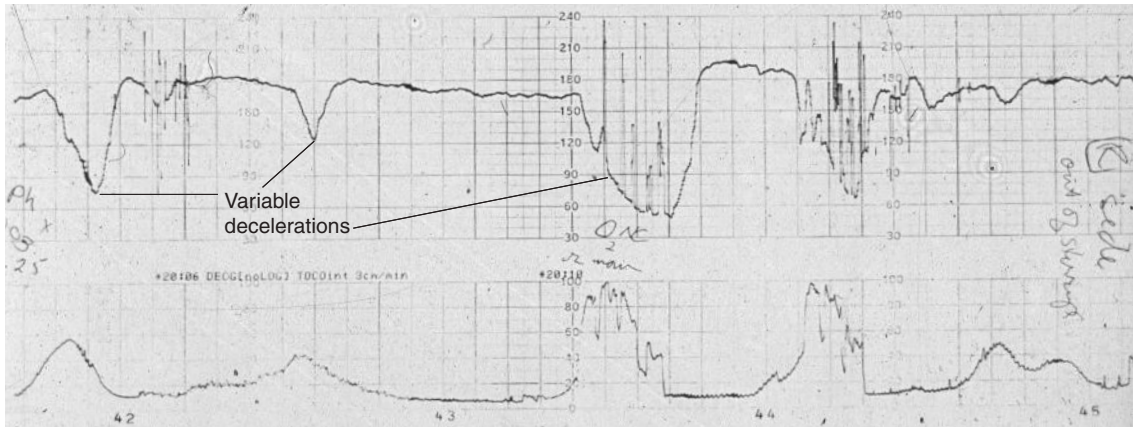
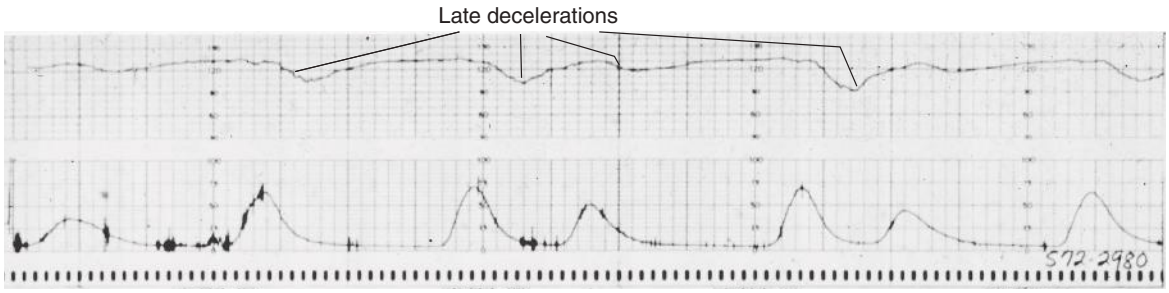


D



E

FIGURE 101-2. (*Continued*)

(if available) should come to the ED rather than risk a precipitous delivery during transport to the delivery suite.

As the cervix fully dilates, effacement becomes complete, the fetus descends into the pelvis, and the patient will experience the urge to push. The cervix should be fully dilated before the patient begins to push in order to avoid cervical lacerations. Determine fetal presentation by palpating skull sutures and fontanelle or the buttock or extremity. Bedside US can confirm presentation.

If time allows, prepare the perineum by washing it with mild soap and water and swabbing with povidone-iodine. Place drapes over the patient. Medical personnel attending to the patient should don gowns, masks, and gloves. Call for obstetric support.

Six cardinal movements describe the process of fetal descent during labor and delivery: (1) engagement, (2) flexion, (3) descent, (4) internal rotation, (5) extension, and (6) external rotation (**Figure 101-3**). *The following discussion describes delivery in the cephalic, occiput anterior position.* As the fetus descends through the birth canal and reaches the introitus, the perineum bulges in order to accommodate the fetal head. Gentle digital stretching of the inferior portion of the perineum can aid delivery. The perineum undergoes gradual thinning and stretching to enable passage of the newborn.

EPISIOTOMY

Routine **episiotomy** for a normal spontaneous vaginal delivery varies with practitioner, institution, and country. Episiotomy may be necessary to expedite a delivery in cases of fetal distress or shoulder dystocia or if forceps or vacuum devices are used (**Figure 101-4**).[12] The episiotomy can be performed in the midline or mediolaterally (45 degrees from the midline). Median episiotomy is easy to perform, but mediolateral episiotomy has a lower risk of extension to the anal sphincter (third-degree extension) or to the rectum (fourth-degree extension) than median episiotomy. If an episiotomy is clinically necessary, first inject 5 to 10 mL of 1% lidocaine solution with a small-gauge needle into the posterior fourchette and perineum. While protecting the infant's head, make a 2- to 3-cm incision with scissors in order to extend the vaginal opening, either at the midline or 45 degrees from the midline. A median incision must be supported with manual pressure from below. Take care to prevent extension of the incision into the rectum.

COMPLETION OF DELIVERY

Do not drop the baby. The combination of amniotic fluid, blood, and vernix generates a very slippery infant. Before delivering the rest of the body, place your posterior hand underneath the axilla of the infant. Use the anterior hand to grasp the ankles of the infant with a firm grip. Following delivery, keep the infant warm and provide gentle stimulation. Do not routinely aspirate the nose and mouth. Gently bulb aspirate only if there are obvious obstructions from secretions. If delivery is uncomplicated, and the infant has responded well to initial stimulation with a clear airway and good respiratory effort, the mother may hold the child immediately while the cord is cut.

Apgar scores are calculated at 1 and 5 minutes after delivery. Scoring parameters include general color, tone, heart rate, respiratory effort, and reflexes (**Table 101-5**).

For an APGAR score of <7 refer to the chapter 108. Provide positive-pressure ventilation for all newborns with a heart rate <100 beats/min or who are gasping or apneic after 30 seconds.

CLAMPING THE UMBILICAL CORD

Do not clamp the umbilical cord of term or preterm infants for at least 1 to 3 minutes after birth. Delayed cord clamping increases neonatal iron stores. **Double-clamp the umbilical cord 3 cm distal to its insertion at the umbilicus and transect with sterile scissors.** In delivery settings where aseptic care is routine, there is no clear benefit to any additional topical care of the umbilicus. When aseptic care is *not* available, however, antiseptic topical care of the umbilicus with chlorhexidine reduces the risk of omphalitis and neonatal mortality.[16] Once the umbilical cord is cut, dry the infant and either give the infant to the mother or place it in a warming unit.

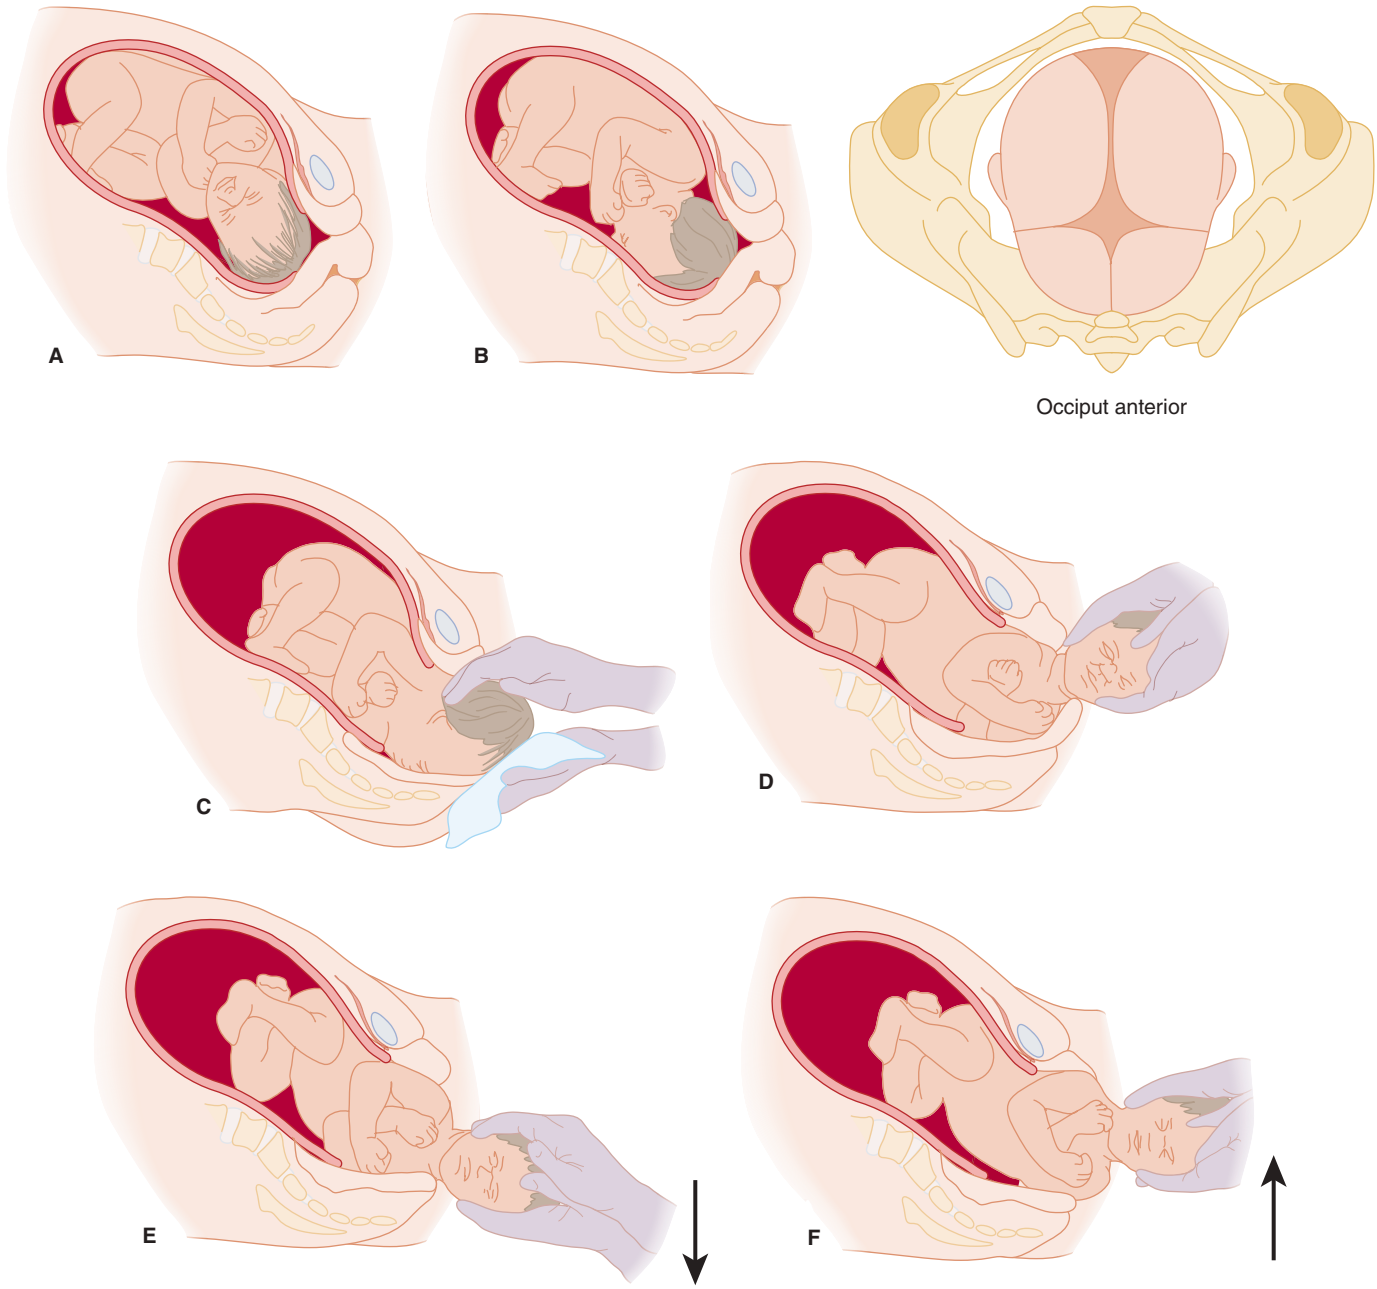


FIGURE 101-3. The movements of normal delivery for a vertex presentation. **A.** Engagement, flexion, and descent with vertex anterior. **B.** Internal rotation with occiput becoming anterior. **C.** Extension and delivery of the head. As the infant's head emerges from the introitus, support the perineum by placing a sterile towel along the inferior part of the perineum with one hand, and support the fetal head with the other hand. Ask the mother to breathe through contractions (rather than bear down) in order to deter rapid expulsion of the baby. Provide mild counterpressure for controlled extension of the fetal head. As the infant's head presents, use the inferior hand to control the fetal chin and keep the superior hand on the crown of the head, supporting the delivery. **D.** External rotation, bringing the thorax into the anteroposterior diameter of the pelvis. As the head delivers, palpate the infant's neck to assess for the presence of a nuchal cord. Nuchal cord is noted in approximately 25% to 35% of all term deliveries.[13] If the cord is loose, move it over the infant's head, and allow delivery to proceed as usual. If the cord is wound tightly around the neck, however, apply two close clamps in the most accessible area, and then cut the cord. **E.** Delivery of the anterior shoulder. Once the head is delivered, it will turn to one side or the other. Grasp the sides of the head with both hands, and apply **gentle** downward traction (go with gravity) until the anterior shoulder is delivered. Jerky or aggressive traction may injure the brachial plexus. If you have not checked for a nuchal cord, do so now. As the head rotates, place the hands on either side of the head, providing gentle downward traction. This maneuver allows for the delivery of the anterior shoulder. **F.** Delivery of the posterior shoulder. Use an upward movement to deliver the upward shoulder. Do not apply traction. If meconium is present or the newborn is limp or poorly responsive, stimulate the baby and be prepared to begin the steps of neonatal resuscitation with ventilation and oxygenation[14,15] (see chapter 108).

DELIVERY OF THE PLACENTA

The placenta usually delivers approximately 10 to 30 minutes after delivery of the infant. Allow the placenta to separate spontaneously and provide only *gentle* traction. Aggressive traction on the cord can lead to uterine inversion, tearing of the cord, or even disruption of the placenta, all of which can result in severe vaginal bleeding. After the placenta has been removed, gently massage the abdomen at the level of the fundus to promote contraction. Give oxytocin (10 to 40 units in 1 L normal saline at 250 mL/h or 10 units IM) to sustain uterine contraction.

The estimated blood loss during a vaginal delivery is usually less than 500 mL. Uterine atony, however, which occasionally follows a precipitous

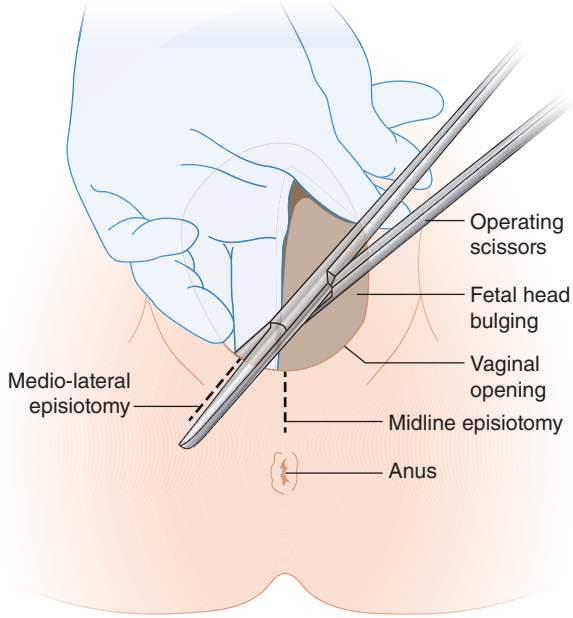

FIGURE 101-4. Methods for episiotomy.

FIGURE 101-5. Clinical appearance of shoulder dystocia. The infant's head is impacted against the perineum. [Reprinted with permission from Buckley RG, Knoop KJ: Gynecologic and obstetric conditions, in Knoop KJ, Stack LB, Storrow AB (eds): *Atlas of Emergency Medicine*, 2nd ed. New York, McGraw-Hill, 2002, Figure 10.46.]

delivery, can lead to excessive vaginal bleeding. In that case, give additional oxytocin or another uterotonic of choice (see Table 101-2). As contractile agents are administered, provide vigorous bimanual massage.[17] Delay episiotomy or laceration repair until an experienced obstetrician is available to close the laceration and inspect for fourth-degree perineal lacerations.

COMPLICATIONS OF LABOR AND DELIVERY

UMBILICAL CORD PROLAPSE

Umbilical cord compression is life threatening to the fetus. Obtain immediate obstetric assistance, as emergent cesarean delivery is indicated. **Should the bimanual examination reveal a palpable, pulsating umbilical cord, elevate the presenting fetal part to reduce compression on the cord. Keep your hand in the vagina while the patient is transported and prepared for surgery to prevent further compression of the cord by the fetal head. Place the mother in the Trendelenburg position. Do not try to reduce the prolapsed cord.**[18]

SHOULDER DYSTOCIA

Shoulder dystocia is the impaction of fetal shoulders at the pelvic outlet after delivery of the head. Typically, the anterior shoulder is trapped behind the pubic symphysis and prevents delivery of the rest of the infant.[19,20] Complications of shoulder dystocia include fetal brachial plexus injury (due to overaggressive traction), clavicle fracture, fetal hypoxia (due to impaired respirations and/or compression of the umbilical cord), postpartum hemorrhage, and fourth-degree perineal lacerations.

Prior to delivery of the head, the head may retract between contractions. Shoulder dystocia then becomes evident when routine downward traction fails to deliver the anterior shoulder once the head has been delivered. After the infant's head is delivered, the head retracts tightly against the perineum (turtle sign; **Figure 101-5**).[21] Several steps can be used to relieve shoulder dystocia (**Table 101-6**). Immediately place the mother in the extreme lithotomy position, with her legs sharply flexed up to the abdomen and the knees held as widely apart as possible (**McRoberts maneuver**; **Figure 101-6**). Either the mother or an assistant should keep the legs held widely apart. **Simultaneously apply suprapubic pressure. If a second assistant is available, he or she should place their hands in a CPR position, and apply downward pressure just above the pubic symphysis for 1 to 2 minutes to disimpact the anterior shoulder. Do not apply pressure to the uterine fundus, as this maneuver can further impact the shoulder.** Suprapubic pressure serves to rotate the shoulder under the pubic symphysis.[21] The combination of the McRoberts position and suprapubic pressure relieves about 50% of shoulder dystocias.

The **Gaskin maneuver** (**Figure 101-7**) can also be employed. It is a simple maneuver, but with IVs and monitors in place or with an exhausted mother, it can be difficult to achieve. Place the patient on all fours. Exert gentle downward traction on the infant's head. In order to remember the direction of traction, remember to "go with gravity."

TABLE 101-5 Apgar Scoring for Newborns

	Sign	0 Points	1 Point	2 Points
A	Activity (muscle tone)	Absent	Arms and legs flexed	Active movement
P	Pulse	Absent	Below 100 beats/min	Above 100 beats/min
G	Grimace (reflex irritability)	No response	Grimace	Sneezing, coughing, pulling away
A	Appearance (skin color)	Blue-gray, pale	Normal, except extremities	Normal over entire body
R	Respiration	Absent	Slow, irregular	Good, crying

TABLE 101-6 Steps to Relieve Shoulder Dystocia

Steps	Comments
Flex thighs and keep knees apart as much as possible	McRoberts maneuver
Apply suprapubic pressure	Keep patient in McRoberts position. Place one hand with wrist clenched, immediately above the pubic symphysis; if an assistant is available, place two clenched wrists in CPR position just above pubic symphysis. Compress for 1 min. Do not compress uterine fundus. This worsens impaction.
Move patient to all- fours position	Gaskin maneuver. Deliver with gentle downward traction on the infant's head.
Corkscrew maneuvers	Typically require episiotomy. See text.

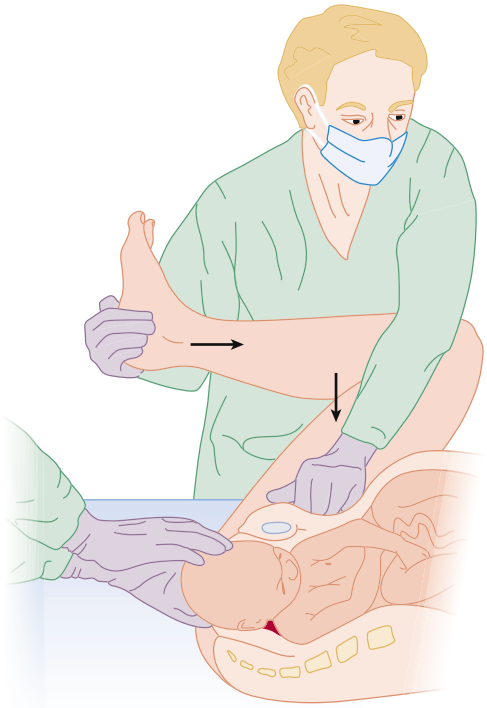

FIGURE 101-6. McRoberts maneuver. Sharply flex the thighs up onto the abdomen, as shown by the *horizontal arrow*, and keep the knees spread widely. Simultaneously provide suprapubic pressure (*vertical arrow*). [Adapted with permission from Cunningham FG, Leveno KL, Bloom SL, et al: *Williams Obstetrics*, 22nd ed. New York, McGraw-Hill, 2005, Figure 20-14.]

In 80% of cases, this maneuver allows the posterior shoulder to successfully deliver.[22]

Should the previous maneuvers fail, rotational maneuvers, which move the shoulders into an oblique position, can be performed. Allow 2 minutes for these maneuvers. The maneuvers typically require an episiotomy. For the Rubin maneuver, place fingers behind the anterior fetal shoulder, and push the shoulder with your fingertips toward the baby's chest. This may reduce the dimension of the shoulder girdle and allow for delivery. For the **Woods corkscrew maneuver** (**Figure 101-8**), keep fingertips behind the anterior shoulder, and with the opposite hand, apply pressure to the back of the posterior shoulder, and rotate the shoulder girdle clockwise into an oblique position, allowing delivery. The **reverse corkscrew maneuver** is in the opposite direction. Place your fingers in front of the posterior shoulder and behind the anterior shoulder, and apply pressure counterclockwise.[23]

FIGURE 101-7. Gaskin maneuver for shoulder dystocia.

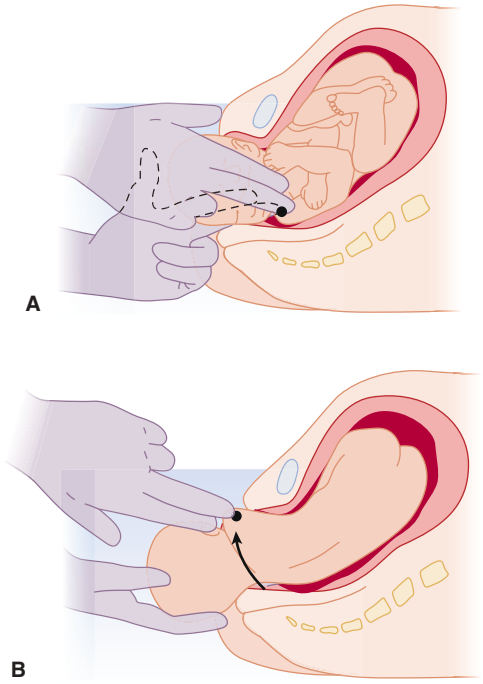

FIGURE 101-8. Corkscrew maneuver. **A.** Place fingertips behind anterior shoulder and in back of posterior shoulder. **B.** Then gently rotate clockwise until shoulder delivers.

BREECH PRESENTATION

Breech presentations occur in 3% to 4% of term pregnancies. Risks of breech presentations include umbilical cord prolapse, trauma, hypoxia, and fetal distress. Breech presentations occur most frequently in the delivery of *premature* infants; approximately 25% to 30% of all preterm infants (<28 weeks' gestation) present in breech position.[24] Given the increased perinatal/neonatal morbidity and mortality associated with vaginal breech deliveries, cesarean section is recommended in breech presentations.[24]

Head entrapment is a major concern in a breech delivery. In a normal cephalic delivery, the larger head dilates the cervical canal, which ensures that the rest of the infant's body can follow. In a breech delivery, however, the head emerges last and may become stuck in an incompletely dilated cervix.

In frank and complete breech deliveries, the buttocks dilate the cervix almost as effectively as the fetal head; therefore, delivery may proceed in an uncomplicated fashion. **In these cases, allow the delivery to proceed spontaneously** (**Figure 101-9**). The emergency physician subsequently places the index and middle fingers over the infant's maxillary bones (not in the infant's mouth) to help keep the head flexed, allowing the mother to expel the infant. It is important to refrain from pulling on the fetus, because this may impact the head in the pelvis or even entrap the extended fetal arm. **Footling and incomplete breech positions are not safe for vaginal delivery due to the risk of cord prolapse or incomplete dilatation of the cervix.** In any breech delivery, obstetric consultation should be obtained immediately.

PRETERM DELIVERY

The incidence of preterm delivery is approximately 12% and contributes substantially to perinatal morbidity and mortality.[25] Preterm labor is also

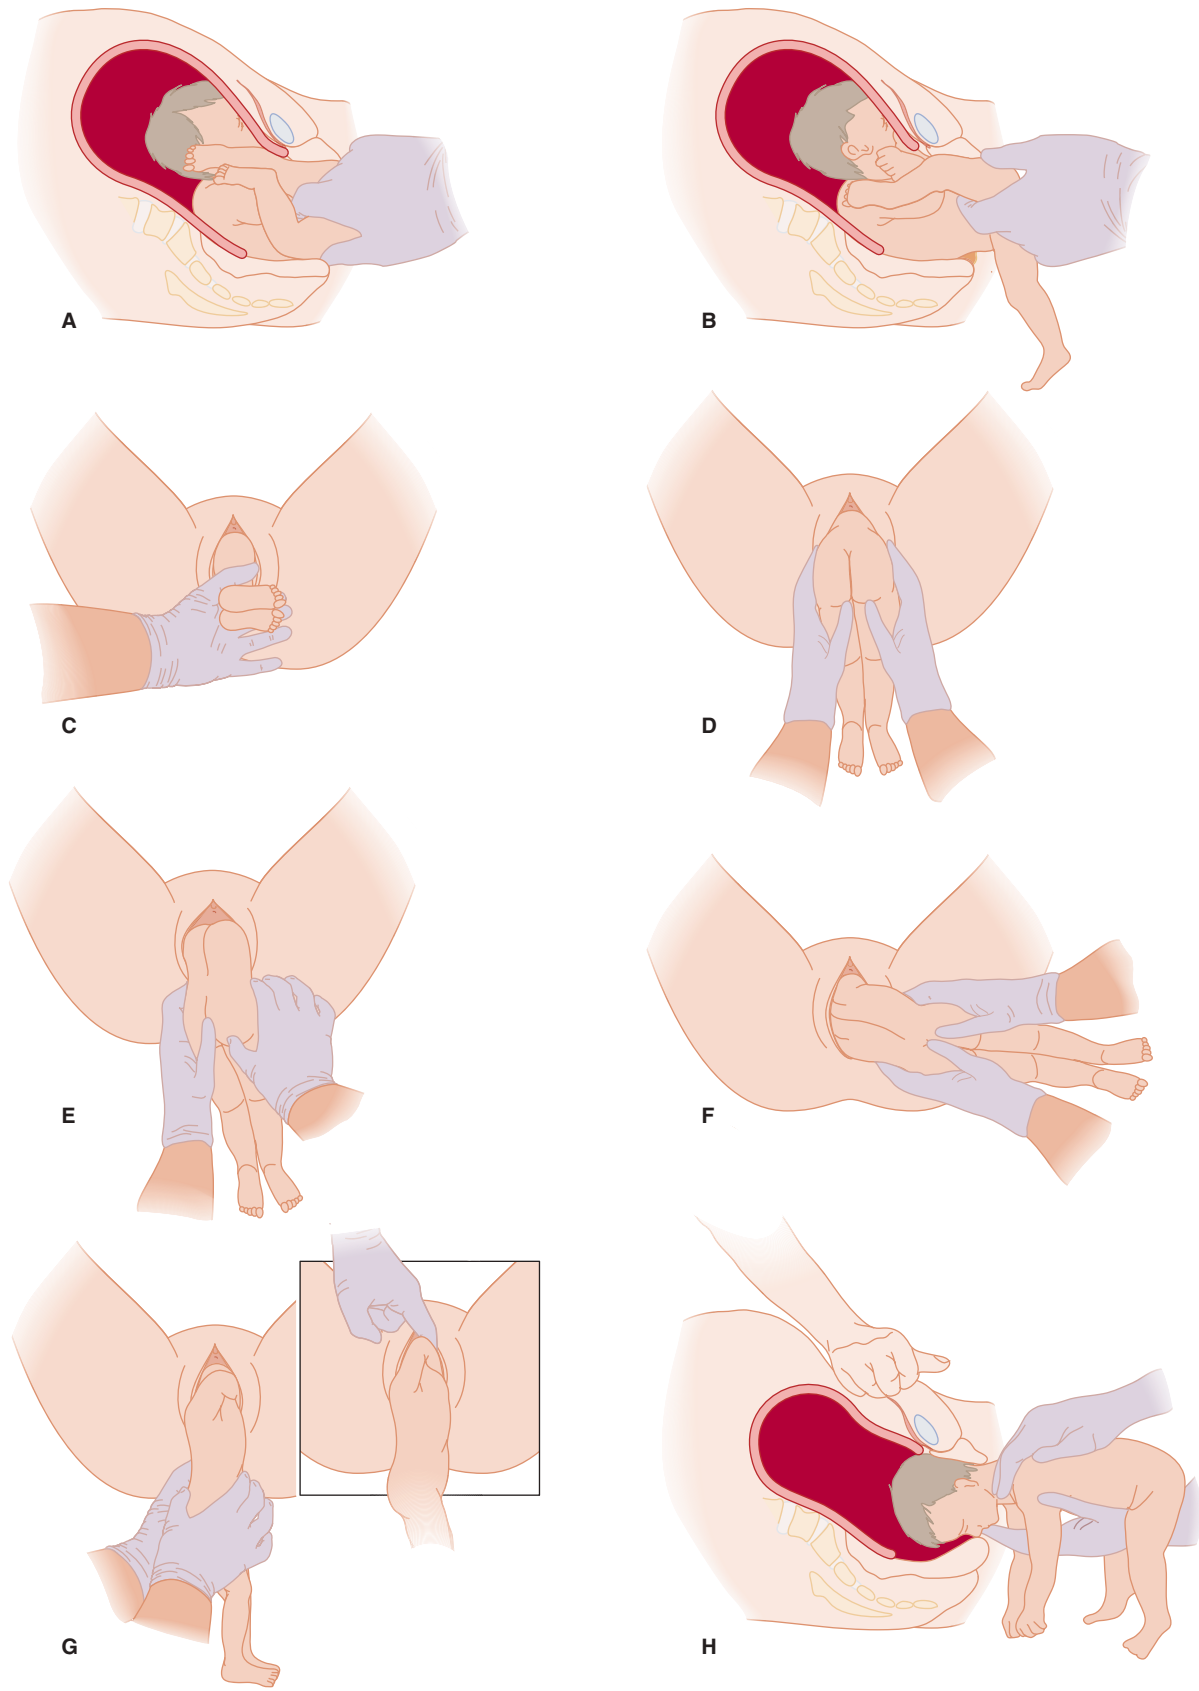

FIGURE 101-9. Breech delivery. **A.** Grasp the thigh to allow delivery of the leg. **B.** Grasp the other leg to allow its delivery. **C.** Grasp the feet at the ankles and rotate the sacrum anteriorly. **D.** The sacrum is rotated anteriorly. Maternal efforts deliver the baby to the level of the umbilicus. Wrap the trunk and legs in a towel. **E.** Maternal efforts further deliver to the level of the scapulae. Apply steady, gentle traction until scapulae come into view. **F.** Once the axilla is visible, the shoulder can be delivered. Rotate counterclockwise to deliver the anterior shoulder. (It does not matter which shoulder is delivered first.) **G.** Delivery of the anterior arm. When the scapulae appear, gently rotate the baby until one humerus can be followed down, rotated across the chest, and swept out. Then turn the baby clockwise to allow delivery of the other arm. **H.** Deliver the vertex of the skull by placing fingers at the maxillary process, and keep body parallel to the horizontal. Do not pull. Do not lift above the parallel to avoid neck hyperextension. Apply suprapubic pressure to aid delivery of the head.

a major cause of precipitous delivery in EDs. Preterm infants present more frequently in the breech position. The delivery maneuvers are similar to those described above. Be prepared to initiate neonatal resuscitation. The decision as to whether to initiate resuscitative efforts in the ED is often difficult because patients may deliver an extremely premature fetus of unknown gestational age. **Survival of the newborn increases significantly for each completed week from 21 weeks of gestation (0% survival) to 25 weeks of gestation (75% survival).**[26] When gestational age is known, initiate resuscitation of newborns 22 weeks of gestation or older. It is justified to cease resuscitative efforts after 10 minutes, and certainly, after 15 minutes of asystole.

CHAPTER 102

Vulvovaginitis

Ciara J. Barclay-Buchanan
Melissa A. Barton

INTRODUCTION

Vaginal discharge is caused by a wide variety of disorders, including vaginitis, cervicitis, and pelvic inflammatory disease.[1] Vaginitis is a spectrum of diseases that cause vulvovaginal symptoms including burning, irritation, itching, odor, and abnormal discharge. The factors associated with acute vaginitis are listed in **Table 102-1**. **The most common infectious causes of vaginitis in symptomatic premenopausal women are bacterial vaginosis (40% to 45%), vulvovaginal candidiasis (20% to 25%), and trichomoniasis (15% to 20%).** Vulvovaginal candidiasis, contact vaginitis, and atrophic vaginitis may occur in virgins and postmenopausal women; however, the other forms of infectious vulvovaginitis are generally found in sexually active women. In approximately 30% of women with vaginal complaints, the disorder remains undiagnosed even after comprehensive testing.[2-4]

The clinical diagnosis may be challenging, because women may have more than one disease, and signs and symptoms are frequently not specific to a particular cause. Polymicrobial infection is not uncommon.

Although infectious vaginitis rarely requires hospitalization, it may have serious sequelae. Both bacterial vaginosis and trichomoniasis have been shown to be associated with premature rupture of membranes, preterm labor, and low infant birth weight.[5,6] Trichomoniasis is associated with pelvic inflammatory disease in patients infected with human immunodeficiency virus and increases risk of human immunodeficiency virus acquisition and transmission.[7,8] When overgrowth of certain bacteria occurs, the protective effect of vaginal lactobacilli strains, which inhibit the growth of bacteria and destroy human immunodeficiency virus in vitro, is lost.[1]

TABLE 102-1 Factors Associated with Acute Vulvovaginitis

Infections
Irritant or allergic contact
Local response to a vaginal foreign body
Lack of estrogen in perimenopausal and postmenopausal women (atrophic vaginitis)
Postirradiation changes

PHYSIOLOGY

In females of childbearing age, estrogen causes the development of a thick vaginal epithelium with a large number of superficial glycogen-containing cells and serves a protective function. Glycogen is used by the normal flora, such as lactobacilli and acidogenic corynebacteria, to form lactic and acetic acids. The resulting acidic environment favors the normal flora and discourages the growth of pathogenic bacteria. Lack of estrogen or a dominance of progesterone results in an atrophic condition, with loss of the protective superficial cells and their contained glycogen, and subsequent loss of the acidic environment.

Normal vaginal secretions vary in consistency from thin and watery to thick, white, and opaque. The quantity may also vary from a scant to a rather copious amount. Secretions are odorless and produce no symptoms. The normal vaginal pH varies between 3.8 and 4.5. Alkaline secretions from the cervix before and during menstruation, as well as alkaline semen, reduce acidity and predispose to infection. Before menarche and after menopause, the vaginal pH varies between 6 and 7. Because of scant nerve endings in the vagina, the patient usually does not have symptoms until both the vagina and vulva are involved in an inflammatory or irritant process.

Vulvovaginal inflammation is the most common gynecologic disorder in prepubertal girls and includes both infectious causes (e.g., bacterial, fungal, pinworm) and noninfectious causes (e.g., contact/irritant, lichen sclerosis, foreign body). Factors thought to contribute to vaginitis in prepubertal females include less protective covering of the vestibule by the labia minora, low estrogen concentration resulting in a thinner epithelium, exposure to chemical irritants such as bubble bath, poor hygiene, front-to-back wiping and the short distance between the vagina and anus, foreign bodies, chronic medical conditions (eczema, seborrhea, and other chronic diseases), and sexual abuse. Infectious causes include respiratory and enteric bacterial organisms such as *Haemophilus influenzae*, *Staphylococcus aureus*, group A streptococci and *Streptococcus pneumoniae*, *Escherichia coli, Shigella flexneri*, *Neisseria gonorrhoeae*, and *Chlamydia*, as well as *Candida* and pinworms. Infectious causes may be more common in adolescents, especially those who are sexually active.[4]

GENERAL APPROACH

Obtain a detailed gynecologic history and perform a pelvic examination. History should include details of vaginal discharge, odor, irritation, itching, burning, bleeding, dysuria, and dyspareunia. Inquire about associated abdominal pain, new sexual partners, use of barrier protection during intercourse, relationship of symptoms to menses, use of antibiotics and contraceptives, and hygiene practices. Note the presence of vulvar edema or erythema, vaginal discharge, cervical inflammation, and abdominal and cervical motion tenderness.

During speculum examination, obtain a swab of the discharge and test for gonorrhea and chlamydial infection. If a patient refuses pelvic examination or it is not feasible, the patient may submit a self-swab of vaginal secretions or a urine sample.[9]

Microscopic examination of secretions and evaluation of pH are useful diagnostic tools. However, microscopes and reagents are not available in all EDs, microscopic examination is time consuming and tedious, and results depend on operator skill. To test pH, obtain a sample from the mid portion of the vaginal sidewall to avoid false elevations in pH caused by mucus. **Sampling from the posterior fornix may yield inaccurate results because cervical mucus, blood, semen, douches, and vaginal medications can elevate the pH.** Microscopic evaluation of fresh vaginal secretions using both normal saline solution and 10% potassium hydroxide slide preparation and fishy odor on whiff test help provide evidence for a diagnosis[10] (**Tables 102-2 and 102-3**). Signs of vulvar inflammation and minimal discharge suggest the possibility of mechanical, chemical, allergic, or other noninfectious causes of vulvovaginitis.

BACTERIAL VAGINOSIS

Bacterial vaginosis is the most common cause of vaginitis and accounts for up to 50% of cases in acutely symptomatic women.

TABLE 102-2 Diagnosis of Vaginitis Based on Vaginal Secretions

Test	Finding	Diagnosis	Comments[13]
pH	4.0–4.5	Normal	—
	4.0–4.5	Candidiasis	If undiagnosed after pelvic examination and evaluation of wet mount, treatment with a single dose of fluconazole is cost effective, but also test for *Neisseria* and *Chlamydia*.
	>4.5	Bacterial vaginosis	If undiagnosed after pelvic examination and evaluation of wet mount, treatment with 2 grams of metronidazole ± a single dose of fluconazole is cost effective, but also test for *Neisseria* and *Chlamydia*.
	>4.5	Trichomoniasis	If undiagnosed after pelvic examination and evaluation of wet mount, treatment with 2 grams of metronidazole ± a single dose of fluconazole is cost effective, but also test for *Neisseria* and *Chlamydia*.
Microscopy of specimen prepared with normal saline solution	Clue cells	Bacterial vaginosis	—
	Motile trichomonads	Trichomoniasis	—
	Pseudohyphae and/or buds	Candidiasis	—
Whiff test of swab specimen prepared with potassium hydroxide	Fishy odor	Bacterial vaginosis	—
Microscopy of specimen prepared with potassium hydroxide	Pseudohyphae and/or buds	Candidiasis	—

However, up to 50% of women who meet clinical criteria for this diagnosis are asymptomatic.

Bacterial vaginosis is a polymicrobial infection that occurs when the normal hydrogen peroxide–producing lactobacilli are replaced by other species including *Gardnerella vaginalis, Ureaplasma, Mycoplasma*, and various anaerobes. Risk factors include multiple sexual partners, intercourse with an uncircumcised male partner, vaginal intercourse immediately after receptive anal intercourse, lack of condom use, douching, and absence of peroxide-producing lactobacilli in the vaginal flora.[1,11] Women who have never been sexually active are less commonly affected. Bacterial vaginosis is not classified as a sexually transmitted infection, but it is generally agreed upon that sexual activity plays a role in transmission and may promote infection.[12]

DIAGNOSIS

The most common clinical presentation of women with bacterial vaginosis is vaginal discharge and odor. Classically, a thin, whitish-gray discharge is present, generally with an increase in discharge volume. The absence of discharge or the presence of only a mild discharge makes the diagnosis less likely. When an odor is present, it may be described as a fishy smell. Introital or vaginal irritation, such as redness, tissue fissures, excoriations, or edema, is not common with bacterial vaginosis.

The diagnosis is based on history, speculum vaginal examination, microscopic evaluation of vaginal secretions, and point-of-care testing. Obtain secretions from the mid sidewall of the vagina, and mix with one to two drops of 0.9% normal saline. Cover with a coverslip for microscopic evaluation for clue cells; to check for fishy or amine odor, add one drop of 10% potassium hydroxide and assess vapors for fishy (amine) smell (see additional methods for amine testing below). To check pH, apply a small amount of secretions directly onto pH paper. The presence of three of the following four criteria makes the diagnosis:

1. A thin, homogeneous vaginal discharge
2. More than 20% clue cells on a wet mount (**Figure 102-1**)
3. Positive results on test for amine release, or whiff test
4. A vaginal pH level >4.5

The criterion with the highest sensitivity (89%) is vaginal pH, whereas that with the highest specificity (93%) is the amine odor, or positive result on whiff test. If vaginal pH is >4.5 and there is an amine odor, the diagnosis of bacterial vaginosis can be made with confidence.[14] A colorimetric card test for bacterial vaginosis detects a vaginal pH of ≥4.7 and volatile vaginal fluid amines. Commercially available tests that might be useful for the diagnosis of bacterial vaginosis include card tests for proline aminopeptidase (Pip Activity TestCard; Quidel, San Diego, CA), a

TABLE 102-3 Vaginitis Signs and Symptoms

Causative Organism	Sign or Symptom
Candida	Thick, curdy discharge Itching
Gardnerella or other bacteria	Fishy odor Whitish-gray, thin discharge
Trichomonas	Frothy odorous discharge Vaginal erythema or edema

FIGURE 102-1. Bacterial vaginosis. Saline wet mount with clue cells (*arrow*). [Reproduced with permission from DeCherney AH, Nathan L, Laufer N, Roman AS (eds): *Current Diagnosis & Treatment: Obstetrics & Gynecology,* 11th ed. McGraw-Hill, Inc., 2013. Fig. 39-9.]

DNA probe–based test for high concentrations of *G. vaginalis* (Affirm VP III; Becton Dickinson, Sparks, MD), and the OSOM BVBlue test (Sekisui Diagnostics, Lexington, MA), all of which have performance characteristics that are comparable to Gram stain. Cards are available for the detection of elevated pH and trimethylamine; however, they have a low sensitivity and specificity and thus are no longer recommended. Cultures of vaginal discharge are not beneficial, because *Gardnerella* organisms are part of the normal vaginal flora. Polymerase chain reaction for various organisms is being used in research but is not clinically relevant at this time.[1]

The combination of bacterial vaginosis and leukorrhea (more WBCs than epithelial cells seen on a wet mount) is associated with a positive test result for *Chlamydia* (odds ratio = 3.8).[15] For this reason, women who complain of vaginal discharge should be screened for and, depending on clinical suspicion, treated presumptively for *N. gonorrhoeae* and *Chlamydia* infection at the initial visit (Table 102-2). The Centers for Disease Control and Prevention also recommends syphilis testing for women engaged in high-risk sexual behavior, such as those having multiple sexual partners or a new sexual partner or engaging in unprotected intercourse. Finally, women of childbearing age should be screened for pregnancy, because this may impact medical treatment.

TREATMENT

Recommended treatment regimens are listed in **Table 102-4**. The use of *Lactobacillus* intravaginal suppositories and probiotics to restore the normal vaginal flora is an ongoing area of research. Treating male sexual partners is not beneficial for preventing recurrence, but consider treating female partners, particularly with frequent recurrences, because bacterial vaginosis can spread between female partners.[2] Counsel patients receiving metronidazole against consuming alcoholic beverages during the treatment period and for the following 24 hours to avoid a disulfiram-like reaction. Advise patients to refrain from intercourse or to use condoms during treatment.[1]

Overall cure rates 4 weeks after treatment do not differ significantly for a 7-day regimen of oral metronidazole, metronidazole vaginal gel, and clindamycin vaginal cream. Metronidazole vaginal gel has fewer side effects (i.e., GI disturbance and unpleasant taste) but should not be used in women who are allergic to the oral preparation.

Recurrence of symptoms is seen within 3 months in 30% of treated patients who initially show a response. The reasons for this are unclear but could be from sexual transmission.[15] Metronidazole gel 0.75% twice weekly for 4 to 6 months prevents recurrence.[1]

TABLE 102-4 Treatment Regimens for Bacterial Vaginosis

Agent	Dosage
Recommended Regimens	
Metronidazole*	500 milligrams PO twice a day for 7 d
Clindamycin cream 2%	One full applicator intravaginally every night for 7 d
Metronidazole gel 0.75%	One full applicator intravaginally once a day for 5 d
Alternative Regimens	
Clindamycin	300 milligrams PO twice a day for 7 d
Clindamycin ovules	100 milligrams intravaginally every night for 3 d
Tinidazole	2 grams PO daily for 2 d
Tinidazole	1 gram PO daily for 5 d
Regimens for Pregnant Women	
Metronidazole*	250 milligrams PO three times a day for 7 d
Metronidazole*	500 milligrams PO twice a day for 7 d
Clindamycin	300 milligrams PO twice a day for 7 d

*Avoid alcohol during and 24 h after treatment. Metronidazole is a pregnancy category B drug.

BACTERIAL VAGINOSIS COMPLICATIONS

Bacterial vaginosis has been associated with several adverse health outcomes, including facilitation of co-infection with sexually transmitted infections such as human immunodeficiency virus, herpes simplex virus-2, *Chlamydia trachomatis*, and *N. gonorrhoeae* by decreasing local secretory leukocyte protease inhibitor levels.[1,12] Bacterial vaginosis is also linked to complications related to pregnancy and surgical procedures, such as spontaneous abortion, premature rupture of membranes, amniotic fluid infection, chorioamnionitis, preterm delivery, postpartum endometritis, pelvic inflammatory disease, postoperative wound infection, and infection after vaginal and abdominal hysterectomy.[16]

PREGNANT WOMEN

The Centers for Disease Control and Prevention recommends treating all symptomatic pregnant women. Recommended treatment regimens are listed in Table 102-4. The Centers for Disease Control and Prevention no longer recommends routine screening of asymptomatic pregnant women.[1] Pregnant women who are at high risk for preterm labor should be considered for treatment to avoid preterm labor and other adverse outcomes of pregnancy.[5] However, studies have not been able to demonstrate clear benefit in preventing adverse outcomes of pregnancy.[1,17-19] **Topical clindamycin preparations should not be used in the second half of pregnancy** because of an increased association of adverse events, including low infant birth weight and neonatal infections.

CANDIDA VAGINITIS

***Candida* species are the second most common cause of infectious vaginitis.**[20] Prevalence data for vulvovaginal candidiasis vary because the disease is not reportable, many women self-medicate with over-the-counter preparations, and as many as half the women in whom candidiasis is diagnosed also have other conditions.[20] The Centers for Disease Control and Prevention estimates that 75% of women will have at least one episode of vulvovaginal candidiasis in their lifetime.[1]

The organism is isolated in up to 20% of asymptomatic, healthy women of childbearing age, some of whom are celibate. Some women remain entirely asymptomatic despite being heavily colonized with *Candida* species.

Vulvovaginal candidiasis is rare in nonestrogenized premenarchal girls but does occur and is common under 2 years of age. Consider undiagnosed juvenile diabetes or other forms of immunosuppression if *Candida* is diagnosed in a toilet-trained child.[4] Incidence decreases after menopause unless replacement estrogen is being used, which further emphasizes the hormonal dependence of the infection.

Candidiasis can be classified as either an uncomplicated or complicated infection. Uncomplicated infections are sporadic, produce mild to moderate symptoms, are the result of *Candida albicans*, and occur in the nonpregnant, immunocompetent host. Complicated infections are recurrent (four or more infections per year), produce severe symptoms or findings, are the result of suspected or proven non-*albicans* candidiasis, and occur in an abnormal host (women who have uncontrolled diabetes, debilitation, or immunosuppression, or are pregnant). Approximately 10% to 20% of women have complicated disease. Recurrent vulvovaginal candidiasis occurs in <5% of women.[1,21]

C. albicans strains account for 85% to 92% of *Candida* organisms isolated from the vagina. *Candida glabrata* and *Candida tropicalis* are the most common non-*albicans* strains and are often more resistant to conventional therapy.

Candidal organisms gain access to the vaginal lumen and secretions predominantly from the adjacent perianal area. Candidal organisms must first adhere to the vaginal epithelial cells for colonization to take place, and *C. albicans* adheres in greater numbers than other species.

The growth of *Candida* is held in check by the normal vaginal flora, and symptoms of vaginitis usually occur only when the normal balance is upset. Increased colonization by *Candida* resulting in subsequent symptomatic infection may be caused by conditions that (1) inhibit the growth of normal vaginal flora, particularly *Lactobacillus* species (e.g., systemic antibiotics); (2) diminish the glycogen stores in

vaginal epithelial cells (e.g., diabetes mellitus, pregnancy, oral contraceptive use, and hormonal replacement therapy); or (3) increase the pH of vaginal secretions (e.g., menstrual blood or semen). Factors that favor increased rates of vaginal colonization include pregnancy, oral contraceptive use, uncontrolled diabetes mellitus, and frequent visits to sexually transmitted infection clinics (perhaps as a result of antimicrobial therapy). This infection is not considered a sexually transmitted infection, although it can be transmitted by sexual intercourse. The wearing of tight-fitting, particularly synthetic, undergarments may also contribute to the problem because of increased temperature. Although all of these factors are thought to be associated with symptomatic disease, there is poor evidence to prove that any of them is causative.[20] Evidence supporting an association between antibiotic use and vulvovaginal candidiasis is limited. However, antibiotics are thought to increase the risk of vulvovaginal candidiasis by killing endogenous normal flora.

DIAGNOSIS

Clinical symptoms include leukorrhea, severe vaginal pruritus, external dysuria, and dyspareunia. **Vaginal pruritus is the most common and specific symptom.** Complaints of discharge vary from little to copious white vaginal discharge. Symptoms vary in severity, but exacerbation is frequently seen in the week prior to menses or with coitus, perhaps because these factors cause the pH to become more alkaline. Odor is unusual and, if present, favors a diagnosis of bacterial vaginosis rather than candidiasis.

Gynecologic examination may reveal vulvar erythema and edema, vaginal erythema, and discharge. Discharge varies from none to watery to homogeneously thick and "cottage cheese–like." Discharge often adheres to the vaginal walls.

The diagnosis is confirmed with a normal vaginal pH (4.0 to 4.5) and visualization of budding yeast and pseudohyphae on slide preparation of vaginal secretions (**Figure 102-2**). The sensitivity of microscopic examination using a sample prepared with normal saline is only 40% to 60%. Adding two drops of 10% potassium hydroxide to the vaginal secretions dissolves the vaginal epithelial cells while leaving yeast buds and pseudohyphae intact. This increases the sensitivity of microscopic examination to 80% and yields almost 100% specificity. Empiric treatment is suggested for symptomatic patients with negative findings on microscopic examination if *Candida* cultures cannot be obtained.[1]

TREATMENT

Recommended treatment regimens are listed in **Table 102-5**. Therapy regimens are effective in treating over 80% of cases of uncomplicated vaginal candidiasis. Topically applied azole drugs are more effective than nystatin, with relief of symptoms in 80% to 90% of patients who complete treatment. Consider patient preference because creams, lotions, sprays, vaginal tablets, suppositories, and coated tampons are all equally efficacious.[22]

The azole drugs are all available over the counter in treatment regimens of 1, 3, or 7 days. Uncomplicated vulvovaginal candidiasis responds to all azoles, including single-dose therapy.[23] Other than initial burning and irritation, side effects of topical agents are unusual.

Single-dose treatment with oral fluconazole is as effective as topical therapy in the treatment of uncomplicated vulvovaginal candidiasis. Patient preference should be considered, because oral therapy is often more convenient, although insurance and cultural variables can influence preference.[24] Oral treatment may occasionally cause GI symptoms, headache, and rash.[25] Ketoconazole can cause liver toxicity, and therefore, it as been removed from many formularies. The oral azoles can interact with a variety of other medications, including astemizole, calcium channel antagonists, cisapride, warfarin, cyclosporine A, oral hypoglycemic agents, phenytoin, protease inhibitors, tacrolimus, terfenadine, theophylline, trimetrexate, and rifampin.

Sexual partners should not be treated unless the woman has frequent recurrences.

Self-medication is sometimes advised in women with recurrence of previously diagnosed vulvovaginal candidiasis; however, studies demonstrate poor ability to accurately self-diagnose candidiasis even with a

TABLE 102-5 Treatment Regimens for Vulvovaginal Candidiasis*

Agent	Formulation	Dosage
Uncomplicated Vulvovaginal Candidiasis		
Butoconazole†	2% cream	1 applicator intravaginally QHS × 3 d
Clotrimazole	1% cream	1 applicator intravaginally QHS × 7 d
	2% cream	1 applicator intravaginally QHS × 3 d
	100-milligram suppository	1 suppository intravaginally QHS × 7 d
	200-milligram suppository	1 suppository intravaginally QHS × 3 d
	500-milligram suppository	1 suppository intravaginally QHS × 1 dose
Miconazole	2% cream	1 applicator intravaginally QHS × 7 d
	4% cream	1 applicator intravaginally QHS × 3 d
	100-milligram suppository	1 suppository intravaginally QHS × 7 d
	200-milligram suppository	1 suppository intravaginally QHS × 3 d
	1200-milligram suppository	1 suppository intravaginally QHS × 1 dose
Nystatin	100,000-unit vaginal tablet	1 tablet QHS × 14 d
Terconazole	0.4% cream	1 applicator intravaginally QHS × 7 d
	0.8% cream	1 applicator intravaginally QHS × 3 d
	80-milligram suppository	1 suppository intravaginally QHS × 3 d
Tioconazole	6.5% ointment	1 applicator intravaginally QHS × 1 dose
Fluconazole†	150 mg oral tablet	1 tablet PO × 1 dose

*Not all possible regimens listed.

†Not recommended in pregnancy. **Pregnant patient should be treated with topical azoles for 7 days. Oral fluconazole is a Category C medication and thus should be avoided in pregnancy.**

Abbreviation: QHS = every night at bedtime.

prior history of the disease.[5,26] Therefore women who fail to respond to over-the-counter therapy or have recurrence within 2 months should be evaluated by a physician.

The treatment of **complicated vulvovaginal candidiasis** (both severe and recurrent cases) requires longer duration of therapy with topical and oral azoles or alternative therapies. In severe cases, consider treating with a topical azole for 7 to 14 days or treatment with oral fluconazole, 150 milligrams on days 1 and 3 for a total of two doses. In cases of recurrence, consider treating with a topical azole for 7 to 14 days or fluconazole, 100, 150, or 200 milligrams on days 1, 4, and 7 for a total of three doses.[1,25,26]

CANDIDIASIS COMPLICATIONS

Vaginal and microscopic examinations should be performed if symptoms persist or recur within 2 months, and precipitating factors, such as high blood glucose levels, should be controlled. However, most women with recurrences do not have obvious precipitating causes. Vaginal cultures should be obtained to confirm clinical diagnosis but also to indentify any unusual species such as *C. glabrata*. Azoles are not very effective in treating vaginitis caused by *C. glabrata.*

Management of women with frequent recurrence is aimed at control with a long-term suppressive prophylactic regimen, rather than cure. The reason that some women, many of whom have no underlying pathology, experience frequent recurrences of infection with resulting morbidity is not fully understood. Current views suggest that local vaginal immune mechanisms may be responsible for frequent relapses. Maintenance regimens with oral fluconazole (100-, 150-, or 200-milligram doses weekly for 6 months) are the first line of treatment.[1]

TRICHOMONAS VAGINITIS

***Trichomonas vaginalis* is the most common nonviral sexually transmitted infection and accounts for 15% to 20% of cases of acute vaginitis.** There are an estimated 3.7 million Americans infected with *T. vaginalis*, more than *N. gonorrhoeae* and *Chlamydia* combined.[27] Both men and women can be infected, and it is spread through sexual contact. Infection is more common in certain racial and ethnic groups. Incidence is highest among black women at 13.3%, compared with 1.8% of Hispanic women and 1.3% of white women.[28] The prevalence of *T. vaginalis* infection increases with age,[1] unlike other sexually transmitted infections, such as *Chlamydia* and *N. gonorrhoeae*, for which the prevalence is highest among adolescents and young adults. Risk of *T. vaginalis* infection is associated with increasing numbers of sexual partners (recent or remote), early initiation of sexual activity, lower educational levels (high school or below), and poverty.

Trichomoniasis is a parasitic infection with the single-celled protozoan *T. vaginalis*, a flagellated organism (**Figure 102-3**). Infection can produce local inflammation when the organism attaches to the vaginal mucosa. As many as 50% of women are asymptomatic. Clinically symptomatic women with *Trichomonas* vaginitis present with vaginal discharge, pruritus, and irritation. The classic discharge is described as frothy and malodorous. Symptoms generally develop within 5 to 28 days; however, untreated infections can last for months to years and produce symptoms at any time.[29]

DIAGNOSIS

Clinical diagnosis of *Trichomonas* vaginitis traditionally relies on microscopic examination of the vaginal secretions and visualization of motile trichomonads (Figure 102-3). Microscopy should be performed immediately following sample collection or the organism will lose motility. The sensitivity of microscopic identification of trichomonads is 60% to 70%.[1] Although associated with low cost and immediate results, there are several disadvantages to this method, including operator error and overall poor sensitivity. Culture is 95% sensitive and considered the gold standard in diagnosis. However, results may not be available for 2 to 5 days. There are several newer testing options, including two different point-of-care diagnostic tests. Results of the immunochromatographic capillary flow dipstick technology test, OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MA), and the nucleic acid probe test, Affirm VP III (Becton Dickinson, San Jose, CA), are available in 10 minutes and 45 minutes, respectively. Both have a sensitivity of >83% and specificity of >97%.[1,30,31] The U.S. Food and Drug Administration–cleared polymerase chain reaction assay for *N. gonorrhoeae* and *Chlamydia* infection, Amplicor (Roche Diagnostics, Indianapolis, IN), has been modified for *T. vaginalis* detection in both vaginal and endocervical swabs, as well as urine. The sensitivity ranges from 88% to 97%, and the specificity ranges from 98% to 99%. APTIMA *T. vaginalis* Analyte Specific Reagents are available for RNA-mediated amplification testing using the instrumentation platform APTIMA Combo2 (Gen-Probe, Bedford, MA) currently used to diagnose *N. gonorrhoeae* and *Chlamydia* infections. The sensitivity ranges from 74% to 98%, and the specificity ranges from 87% to 98%.[1]

FIGURE 102-3. Trichomonad. [Reprinted with permission of Piotr Rotkiewicz.]

TREATMENT

Treatment regimens for acute *Trichomonas* vaginitis are listed in **Table 102-6**. The nitroimidazoles, metronidazole and tinidazole, are the only medications effective in treating trichomoniasis. Metronidazole gel is considerably less effective (<50%) than oral metronidazole preparations, and so the gel is not recommended. Single-dose treatment is preferable because of lower cost, fewer side effects, and greater patient adherence to the regimen. However, patients whose infection is not responsive to single-dose therapy may require a 7-day course of therapy. There is a 90% cure rate with either the single- or multiple-dose regimen. Cure rates increase to >90% when sexual partners are treated simultaneously. Patients with a true allergy can undergo desensitization in consultation with a specialist.[1]

TABLE 102-6 Treatment Regimens for Trichomoniasis

Agent	Dosage
Recommended Regimen	
Metronidazole*	2 grams PO in a single dose
Tinidazole†	2 grams PO in a single dose
Alternative Regimen	
Metronidazole*	500 milligrams PO twice a day for 7 d

*Metronidazole is a pregnancy Category B drug.

†Tinidazole is a pregnancy Category C drug.

Counsel patients to abstain from sexual intercourse until drug therapy has been completed and the patient and their partner(s) are asymptomatic and to avoid alcohol use during therapy and for 24 hours after completion of drug therapy with metronidazole to avoid a disulfiram-like reaction.

TRICHOMONIASIS COMPLICATIONS

The spread of *Trichomonas* infection is difficult to control, because up to 50% to 75% of those infected are asymptomatic and reinfection is common. Recurrence of disease is frequent and may necessitate multiple courses of treatment.

T. vaginalis infection is associated with several adverse health outcomes, including preterm birth, delivery of low-birth-weight infants, and pelvic inflammatory disease. It has also been associated with increased transmission of several other infections, including human immunodeficiency virus, herpes simplex virus, and human papillomavirus infection. Not only does *Trichomonas* infection increase the likelihood of human immunodeficiency virus acquisition, but it also promotes human immunodeficiency virus transmission and viral shedding.[32,33]

SPECIAL POPULATIONS

Human immunodeficiency virus–positive individuals are more likely to become infected with *T. vaginalis* and have higher complication rates. Consider 7-day therapy for human immunodeficiency virus–positive individuals because studies have indicated that single-dose therapy is less effective.[1]

Due to the potential adverse outcomes, pregnant women should receive treatment with oral metronidazole. Women can be safely treated with single-dose metronidazole therapy at any stage of pregnancy. Tinidazole safety in pregnancy is not well studied. Breastfeeding mothers should withhold nursing during treatment with metronidazole and for 12 to 24 hours after the last dose. If treated with tinidazole, patients should hold breastfeeding for 3 days after the last dose.

CONTACT VULVOVAGINITIS

Contact dermatitis results from the exposure of the vulvar epithelium and vaginal mucosa to a primary chemical irritant or an allergen. Irritant dermatitis is more common than allergic dermatitis.[34] Common irritants and/or allergens include chemically scented douches, soaps, bubble baths, and deodorants; perfumes, dyes, and scents in toilet paper, tampons, pads, and feminine hygiene products; topical vaginal antibiotics; laundry detergents, dryer sheets, and fabric softeners; and tight slacks, pantyhose, and synthetic underwear. Benzocaine, used by women to control vulvar discomfort, can also cause a particularly severe contact dermatitis.

DIAGNOSIS AND TREATMENT

Diagnosis may be difficult due to variation in severity of symptoms and presence of other preexisting conditions. Clinically, patients report local swelling and itching or a burning sensation. Physical findings range from local erythema and edema to excoriation, ulceration, and secondary infection. Local vesiculation and ulceration are more common with allergens or with primary irritants used in strong concentrations. Also consider herpes infections if vesicles are present. Vaginal pH changes may promote colonization and infection with *C. albicans*, which can obscure the primary cause.

Diagnosis of contact vulvovaginitis is made by ruling out an infectious cause and identifying the offending agent. Most cases of mild vulvovaginal contact dermatitis resolve spontaneously when the causative agent is withdrawn. Cool sitz baths and application of wet compresses of dilute boric acid or Burow's solution may afford relief for patients with severe painful reactions. A few days of therapy with topical corticosteroids, such as hydrocortisone acetate (0.5% to 2.5%), fluocinolone acetonide (0.01% to 0.2%), or triamcinolone acetonide (0.025%), applied two or three times daily, provide symptomatic relief and promote healing. Oral antihistamines may be helpful if a true allergic reaction is present. Superinfection with *C. albicans* should be treated as previously described in the section on *Candida* vaginitis.

ATROPHIC VAGINITIS

Vaginal atrophy, present in 60% of women 4 years after menopause, can result in atrophic vaginitis.[35] Decreases in ovarian steroid production that occur in the menopausal woman lead to profound changes in the vulva, vagina, cervix, urethra, and bladder. The changes vary widely from one patient to another. The vagina loses its normal rugae, and the vaginal mucosa becomes attenuated, pale, and almost transparent as a result of decreased vascularity. The squamous epithelium atrophies, the glycogen content of the cells decreases, and the vaginal pH ranges from 5.5 to 7.0. The upper one third of the vagina constricts, and the entire vagina becomes shorter in length and loses its elasticity. The mucosa is only three or four cells thick and is less resistant to minor trauma and infection. The cervix atrophies and retracts and may become flush with the apex of the vault.

DIAGNOSIS AND TREATMENT

Symptoms include vaginal dryness, soreness, itching, dyspareunia, and occasional spotting or discharge. Discharge is thin, scant, and yellowish or pink. The vaginal epithelium appears thin, inflamed, and even ulcerated.

A clinical vaginal infection with copious purulent discharge may develop due to increased vaginal pH, which permits growth of nonacidophilic coliform organisms and the disappearance of *Lactobacillus* species. *Candida* and *Trichomonas* infections are rare in the postmenopausal woman unless estrogenic replacement therapy is used.

Wet preparations demonstrate erythrocytes, increased polymorphonuclear neutrophils, and small, round epithelial cells, which are immature squamous cells that have not been exposed to sufficient estrogen.

Treatment of atrophic vaginitis consists primarily of topical vaginal estrogen. Creams, pessaries, tablets, and the estradiol vaginal ring are all effective in treating the symptoms.[35] Side effects of treatment may include uterine bleeding, breast pain, perineal pain, and endometrial hyperstimulation. Estrogen should not be prescribed to patients with a history of cancer of any of the reproductive organs. Atrophic vaginitis is usually not seen in patients who are already taking systemic estrogen replacement therapy.

Patients should be referred to their own doctors or a clinic for treatment and follow-up to monitor therapy, because all formulations of estrogen, even at low dosages, show systemic absorption and have potentially harmful side effects.[36] In addition, any patient with postmenopausal bleeding, either by history or physical examination, should be referred to a gynecologist to rule out carcinoma.

BARTHOLIN GLAND CYST AND ABSCESS

Bartholin glands are located in the labia minora. The ducts of the glands drain into the posterior vestibule at the 4 o'clock and 8 o'clock positions. Normally the glands are pea sized, but may form a cyst or abscess. The glands begin to function at puberty to provide moisture for the vestibule and involute as women age. Obstruction of the duct may result in a cyst or abscess. A cyst does not need to be present for an abscess to develop. Abscesses may become quite large and cause extreme pain. Bartholin gland abscesses tend to be polymicrobial, although *N. gonorrhoeae* and *C. trachomatis* have been implicated.[37]

DIAGNOSIS AND TREATMENT

Bartholin gland abscess is characterized as a mass in the posterior introitus near the 4 o'clock or 8 o'clock position that has developed over several days. If the abscess was preceded by a cyst, the abscess may develop over a longer period of time. Pain, induration, and fluctuance are usually present. Systemic symptoms such as fever and chills are rarely present.

FIGURE 102-4. Word catheter. [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures,* 2nd ed. McGraw-Hill, Inc., 2013. Figure 138-2, p. 932.]

Incision and drainage of an abscess is usually necessary but should not be performed until the abscess is a well-defined, walled-off structure. If the abscess is not ready for incision and drainage, give the patient broad-spectrum antibiotics and analgesics, and advise warm sitz baths. Most patients present with an exquisitely tender, hyperemic, fluctuant mass that needs drainage.

Provide analgesia with a local injection of 2 to 4 mL of 1% lidocaine. To drain the abscess, make a stab incision with a #11 scalpel on the mucosal surface of the vestibule, just lateral to the hymenal ring in the region of the Bartholin gland, where the abscess cavity is closest to the mucosal surface. Extend the stab incision only for a few millimeters—an incision that is too large will result in displacement of the Word catheter. A Word catheter (**Figure 102-4**) is the size of a #10 Foley catheter with a 1-in (2.5-cm) stem and an inflatable balloon. Insert the Word catheter into the incision site, and inflate the balloon with 2 to 4 mL of water. Tuck the end of the catheter into the vagina. The catheter should remain in place for 4 to 6 weeks to avoid recurrence.[38] Case reports describe using plastic tubing (**Figure 102-5**) and pediatric Foley catheters for abscess drainage when a Word catheter is not available.[39,40] Prescribe analgesics and broad-spectrum antibiotics, and give instructions for follow-up care. If *N. gonorrhoeae* and *C. trachomatis* infection are possible, direct antibiotic coverage accordingly (Table 102-2). Patients with recurrent abscess may require definitive surgical care and should be provided with specialty referral.

VAGINAL FOREIGN BODIES

Consider a vaginal foreign body in patients with chronic vaginal discharge. Objects removed in the ED include retained tampons and toilet tissue, items used for sexual stimulation, packets of illegal drugs, and various other items.

Premenarchal children presenting with vaginal discharge, especially if bloody or brown, should be evaluated for a vaginal foreign body, which is found in 4% to 10% of such cases. The discharge associated with a foreign body occurs daily and is often malodorous.[4] Potential foreign bodies include small pieces of toilet paper or cloth and small toys/objects.

Vaginal irrigation with 0.9% normal saline can be attempted to visualize and remove a foreign body in cooperative children >7 years of age. Vaginoscopy under anesthesia in the operating room may be necessary in younger children.

The use of imaging modalities is limited by the composition of the foreign body. Radiolucent foreign bodies are not seen on plain radiographs and may not be detected by pelvic ultrasound. MRI may aid in the localization of nonmetallic objects but is not always available and is not necessarily conclusive.

Treatment of vaginal foreign bodies is removal either manually or by irrigation.

PINWORMS

Patients with pinworms (*Enterobius vermicularis*) complain of anal and/or vaginal pruritus, which is more intense at night (when the gravid female pinworms pass out from the intestinal tract to lay eggs on the

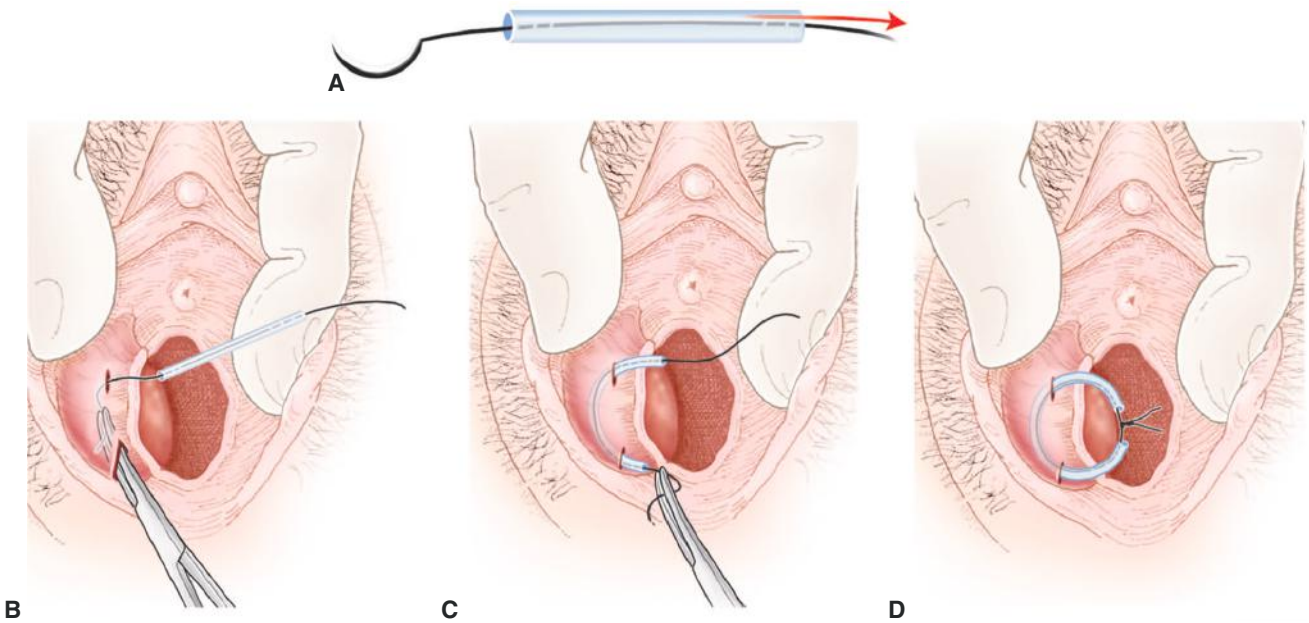

FIGURE 102-5. A. Obtain 7 cm of narrow tubing, and insert silk suture through tubing. B. After drainage, make a second stab incision into the abscess cavity and insert the threaded tubing. C. Use a hemostat to grasp the threaded tubing through both stab sites. D. Suture the threads so they are secure. [Reproduced with permission from Reichman EF: *Emergency Medicine Procedures,* 2nd ed. McGraw-Hill, Inc., 2013. Figure 138-5, Parts A, E, F, G, p. 934.]

TABLE 102-7 Treatment Regimens for Trichomoniasis

Agent and Dosage	Comments
Mebendazole 100 milligrams PO × 1 Repeated in 1 wk	Use with caution in pregnancy
Albendazole 400 milligrams PO × 1 Repeated in 2 wk	Contraindicated in pregnancy
Pyrantel pamoate 11 milligrams/kg PO × 1 (maximum single dose, 1 gram) Repeat dose every 2 wk × 2	Available without prescription

perineal skin). The worms may migrate from the anus to the vagina in children.

The diagnosis is made by visualization of 1-cm-long, thin white worms exiting the anus. Alternately, a sample can be obtained on cellophane tape and used for identification of ova, which are large and double-walled in appearance, on microscopy.

Treat the child and all family members with an antiparasitic agent (**Table 102-7**). Treatments are repeated, because mature worms are more vulnerable to treatment than young worms.[4]

VULVAR TRAUMA

Nonobstetric vulvar trauma is uncommon; however, it is associated with significant physical and psychological consequences. Various types of trauma can be seen including injuries sustained during consensual and nonconsensual sexual activity, accidental injuries including straddle-type injuries, other forms of physical assault, and self-mutilation. Patients may present with abrasions, tears, lacerations, hematomas, burns, and bite wounds. Depending on the situation, gynecologic consultation and examination under anesthesia may be necessary.

Evaluate patients with vulvar trauma for associated vaginal, urethral, anal, and bony pelvis injuries, and treat accordingly.[41]

CHAPTER 103

Pelvic Inflammatory Disease

Suzanne M. Shepherd
Brian Weiss
William H. Shoff

INTRODUCTION AND EPIDEMIOLOGY

The term pelvic inflammatory disease (PID) comprises a spectrum of infections of the female upper reproductive tract. It is a common and serious disease initiated by ascending infection from the vagina and cervix. PID includes salpingitis, endometritis, myometritis, parametritis, oophoritis, and tubo-ovarian abscess and may extend to produce perihepatitis, pelvic peritonitis, and perihepatitis (Fitz-Hugh–Curtis syndrome). PID is the most common serious infection in sexually active women age 16 to 25 years.[1]

Long-term sequelae, including tubal factor infertility, implantation failure after in vitro fertilization, ectopic pregnancy, and chronic pain, may ultimately affect 11% of reproductive-aged women.[2] The most common cause of death is rupture of a tubo-ovarian abscess, and the mortality associated with rupture remains at 5% to 10%, even with current treatment methods.

PATHOPHYSIOLOGY

ORGANISMS ASSOCIATED WITH PID

Neisseria gonorrhoeae and *Chlamydia trachomatis* can be isolated in many cases of PID, and therapy is directed primarily against these organisms. However, polymicrobial infection, including infection with anaerobic and aerobic vaginal flora, is evident from cultured material from the upper reproductive tract.[3] **Table 103-1** lists common pathogenic organisms associated with PID. *N. gonorrhoeae* and *C. trachomatis* are often instrumental in initial infection of the upper genital tract, whereas anaerobes, facultative anaerobes, and other bacteria are isolated increasingly as inflammation increases and abscesses form.

Bacterial vaginosis (BV) is frequently identified in women with PID, and the type of BV-associated microorganism (*Gardnerella vaginalis, Mycoplasma hominis, Ureaplasma urealyticum*, pigmented or nonpigmented anaerobic gram-negative rods) may make a difference in the likelihood of developing PID.[4,5]

Infection with ***Trichomonas vaginalis*** is associated with a fourfold increase in the incidence of acute endometritis. Co-infection with **herpes simplex virus 2** and ***C. trachomatis, N. gonorrhoeae,*** or bacteria causing vaginosis is also associated with acute endometritis. Infection with herpes simplex virus 2 causes fallopian tube inflammation and lower tract ulceration that may disrupt the endocervical canal mucous barrier.[6] **Human immunodeficiency virus 1 (HIV-1)** infection is associated with an increased incidence of *C. trachomatis* infection, increased incidence of co-infection with *Candida* and human papillomavirus, and increased risk of progression to PID.[7]

PID may result from ***Mycobacterium tuberculosis*** infection in endemic areas.[8] **Schistosomes** can cause genital infection, including a PID-like tubal infection, infertility, and chronic abortion, and a recent report links schistosomiasis to HIV transmission in Africa. ***Actinomyces*** species have been identified almost exclusively in patients with intrauterine devices (IUDs).[9]

ASCENDING INFECTION

Most cases of PID are presumed to originate with sexually transmitted infections (STIs) of the lower genital tract, followed by ascending infection of the upper tract. The original STI may be asymptomatic. The precise mechanisms by which upper genital tract infection and inflammation are initiated and propagated are not well known. Although the cervical mucus serves as a functional barrier to ascending infection much of the time, its efficacy may be decreased by hormonal changes during menstruation and ovulation and by retrograde menstruation. Intercourse may contribute to the ascent of infection due to rhythmic

Adolescence, younger adulthood
Lower socioeconomic status
Postabortal

mechanical uterine contractions. Bacteria also may be carried by, or along with, sperm into the uterus and tubes. Uterine infection usually is limited to the endometrium but can be more invasive in a gravid or postpartum uterus. Tubal infection initially affects only the mucosa, but acute, complement-mediated transmural inflammation may develop rapidly and increase in intensity with repeated infection. Inflammation may extend to uninfected parametrial structures, including the appendix and bowel. Infection may spread by direct extension of purulent material from the fallopian tubes or via lymphatic spread beyond the pelvis to involve the hepatic capsule with acute perihepatitis (Fitz-Hugh–Curtis syndrome) and produce acute peritonitis.

RISK FACTORS FOR PID

Multiple risk factors are associated with development of PID (**Table 103-2**).[4,10-17]

IUD use has been associated with an increased risk for PID. Although the majority of risk occurs within 21 days of insertion, the presence of an IUD is associated with complicated PID irrespective of the duration of use.[9,13-15] The risk of PID in IUD users is more related to the development of STI than the IUD,[18,19] and STI screening and treatment at the time of insertion can significantly decrease the likelihood that PID will develop.[20]

Pregnancy decreases the risk of PID because the cervical os is protected by the mucous plug. However, PID can occur during the first trimester and is associated with substantial fetal loss and preterm delivery.

COMPLICATIONS OF PID

PID is associated with a number of serious clinical sequelae. Tuboovarian abscess is reported in up to one third of women hospitalized for PID. Infection and inflammation can lead to scarring and adhesions within tubal lumens. **Ectopic pregnancy is more frequent in women who have had PID than in those who have never had an ectopic pregnancy.** Tubal factor infertility is increased by 12% to 50% in women with a past diagnosis of PID, and the incidence increases with the number and severity of past PID episodes.[21] Asymptomatic or silent PID appears to be associated with tubal factor infertility as well. Sequelae of PID include recurrence of PID, chronic pelvic pain, menstrual disturbances, and chronic dyspareunia. Recurrence of PID may occur because of inadequately treated infection, nontreatment of partner(s), or reinfection from another sexual contact. In follow-up to the Pelvic Inflammatory Disease Evaluation and Clinical Health trial, those with recurrence of PID were five times more likely to experience chronic pelvic pain.[22] PID may also be associated with an increased risk of ovarian borderline tumors.[23]

CLINICAL FEATURES

The clinical presentation of PID is variable. The most common presenting complaint is lower abdominal pain, most frequently described as bilateral and dull or crampy. Pain may be exacerbated by movement or by sexual activity. Other symptoms include abnormal vaginal discharge (75% of individuals), vaginal and postcoital bleeding (more than one third of patients), irritative voiding symptoms, fever, malaise, nausea, and vomiting.[24] Symptoms occur most commonly early in the menstrual cycle or at the end of the menses and are attributed to low progesterone levels and coincident thinning of the cervical mucosal barrier.

The physical examination is usually notable for lower abdominal tenderness, cervical motion tenderness, and uterine or adnexal tenderness. Involuntary guarding and rebound tenderness may be present and may indicate associated peritonitis. The positive predictive value of these findings varies depending on the prevalence of PID in a given clinical population. Adnexal tenderness appears to have a sensitivity of 95%.[25] Mucopurulent cervicitis is a common finding, and its absence should raise consideration of another diagnosis. In women who are suspected of having PID and for whom there is no likely alternative diagnosis for abdominal pain, the presence of fever, adnexal tenderness, and an elevated erythrocyte sedimentation rate are significant independent predictors of endometritis and correctly classify 65% of patients with laparoscopically proven PID (95% confidence interval, 61% to 99%).[25,26]

Right upper quadrant tenderness, particularly with jaundice, may indicate perihepatic inflammation. **Fitz-Hugh–Curtis syndrome** is perihepatitis, demonstrated by right upper quadrant pain in a woman with a clinical diagnosis of PID and no other cause for this pain. It is an uncommon complication and responds to standard antibiotic treatment for PID.[27]

The differential diagnosis of PID is broad and includes cervicitis, ectopic pregnancy, endometriosis, ovarian cyst, ovarian torsion, spontaneous abortion, septic abortion, cholecystitis, gastroenteritis, appendicitis, diverticulitis, pyelonephritis, and renal colic. Look for signs of other STIs, such as herpes simplex, syphilis, and human papillomavirus infection.

DIAGNOSIS

The diagnosis is based on history and clinical findings. No single piece of historical, physical, or laboratory information is sensitive and specific for the disease. **Laboratory evaluation of any woman of childbearing age in the ED always should include a pregnancy test.** Consider the possibility of ectopic pregnancy or septic abortion; the most common alternative diagnosis in missed ectopic pregnancy is PID. Concurrent pregnancy also influences patient treatment and disposition.

Current Centers for Disease Control and Prevention guidelines encourage initiation of empiric treatment in women at risk for PID who exhibit lower abdominal pain, adnexal tenderness, and cervical motion tenderness. Guidelines stratify diagnostic criteria into the three groups shown in **Table 103-3**.

TABLE 103-3 Diagnostic Criteria for Pelvic Inflammatory Disease (PID)

Group 1: Minimum criteria. Empiric treatment if no other cause to explain findings.
Uterine or adnexal tenderness
Cervical motion tenderness
Group 2: Additional criteria improving diagnostic specificity.
Oral temperature >101°F (38.3°C)
Abnormal cervical or vaginal mucopurulent secretions
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein level
Laboratory evidence of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis* (i.e., culture or DNA probe techniques)
Group 3: Specific criteria for PID based on procedures that may be appropriate for some patients.
Laparoscopic confirmation
Transvaginal US (or MRI) showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex
Endometrial biopsy results showing endometritis

LABORATORY TESTING

Obtain saline- and potassium hydroxide–treated wet preparations of vaginal secretions to identify leukorrhea (more than one polymorphonuclear leukocyte per epithelial cell) and trichomonads, and to test for BV, including clue cells, pH, and a whiff test. Leukorrhea is sensitive but not specific for upper tract infection,[28] and the absence of leukorrhea is a negative predictor for PID. Although endocervical swab specimens may be sent for culture and can be gram stained for gonococci, nucleic acid amplification tests and DNA probes for *N. gonorrhoeae* and *Chlamydia* have replaced culture and gram staining in many settings. Unfortunately, these results are not available to the ED at the time of initial evaluation. Several sensitive and specific diagnostic tests are currently available for *Trichomonas* testing, including a nucleic acid amplification test (Aptima®; GenProbe, San Diego, CA), approved in 2013, that is performed on the same clinical samples as those for *Chlamydia* and gonorrhea testing.[29,30]

If PID is clinically suspected, an elevated WBC count, erythrocyte sedimentation rate, or C-reactive protein level supports the diagnosis.[28] Because a patient may have multiple STIs, also obtain a rapid plasma regain test for syphilis. Test for HIV and hepatitis. Urinalysis can exclude urinary tract infection, but a positive urinalysis does not exclude PID, because any inflammatory process in the contiguous pelvis can produce WBCs in the urine. Blood cultures do not aid in diagnosis or treatment.

IMAGING

Transvaginal pelvic US may demonstrate thickened (>5 mm), fluid-filled fallopian tubes or free pelvic fluid in acute severe PID. Pelvic or tubo-ovarian abscesses appear as complex adnexal masses with multiple internal echoes. Pelvic US can demonstrate as many as 70% of adnexal masses missed on physical examination. US also may be helpful in ruling in or out other causes in the differential diagnosis of pelvic pain, including ectopic pregnancy, ovarian torsion, hemorrhagic ovarian cyst, and possibly appendicitis or endometriosis.[31]

Abdominopelvic CT and MRI may also be used in the diagnosis of PID and the exclusion of other important causes of pelvic pain. If appendicitis or other surgical or GI diagnoses cannot be excluded, obtain an abdominopelvic CT. For further discussion, see chapter 97, "Abdominal and Pelvic Pain in the Nonpregnant Female." CT findings in PID include obscuration of the pelvic fascial planes, cervicitis, oophoritis, salpingitis, thickening of the uterosacral ligaments, and the presence of simple or complex pelvic fluid or abscess collections. MRI is especially helpful in characterizing complicated soft tissue masses, including dilated fallopian tubes and abscesses. MRI imaging is more specific and accurate than US to assess PID, with a sensitivity of 95% and a specificity of 89%.[32,33]

TREATMENT

Treatment is aimed at relieving acute symptoms, eradicating current infection, and minimizing the risk of long-term sequelae. From a public health perspective, another objective of treatment is to reduce the risk of transmission of infection to other new partners and to identify and treat past and current sexual partners to prevent disease spread. Early diagnosis and treatment are critical because duration of symptoms is an independent risk factor for infertility.

Due to the difficulty of diagnosis and the potential for serious sequelae, the Centers for Disease Control and Prevention recommend a low threshold for empiric treatment, with overtreatment preferred to a missed diagnosis with resultant delayed or no treatment.

Provide adequate analgesia, control of emesis and fever, and fluid replacement in those with nausea, vomiting, and dehydration and in those who appear toxic. Nonsteroidal anti-inflammatory drugs are very useful for the management of pain of pelvic origin. ED treatment should include empiric broad-spectrum antibiotic therapy to cover the full range of likely organisms. Screen for BV and treat when screening is positive. Treatment regimens should follow both national guidelines from the Centers for Disease Control and Prevention and local health department surveillance reports.

The Pelvic Inflammatory Disease Evaluation and Clinical Health trial, which included 654 females age 14 to 37 years old and excluded those who had been treated with antibiotics during the preceding 7 days, had experienced an abortion, delivery, or gynecologic surgery during the preceding 14 days, were homeless, or had an allergy to study medications, demonstrated no differences between oral and parenteral regimens in women with mild to moderately severe acute PID uncomplicated by pregnancy or the presence of a tubo-ovarian abscess.[34,35]

Currently accepted inpatient and outpatient treatment regimens are summarized in **Tables 103-4 and 103-5**. Current geographic patterns of drug resistance may change recommendations. Patients with PID who require IV antibiotics initially can be switched to oral antibiotics after clinical improvement.

TABLE 103-4 Parenteral Treatment Regimens for Pelvic Inflammatory Disease

Cefotetan, 2 grams IV every 12 h, or cefoxitin, 2 grams IV every 6 h
plus
Doxycycline, 100 milligrams PO or IV every 12 h*
or
Clindamycin, 900 milligrams IV every 8 h
plus
Gentamicin, 2 milligrams/kg IV or IM loading dose, followed by gentamicin, 1.5 milligrams/kg every 8 h maintenance dose†
Alternative Parenteral Regimen (limited data on effectiveness)
Ampicillin/sulbactam, 3 grams IV every 6 h
plus
Doxycycline, 100 milligrams PO or IV every 12 h*

*PO doxycycline has the same bioavailability as IV doxycycline and avoids painful infusion.

†Gentamicin dosing may be 3–5 milligrams/kg every 24 h.

TABLE 103-5 Oral and Outpatient Treatment Regimens for Pelvic Inflammatory Disease

Ceftriaxone, 250 milligrams IM once, *or* cefoxitin, 2 grams IM once, *and* probenecid, 1 gram PO once administered concurrently
or
Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime)
plus
Doxycycline, 100 milligrams PO twice a day for 14 d
with or without
Metronidazole, 500 milligrams PO twice a day for 14 d
If parenteral cephalosporin therapy is not feasible and community prevalence of fluoroquinolone resistance is low:
Levofloxacin, 500 milligrams PO, *or* ofloxacin, 400 milligrams twice daily every day for 14 d
with or without
Metronidazole, 500 milligrams PO twice a day for 14 d

Note: Other parenteral third-generation cephalosporins can be substituted for ceftriaxone or cefoxitin. Since the Centers for Disease Control and Prevention guidelines were published in 2006, clinically significant resistance to the fluoroquinolones (6.7% of infections in heterosexual men, an 11-fold increase from 0.6% in 2001) has emerged in the United States. Fluoroquinolone antibiotics are no longer recommended to treat gonorrhea in the United States.[27] Fluoroquinolones may be an alternative treatment option for disseminated gonococcal infection if antimicrobial susceptibility can be documented.
